The minutes of the Ordinary Meeting of the 18th December, 1924, were taken as read and were confirmed and signed.

A list of candidates for election and transfer, approved by the Council for ballot, was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see page 155) was taken as read and the thanks of the meeting were accorded to the donors.

A paper by Mr. H. W. Taylor, Associate Member, entitled "Three-Wire Direct-Current Distribution Networks: Some Comparisons in Cost and Operation" (see page 337), was read and discussed.

On the motion of the President a hearty vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.50 p.m.

724TH ORDINARY MEETING, 22 JANUARY, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 8th January, 1925, were taken as read and were confirmed and signed.

Messrs. A. E. Kennard and A. W. Marshall were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows :—

ELECTIONS.

Members.

Appleyard, Rollo, O.B.E., J.P., Commander, R.N.V.R.
Boulton, Percival Raymond.
Murdoch, William Henry F., B.Sc.

Associate Members.

Allan, David Taylor.
Carter, Joseph Walter.
Dalley, Christopher.
Erlebach, Wilfrid Arthur, B.Sc.(Eng.).
Everett, Reginald Marsh.
Harris, Thomas Emlyn.
Jackson, Henry, B.Sc. (Eng.).
Lakeman, Henry George.
Linzell, Harry.
Orbell, Robert Hugh.
Page, Albert, B.Sc.
Partridge, Charles Frederick, B.Sc.(Eng.).
Payne, Douglas Harold.
Peronne, Philippe Ernest.
Proctor, Roland Faraday, B.Sc.(Eng.).
Richards, Reginald, B.Sc. (Eng.).
Rowles, Henry Percival.
Smith, Donald George, B.Sc.(Eng.).
Stevenson, George Eugene.
Toplis, William Sharman.
Varney, Theodore, B.Sc.
Welch, Frederick Maurice.
Wiseman, Robert Joseph, D.Sc.

Graduates.

Allen, James.
Bailey, Roland Frederic, B.Sc.(Eng.).
Balasubramanian, M.S., B.A., B.E.
Ball, Alfred.
Beney, Harry.
Bhargava, Goverdhan Prasad.
Bishop, John Leo.
Bull, Walter John H., B.Sc.
Campbell, Percy Oliver.
Cass, Vernon Sydney.
Chase-Currier, Victor Charles.
Clarke, Albert Edward.
Curd, David Alfred G.
Dickson, William Laybourne E., B.Sc.(Eng.).
Gangoly, Umadhava, M.Sc.
Giles, Ralph Bostock.
Gogan, James.
Green, George Ernest.
Grimmitt, Howard Walker.
Hahn, Otto Henry, B.Sc. (Eng.).
Harrison, Harold Edward.
Johnston, Reginald James.
Jones, Reginald Hugh, M.Sc.(Eng.).
Joshi, Gopal Anant, B.A., B.E.
Keast, Norman Radden.
Kirtikar, Shrikrishna.
McGuigan, William.
Masters, Thomas Bertram.
Musson, Stanley Ford.
Nadhan, Vaiankalatur Ramaswami H.
Narbeth, Charles Anstey.
Pardoe, Leonard Gardiner, B.E.
Provand, Ninian.
Savage, Joseph.
Sen, Mahendra Nath.

Graduates—continued.

Somayajulei, Bulusu Rama
Srinivasa Moorthy Rao, Srinivasarao.
Subramanian, Mrityunjaya.
Thompson, Thomas Barnes.
Upasena, Esapala.
Walker, Herbert.
Ward, George.
Waring, Alfred James.
White, Ernest Henderson.
Whitehead, John Herbert, B.Sc.Tech.
Wijisinghe, Don Martin.
Wyatt, Thomas Harold.

Students.

The President: The next business is unusual but very welcome. We have with us this evening Mr. J. Ferguson Bell, President of the Institution of Gas Engineers, with a deputation from his Council, and I propose to ask him to explain the object of their visit.

Mr. J. Ferguson Bell: I should like in the first place to thank the members for their very cordial welcome. I have attended for the purpose of asking the Institution to accept an engraved plate and a framed presidential certificate, which will be presented to Dr. Alexander Russell, who was President last

session. This certificate is signed by the present President, Mr. Woodhouse. At the Annual Meeting of the Institution of Gas Engineers last year, a presidential certificate designed by Mr. F. D. Marshall was presented by me to our retiring President, Mr. Samuel Tagg, in commemoration of his year of office. The certificate was exhibited in this building, where our meetings were held, and was much admired. Our Council desired to make some tangible acknowledgment of the kindness that we have received from the Institution, not only last year but in former years, in giving us the free use of these fine premises for our meetings, and we therefore thought that we should like to express in some form our appreciation by presenting to the Institution a souvenir, which has taken the form of a presidential certificate. The acceptance of this engraved certificate indicates the good feeling that happily exists between the members of both Institutions, and I venture to say that we hope this happy feeling of friendliness will long continue. I should like now to strike a personal note and mention that 30 years ago I was associated with the late Dr. John Hopkinson. Mr. J. S. Highfield was also associated with me at the Stafford Corporation Electricity Works. In those days electricity was in its infancy; it was considered a luxury. So far back, however, as over 30 years ago—I believe that the date was 1890—I advised the Corporation to erect an electricity works. I told them that electricity had a great future, and that it eventually would become one of our important public utility services. That forecast has been fully justified; and the great advance made by electricity, due to the high technical skill, the enterprise, and the efficiency of the various members of the Institution, is indicated by the enormous use that is now made of electricity for very many purposes. The advance of light and power is indicated on all hands and in many directions. The importance of electro-chemistry may be gauged by the fact that many products now on the market are made by electrical processes which in some instances are doing away with the older processes. Electro-metallurgy applied to the products of chemical reactions and molecular changes at furnace temperatures are well known. Electricity is also used in most of our great infirmaries and hospitals for the alleviation of suffering and pain. We also know the enormous advance which has been made in the development of the telephone, and then we have the almost incredible wonders of wireless. All these indicate the immense and the alluring pursuits in the further application of electricity. It may be that in years to come we shall get a great deal of energy from sources other than coal. I think that that will be to the advantage of the community, because our supplies of coal are not altogether inexhaustible. Coal is dear, and thus if electricity can be generated from other sources and coal saved for those processes for which it is essential, electrical engineers will be conferring a further benefit on the community. In conclusion, I should like to congratulate the electrical industry upon the well-known scientific men—I might say brilliant scientific men—who are engaged within its ranks and who are supported by well-trained, enthusiastic younger men. Also, it is well supported by its technical Press. All these have tended towards the extension of electricity. On behalf of the Institution of Gas Engineers, which the deputation represents, I wish the Institution of Electrical Engineers continued prosperity; and in this connection we members of the Institution of Gas Engineers believe that there is ample scope for both industries to prosper. There must at times be inevitable competition between the different forms of energy, but competition tends to progress, and competition, so long as it is reasonable, is to the benefit of both our industries. I do not think, speaking for the gas industry, that we should have made so much progress during the last quarter of a century if we had not been pushed forward by electrical engineers. It is with the greatest pleasure that I ask the President to accept this presidential certificate, along with the engraved plate from which it is a first impression and from which I hope that he will later receive a certificate for himself.

Mr. Bell then formally presented to the President the engraved plate and the presidential certificate, the latter being in a gilt frame and containing the following words:—

"Institution of Electrical Engineers, Founded 1871, Incorporated by Royal Charter 1921. This is to record that Dr. Alexander Russell, LL.D., F.R.S., held the office of President for the year 1923–24. Witness our hands and seal this 8th day of January, 1925. (Signed) W. B. Woodhouse, President; F. Gill, Member of Council; P. F. Rowell, Secretary."

The President: I have very great pleasure in accepting, on behalf of the Council of the Institution of Electrical Engineers, this charming certificate, carrying out the very artistic and appropriate design which Mr. F. D. Marshall has been kind enough to prepare. In granting to the Institution of Gas Engineers the use at times of this lecture theatre we did not expect any such tangible return as this. We ourselves in the past have been the guests of other scientific Institutions, and we are very happy now to be in a position to show hospitality to other engineering societies. I am sure I am only voicing the views of all the members in saying that we appreciate very deeply indeed this graceful act on the part of the members of a sister engineering Institution. The members of the Institution of Gas Engineers, like many of our own members, are concerned with the proper utilization of coal, and probably the differences of opinion which exist as to what is quite the best way to do it are apt to overshadow the very numerous and very important interests which we have in common. We are both attempting to solve the same problem. We have very largely worked on independent lines, but we who are engaged in the supply of electricity to the public are very much indebted to the gas engineers for having first of all made the public aware that they could purchase a means of light, of heat, and of power from a public source, and that they could turn on the tap and get just as much or just as little as they wanted. When we came on the scene with another means of light, heat and power we had a public which was to some extent educated. I look forward in the future to

a closer approach between all those who are engaged in the utilization of coal. Gas engineers, those who are engaged in producing coke for metallurgical purposes, those who are engaged in mining coal, and ourselves, are all closely and very deeply concerned in finding the best possible way to use that coal, and the best possible way to bring to the public the light, the heat and the power that they require. I think the present occasion is a very happy augury of future association in discussing such matters. I believe that a discussion of our common problems, as well as a discussion of our differences, will be all to the good. I am sure we are all at one in the object in view, which is to make the best possible utilization of our national resources of coal in every possible way. I am very glad to accept, on behalf of the Institution, this kind gift, and I now have to ask Dr. Alexander Russell, as the immediate Past-President, to accept this very handsome certificate as a record of his year of Presidency.

The President then presented the certificate to Dr. Alexander Russell, and the deputation withdrew.

The President: I have pleasure in announcing that at their meeting held this afternoon the Council decided to award the Faraday Medal to Sir Joseph John Thomson in recognition of the distinguished work which he has done for electrical science. Sir Joseph's work is so well known that there is no need for me to refer to it in detail, but I may remind the members that he is an Honorary Member of our Institution, and we are proud to offer him this additional recognition of our appreciation.

A paper by Mr. H. W. Clothier, entitled "The Design of Electrical Plant, Control Gear and Connections for Protection against Shock, Fire and Faults" (see page 425), was then read and discussed. On the motion of the President a hearty vote of thanks was accorded to the author for his paper, and the meeting terminated at 8 p.m.

INSTITUTION NOTES.

Associate Membership Examination Results, February, 1925.

ROYAL CORPS OF SIGNALS.

Passed in "The Theory of Electrical Military Signalling."

Charlesworth, Lieutenant J. F., Middlesex Regiment.
Gray, Lieutenant F. P. L., R. Inniskilling Fusiliers.
Knight, Lieutenant C. W., Royal Artillery.
Newington, Captain M. T. L., 18th K.E.O. Cavalry.
Paterson, Second-Lieutenant D. R., Royal Signals.
Peachell, Lieutenant W. A., Q.O. Royal West Kent Regiment.
Raikes, Lieutenant R. F., 2/15th Punjab Regiment.
Roberts, Captain V. P., 16th Light Cavalry.
Rowley, Captain B. G., 14th Punjab Regiment.
Salter, Captain E., 1/3rd Q.A.O. Gurkha Rifles.
White, Lieutenant C. M. F., Royal Artillery.
Wilson, Lieutenant F. K., Gloster Regiment.

National Certificates and Diplomas in Electrical Engineering.

The following Institute has been approved under the scheme drawn up by the Board of Education and the Institution :—

Approved for Higher Grade Certificates (Advanced Part-time Course).

Borough Polytechnic Institute.

Third International Conference on Large Electric Supply Systems.

The Council of the Institution have nominated the following to be the British official delegates at the above Conference (see *Journal I.E.E.*, vol. 62, page 974) to be held in Paris from the 16th to the 25th June :—

Mr. W. B. Woodhouse (first British delegate),
Mr. A. R. Everest,
Mr. P. V. Hunter, C.B.E.,
Mr. A. Page,
Mr. E. B. Wedmore.

Additional official delegates may be appointed by the Council later.

Members of the Institution desiring to attend the Conference unofficially should send in their names, with a remittance of £1 2s. 6d., to the Secretary of the Institution, who will obtain the necessary membership cards for them.

The Secretary of the Conference states that the holder of a card will be entitled to: (1) Attendance at the meetings, and participation in the discussions; (2) Two copies of each paper submitted to the Conference; (3) Participation in all entertainments and visits to works or excursions organized in connection with the Conference; (4) Special terms (if any) in connection with (3) above.

Informal Meetings.

The following Informal Meetings have been held :—

60TH INFORMAL MEETING (8TH DECEMBER, 1924).
Chairman: Mr. J. Coxon.
Lecture: "A Walk round the Pretoria Power Station" (delivered by Mr. G. M. Clark, M.A.).
Speakers: Messrs. B. A. Bent, A. F. Harmer, A. N. Aikman, W. A. Ritchie, W. L. E. Jones, A. G. Hilling, P. Dunsheath, O.B.E., W. Day, W. E. Rogers, V. N. Halliday, M. Whitgift and J. Coxon.

61ST INFORMAL MEETING (15TH DECEMBER, 1924).
Chairman: Mr. F. Pooley.
Subject of Discussion: "I.E.E. Wiring Regulations" (introduced by Mr. F. C. Raphael).

Speakers : Messrs. Ll. B. Atkinson, W. E. Rogers, H. J. Cash, W. R. Rawlings, K. A. Scott-Moncrieff, E. P. Hunter, H. T. Young, F. W. Purse, H. Marryat, W. E. Warrilow, J. G. C. Bacon, P. S. Davies, J. M. Donaldson and A. W. Tate; also F. Peake Sexton (written communication).

62ND INFORMAL MEETING (12TH JANUARY, 1925).

Chairman : Mr. P. Dunsheath, O.B.E.

Subject of Discussion : "Telephonic Development in Great Britain and in the United States" (introduced by Mr. W. Day).

Speakers : Messrs. A. F. Harmer, H. E. Morrish, J. R. Bedford, J. F. Shipley, R. J. Hines, S. M. Catterson, B. O. Anson, J. W. Wheeler, A. G. Hilling, E. S. Ritter, F. Pooley, H. J. H. Tabor and P. Dunsheath, O.B.E.

63RD INFORMAL MEETING (26TH JANUARY, 1925).

Chairman : Mr. A. F. Harmer.

Subject of Discussion : "The National Physical Laboratory and its Work" (introduced by Mr. S. W. Melsom).

Speakers : Messrs. P. Dunsheath, O.B.E., H. T. Young, J. R. Bedford, W. Day, C. F. Phillips, E. S. Ritter, F. Gill, C. L. Lipman and A. F. Harmer.

64TH INFORMAL MEETING (2ND FEBRUARY, 1925).

Chairman : Mr. F. Pooley.

The Chairman reported the death of Mr. C. H. Wordingham, C.B.E., Past-President, and as a mark of respect and to express their sympathy with the widow, the members stood for a few moments in silence.

Subject of Discussion : "The New I.E.E. Wiring Regulations" (further discussion).

Speakers : Messrs. J. Coxon, J. R. Bedford, W. A. Ritchie, A. F. Harmer, R. Grierson, E. S. Ritter, A. H. Allen, C. J. Lawrence, H. T. Young, F. C. Raphael, S. W. Melsom, L. J. Gooch, H. J. Cash, W. R. Rawlings and Ll. B. Atkinson.

Accessions to the Lending Library.

ALLMAND, A. J. The principles of applied electrochemistry. 2nd ed., revised and enlarged by the author and H. J. T. Ellingham. 8vo. 738 pp. *London,* 1924

THE DESIGN OF ELECTRICAL PLANT, CONTROL GEAR AND CONNECTIONS FOR PROTECTION AGAINST SHOCK, FIRE AND FAULTS.

By H. W. Clothier, Member.

(*Paper first received* 23*rd October, and in final form* 31*st December*, 1924; *read before* The Institution 22*nd January, before the* North-Western Centre 17*th February, before the* South Midland Centre 18*th February, before the* North-Eastern Centre 23*rd February, before the* East Midland Sub-Centre 10*th March, before the* North Midland Centre 24*th March, and before the* Western Centre 4*th May*, 1925.)

Summary.

The risks to life and plant are set out.

Means for prevention are discussed in full and summarized in conclusion.

In the main an endeavour has been made to collate present practice and to ventilate some demands which are in a nebulous stage, including the duplication of components, the changing over of live circuits, the meaning of the breaking-capacity rating of circuit breakers, the use and effect of reactances, charging resistances and lightning arresters, and the best means of economy in switchgear without loss of safety.

In reviewing known automatic protective systems, stress is laid upon the importance of what has been termed, for the purpose of this paper, the "stability ratio." Stability takes precedence over sensitivity. In balanced automatic protective systems stability is jeopardized by influences, some of which are of recent discovery and have been brought to light by new conditions of service. They include the unbalancing effect of high-frequency oscillations on main lines, and interference by induction between the main line and the pilot line. Suitable remedies are available and have been applied.

The relation of interference with telephone service and fault occurrences on power supply systems provides a further argument in favour of good bonding, earthing the neutral and the instantaneous isolation of faults.

Mechanical consideration is given to the layout of switchgear and to the terminal construction of plant, and a diagrammatic illustration of the alternator main, field, and neutral connections is shown.

General Introduction.

The objects of this paper are to record the practice of enclosing conductors, and the automatic isolation of faults on electric power supply systems; also to consider the design from the point of view of protection to life and property, and the maintenance of continuity in the supply to the consumer. The dangers to "life" include shocks and burns; to "property," short-circuits and earth faults, explosion, fire or arcing to and from adjacent plant, and overloading of plant; and to "continuity of supply," the failure of plant and connections and incorrect sequence in manual operation.

To avoid shocks, it must be impossible for a person to make accidental contact with, or to come within arcing distance of, a live conductor. The ideal, then, is to enclose every conductor so as to render it inaccessible when alive. Burns may be due to direct contact or to arcs and flames spreading out from conductors and plant on the occurrence of faults or on the faulty operation of apparatus. This danger imposes the further condition for safety—that the enclosure must prevent the protrusion of hot gases and flame, and the discharge of inflammable gases in quantities likely to explode when mixed with the air in the switch-room.

The extent of the damage to plant and the consequent cost of repair increases with the duration of the fault disturbance. Prevention rests in perfecting the insulation, in using conductors and insulators of sufficient mechanical strength, and in placing them out of reach of any foreign substance. The duration of a fault may be restricted by their proper enclosure, which also will prevent the arc from spreading to adjacent plant. The prompt automatic isolation of the faulty section of plant by efficient discriminating systems of protection is a further essential in limiting the extent of injury to property. The explosion of gases and air within the building can best be avoided by suitable enclosure of the plant and switchgear.

Continuity of supply to any locality can only be assured by having duplicate ways, preferably entering from different routes as in the case of a ring main. The proper enclosure reduces the number of faults, but when they do occur they must be instantly isolated without interference with other sound parts or sections. The stability of sound parts during a heavy fault disturbance is of the utmost importance, and at the same time it is the most difficult feature to procure with certainty. It is frequently jeopardized by demands for relay settings which are unnecessarily sensitive and lower than need be, considering the fault-current amplitude which would be a real menace to the continuity of supply.

In order to reduce to a minimum the amount of work in operating supply systems of all sizes, the whole of the plant should be linked together in one common copper network. By this means the supply voltage to all consumers can be maintained throughout the day and night without a number of change-over and switching operations, and large fluctuations in load of an individual consumer are permissible without risk of undue variation in voltage to neighbouring consumers.

The human errors have been minimized by interlocking made to ensure correct sequence of operation, and by optical indication to show at a glance the condition of plant and connections. As time goes on, the further development of automatic service will doubtless remove many pitfalls from the path of operating engineers. The term "foolproof," sometimes applied to electrical apparatus, is a misnomer. "Mistake-proof" is better, because it must be remembered that rapid decisions have not infrequently to be made in the manual operation of plant, and also that even the most skilled persons are not always immune from error.

For many years the author has advocated the consis-

tent enclosure of all conductors and insulators, including a continuous earthed metal cover throughout the whole supply system, from the generators to the load, and even to lighting fittings. All portable plant and appliances should have the earth circuit to their metal covers continued through an earth conductor in the flexible cable. In the supply to coal-cutters and conveyers in mines it is a recommended practice * to surround the outer insulation of the flexible cable (" trailer ") with an earthed sheath of copper braiding in addition to the compulsory earth conductor, thus continuing the metal covering over flexible cables also.

Carried to a logical conclusion, overhead lines would be replaced by underground cables, which are much to be preferred on all counts with one unfortunate exception, the initial cost.

" Metal-enclosed " is a term used to denote that type of construction in which all conductors and insulators are totally enclosed within an earthed metal casing.

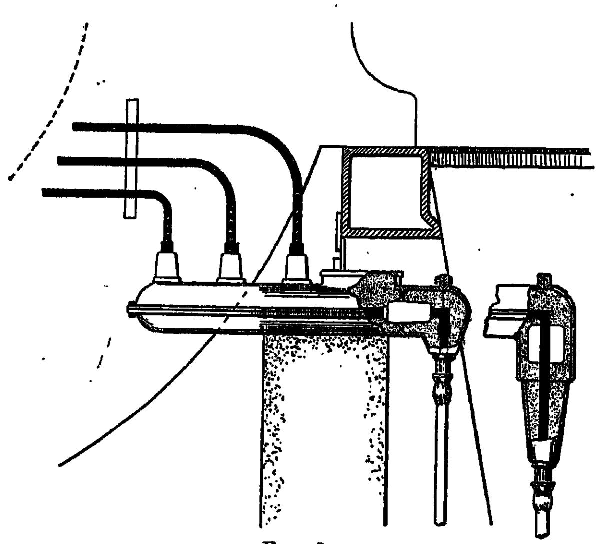

Fig. 1.

" Metal-clad " has been used in preference to " ironclad," " armour-clad," etc., to denote that type of construction in which conductors and insulators, either singly or in groups, are contained and surrounded with metal covers fitting over them like a garment. Thus the several component parts are separately covered and are capable of assembly in relation to each other to form a self-supporting and self-contained unit.

Construction.

Metals used for enclosure.—Metal for casings must be so disposed that the magnetic circuits are broken where necessary to avoid heating by hysteresis and eddy currents. Whilst non-magnetic metal is necessary to sheath a separate single-phase conductor, much larger currents may be carried by conductors sheathed in ordinary iron or steel if grouped so that the resultant flux due to their respective magnetic fields is negligible. When conductors for very large currents are to be metal-clad, the grouping of the several conductors may not sufficiently reduce the resultant magnetic flux; in this case one or both sides of the sheathing must be made of non-magnetic material such as cast gunmetal, brass, or aluminium, according to its situation on the gear. Non-magnetic cast iron has also been found to have the required reluctance and also has the further advantage of high resistance to eddy currents. Non-magnetic steel has occasionally been used in some places, particularly where cast iron is unsuitable owing to its liability to fracture. In other cases copper is used for its toughness, and advantage is taken of its high conductivity which enables it to carry eddy currents without excessive heating. When the clearance between the conductors, insulation and enclosure is not filled in, the gear is described as " air-insulated." When it is filled in with compound it is described as " solid," and when with oil, " oil-immersed."

Metal covering on plant.—The principle of metal enclosure has been well evolved in the general designs of alternators, motors, and other rotating plant. Electrical design dictates that the windings shall be embedded in iron, and ordinary robustness that the projecting ends

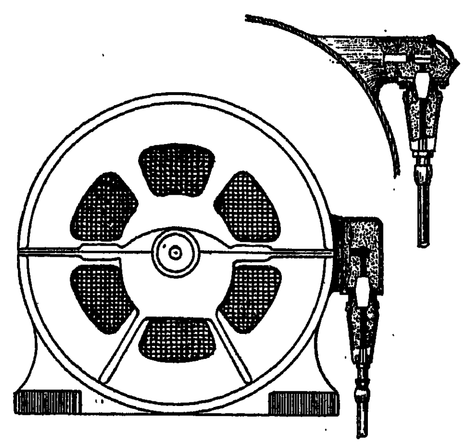

Fig 2.

of the windings shall be protected by a metal end-cover. The entire framework must also be earthed to avoid the risk of shock to attendants. More often than not, however, the proper finishing off of the metal enclosure has been neglected at a most critical place, namely, at the terminal ends of the stator windings. A solid type of metal-clad fitting, providing at the same time a sealing box for the cables, is appropriate at this position. A typical arrangement for a large alternator is shown in Fig. 1.*

Terminal and cable-sealing boxes for smaller machines and motors have been made in various shapes and sizes, and are now a subject for standardization. One method is illustrated in Fig. 2. During the past three or four years power transformers have been subjected to the treatment of enclosure. The demand for economy has led to placing transformers out of doors, and this has been an extra inducement to the complete metal enclosure. A typical pair of sealing end-boxes is shown in Fig. 3. The insulation has required special

* See Coal Mines Act, Explanatory Memorandum (1921), page 52.

* Woodhouse and Melton, Yorkshire Electric Power Co.

research owing to the high temperatures at which it is permissible to run this form of plant on load. Moreover, transformer oil is very penetrating. Joints between the insulator and the metal covering must hold the oil without any creepage, notwithstanding the contraction and expansion of different adjacent materials throughout a great range of temperatures varying from below freezing point to 95° C., not taking into account the extra heat due to the sun's rays. The design shown includes a vitreous porcelain insulator with a surface ground perfectly true and flat and clamped hard upon an oil-proof insertion washer over a machined metal seating. This has given better results than many others tried. The metal enclosure also has presented problems peculiar to this plant. Generally the conductors are enclosed therefore, the principal requisite for complete and continuous enclosure consists in a carefully designed connection between the ends of the metal-clad cable and the metal enclosure. Although often in British practice, and almost invariably in American and Continental practice, the intervening switchgear conductors have provided the biggest obstacle, extensive British development and experience in metal-enclosed switchgear are now available to surmount this. This includes " cubicle," " truck," and " metal-clad " types. The two former have usually been " air-insulated " types, and the latter a " solid " type. The air-insulated types are a half-way measure; the sets of conductors are covered by a sheet-steel enclosure, but there is not the distinct inaccessibility of every conductor throughout its whole

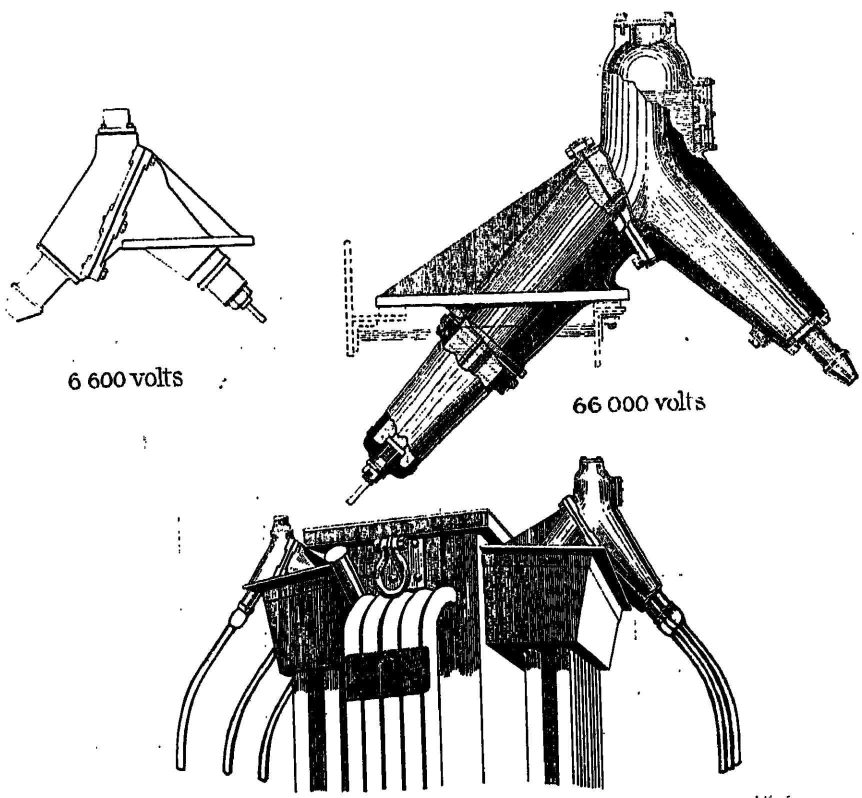

FIG. 3.

separately, and for heavy currents must be non-magnetic. Conservator tanks maintain a slight pressure of oil from within, and it has not been so simple as might at first be thought to procure suitable castings to withstand the specified oil pressure-test of 15 to 30 lb. per sq. in. without the slightest trace of oil leakage.

The enclosure of reactances when immersed in oil tanks can be dealt with in the same way as that of transformers. Reactances made in the form of coils of lead-covered cables embedded in a concrete block with ends finishing in metal terminal boxes are truly metal-clad, and as such are very suitable for the purposes under consideration, as the apparatus is virtually a coil of metal-clad cable.* Throughout the layout of plant,

* Beard.

length that is afforded in the solid types by the compound filling.

Metal-clad switchgear construction.—Metal-clad " draw-out " switchgear has been made in three general classes as follows :—

(1) Horizontal isolation (Fig. 4).*
(2) Upward isolation (Fig. 5).*
(3) Downward isolation (Fig. 6).†

Great care has been exercised in the design in order to prevent accidental access to the live socket contacts within the isolating orifice. In the horizontal draw-out gear they are deeply recessed and the orifice is automatically closed over with a door when the switch is withdrawn. Similar locking-off doors are applicable to

* The author. † Erskine, Heap.

the upward isolation draw-out types, but in addition this plane for withdrawal permits the oil immersion of the isolating socket contacts.*

Duplication of components.—In the general layout of switchgear the amount of duplication should be

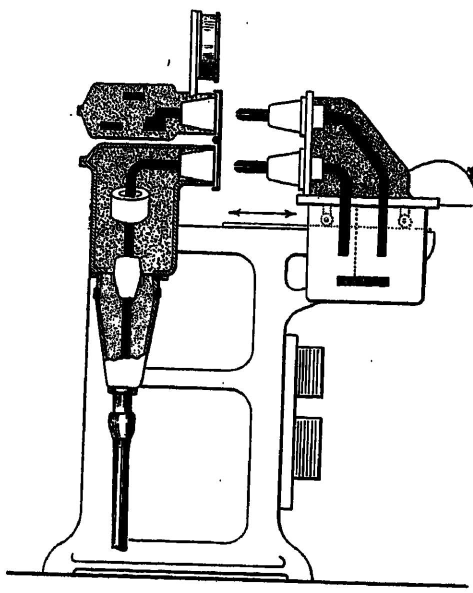

FIG. 4.†

governed by the liability to breakdown. Given absolute immunity from breakdown, the simplest arrangement solely required for the control, protection and indication should be adopted. The metal-clad enclosure of all conductors certainly does reduce the possible extent of switchgear breakdowns, thanks to its unit form and to

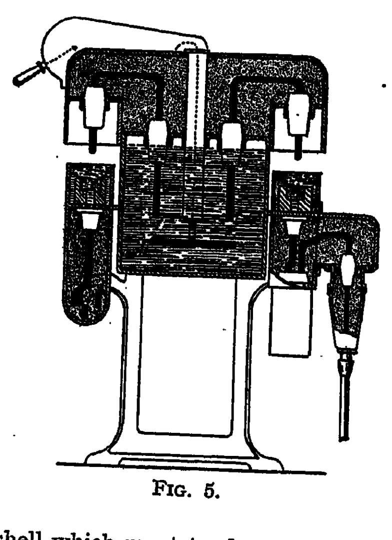

FIG. 5.

the metal shell which must tend to localize the disturbance and prevents the spread of arcing. It is better economy to increase the initial expenditure in obtaining quality and strength of parts, thus tending to make them immune from failure, than to duplicate such parts ;

* The author.

† Figs. 4, 5 and 6 are diagrammatic of classes only and are not intended to show details of any particular manufacture. Busbars are shown compound filled (Highfield).

for instance, one good circuit breaker is better than two of inferior quality—it engages less attention and maintenance, to say nothing of the saving in initial outlay for housing.

The draw-out feature has been shown to be a good substitute for the duplication of circuit breakers, in so far as it furnishes a ready means of inspection in safety and of the substitution of one circuit breaker for another at short notice.

On a few occasions during the life of the plant the duplication of busbars may be advantageous. For example :—

(1) When running up a new or doubtful machine on an independent circuit or test-circuit.
(2) When making extensions one bar may be made dead at a time.
(3) For cleaning purposes.
(4) In case of breakdown of switchgear.

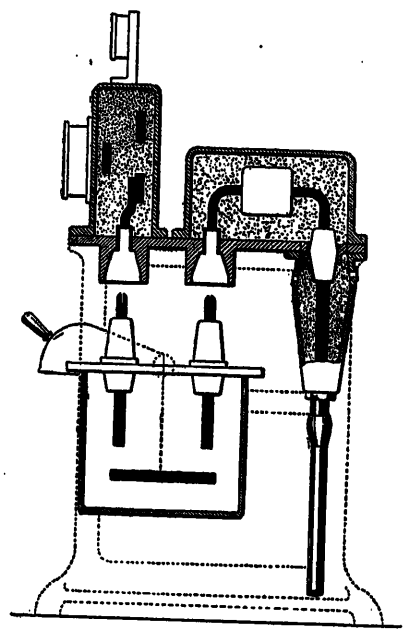

FIG. 6.

One of the objects of the metal-clad form is to eliminate items (3) and (4). The complete enclosure of all insulators does save cleaning operations, and the chances of breakdown are certainly remote if due care is taken in the selection of gear suitable for the most severe conditions of service.

Duplicate busbars and changing circuits.—The changeover from one circuit to another is always more or less risky, according to circumstances of the load and the design of the apparatus. Many serious accidents and shut-downs have occurred due to the faulty opening of busbar selector switches whilst carrying load on open-type switchgear. One large power supply station was shut down three times in one year on this account, and so, from the earliest* metal-clad power station switchgear, care was taken to remove this danger by suitable designs and interlocking, making it impossible to change

* Stepney and Neepsend.

circuits over when on load. To accomplish this the hood of the circuit breaker was fitted with two sets of plug sockets, corresponding to the top and bottom busbars, and one set of plugs. Access to change-over plugs can only be obtained by first withdrawing the circuit breaker carriage (see Figs. 8 and 14). The change-over fittings are thus safe, and it is impossible to change over when load is passing through the circuit. A device either hand-operated or automatic, interlocked with synchronizing connections and auxiliary switches, gives

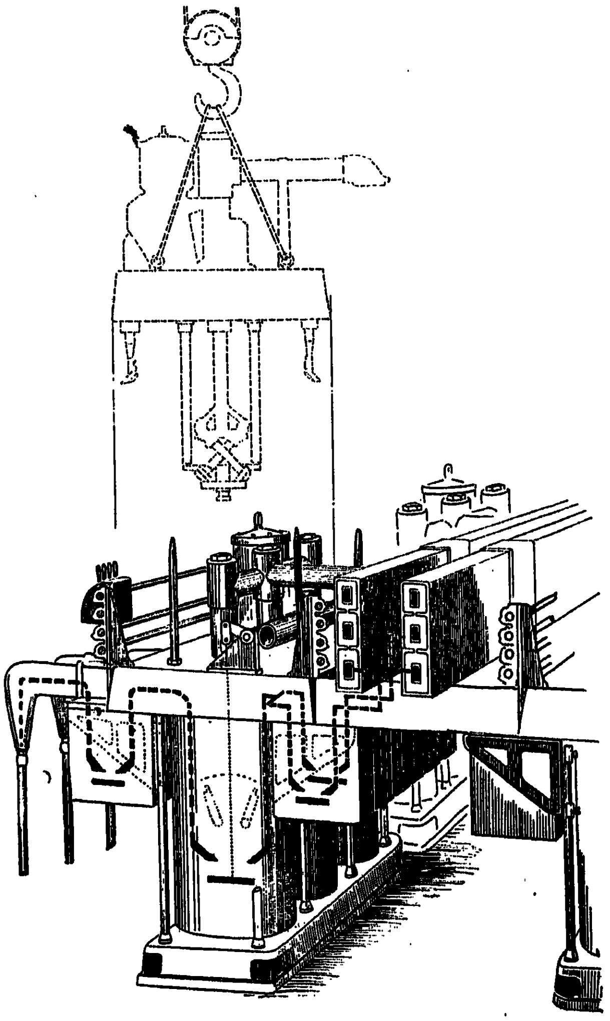

FIG. 7.

direct and remote, " top " or " bottom " busbar indication.

To be able to make the change-over without having first to open the circuit on the oil circuit breaker has recently been claimed to be an advantage, and several methods have been investigated. One proposal * consists of enlarging the hood (see Fig. 9) and withdrawing the plugs from the front of the switch, interlocks being provided that will allow both sets of plugs to be " in " at the same time when the bars are in parallel. Care must be taken that no portion of the live plug is accessible during the process of withdrawal. Another plan involves the use of two circuit breakers suitably interlocked (Fig. 10). A modification of this practice is to put the two circuit breakers into one double-contact circuit breaker (Fig. 11).* Another proposal is to substitute for the plugs a set of change-over switches immersed in oil or a semi-fluid insulating compound within the hoods on the circuit breaker (Fig. 12).

* Christianson.

The interlock must in any case be so arranged that

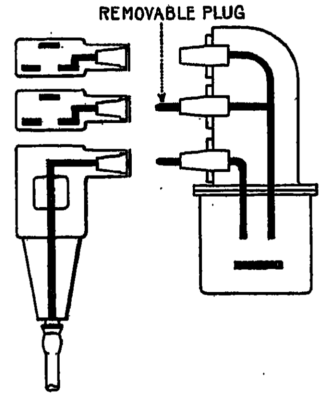

FIG. 8.

electrical contact between the busbars is never made on the change-over device unless the busbars are in synchronism. That is to say, the coupling switch joining the busbars must be closed and cannot be opened until the change-over has been completed. Sometimes a coupling switch must be installed only for this purpose, involving considerable extra expense. To open the

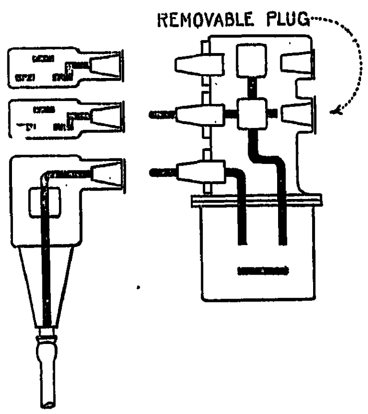

FIG. 9.

circuit before changing over is the safe way and is more simple in design. The need for changing over whilst the circuit is alive is often more imaginary than real. It is necessary in either case to arrange the circuits on the system so that any one of them can be made dead without interfering with the continuity of supply. For example, a generator can always be disconnected for a short time when others are running, and the layout

* Ferguson and Pailin.

of feeders also, if made with parallel feeders or ring mains, provides for the disconnection of any feeder at short notice. If only for the proper maintenance of switchgear these facilities are required, one reason being that circuit breakers can be periodically tried to ensure that they trip correctly on the occurrence of faults. Moreover, it must be so in practice because at any time a generator or feeder might be cut out automatically —an incident which should not interrupt supply. Rapid and hasty changing-over during times of emer-

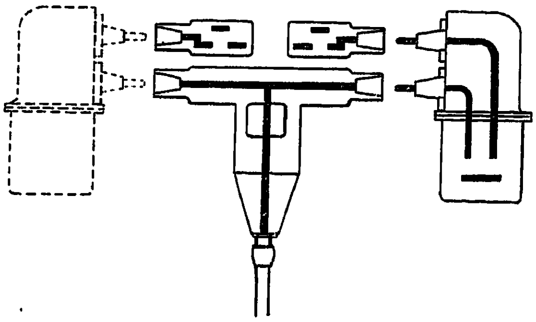

FIG. 10.

gency inevitably leads to errors and consequent interruption of supply. In one type of upward isolation draw-out gear, oil-immersed busbar selector switches are included in the fixed portion (Fig. 7). There is less difficulty where selector switches are used, as in this form of gear, in changing over on the live circuit, but it is still best, in order to simplify the design of interlocks and to limit the operating functions, to make it impossible to move these selector switches whilst the circuit is closed.

Separation of phases.—The separate phase enclosure

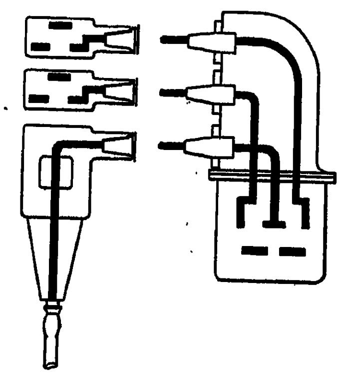

FIG. 11.

in metal-clad switchgear is, as a general rule, only adopted where circumstances of heavy duty and comparatively high voltage occur or combine to make it advisable. These conditions certainly exist in the case of capital stations and in extra-high-voltage networks of large kVA capacity, but present experience indicates that the multi-phase enclosure of busbars, instrument transformers and connections sealed in compound is quite sufficient for power stations in which the aggregate full load is below 100 000 kW, or in which the pressure is below 40 000–50 000 volts. The practice in this respect is somewhat analogous to the respective use of 3-core or single-core cables.

The likelihood of an internal fault is remote, but should one occur the arc cannot be long or sustained, because it is confined to the earthed metal in its own

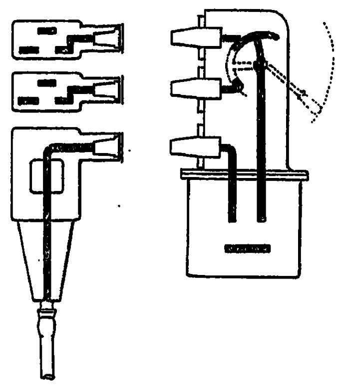

FIG. 12.

close vicinity. It is not so with the cellular switchgear in which there are open conductors separated from earth by large air spaces. In some of the largest stations in the world the phase separation has been carried out to the extent of providing what is virtually a separate building for each phase. Experience has shown that even with this extreme precaution a fault can spread from one phase to another and—even more serious from the point of view of continuity of supply—from one circuit to another. At least one incident is on record where the entire switchgear was destroyed

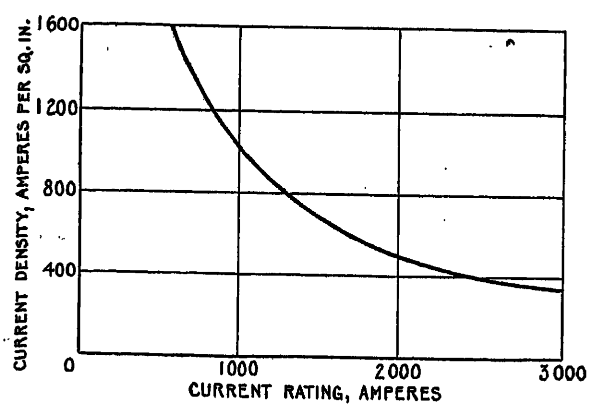

FIG. 13.

irretrievably by fire caused and sustained by an arc having a resistance too high to cut out the generators, and there are many cases where arcs have spread over two or more panels, necessitating a complete shut-down of the power station.

An example of complete phase separation with metal-clad switchgear is shown in Fig. 7.* The busbar

* First design: Dalmarnock (1917), Carville (1917), Nechells (1919). Gregory and Electrical Improvements, Ltd.

chamber is divided into three compartments, earthed metal surrounding each phase. The isolating switches, circuit breaker, current transformer and single-phase potential transformer, and all connections down to the cable dividing-box, are in separate phase enclosures. The principle may be extended by using single cables for generator and transformer leads.

Busbars.—The simpler the busbar system the better. The only connections to them should be those which pass through the main oil circuit breakers which, when drawn out entirely, isolate all other conductors in the panel from the busbars. The design allows for filling in all busbar sections at the factory, and afterwards a pressure test of three times the line voltage between phases and between all phases in turn and earth is carried out. Unfortunately, the compound filling is a poor conductor of heat and, therefore, current densities must be low, particularly so at the heavy current ratings with the ordinary form of construction. Fig. 13 is an approximate curve for the safe rating, and shows the relation of current rating to current density.

The magnetic forces which set up mechanical stresses between conductors during the passage of heavy "through" fault currents, present no difficulty to the metal enclosure and compound filling. On the contrary, cell gear with its long open-type conductors must have insulating supports additional to those required for natural construction and connections. These are not required on solid metal-clad gear, because not only are the centres and general dimensions more compact and the conductors shorter, but the compound in which the conductors are embedded acts as a solid buffer to movement under impulsive stress.

Circuit Breakers.

Circuit breaker enclosure and breaking capacity.—The enclosure of the circuit breaker is a large factor in determining the breaking capacity. The majority of circuit-breaking failures have been the result of weakness in the tanks and top plates. The predominant feature is the relation of the arc energy to the impulse pressure on the walls, top and bottom of the oil-switch enclosure.

The impulse pressure on the sides of the tank varies roughly as the inverse square of the distance from the arc, and this factor enters into the determination of the most economic and effective dimensions of the tank, the minimum dimensions being controlled by the clearances necessary for the working voltage. In the case of metal-clad gear in ordinary industrial service the circuit breaker has been more economically and conveniently arranged in one tank than in three separate tanks. Metal divisions inside the tank surrounding three sides of the sparking contacts, for a breaking capacity above 100 000 kVA, eliminate the risks of arcing between phases, in addition to strengthening the tank (Fig. 15).

Vent pipes can never be large enough to give adequate relief to local pressures established by the arc within the tank. Moreover, open vents throw large quantities of oil. On the other hand, as some outlet is necessary to allow for the exhaust of the gases and smoke which are products of the arc, the practice of a baffled vent has been evolved. To prevent fouling the atmosphere in the switch-room it is best to conduct the vent pipes to the outside of the building. An open area in the centre of the building (see Fig. 20) is useful for this purpose.*

Reduction of arc energy.—Various methods have been advanced to limit the amount of arc energy and the resultant stress upon the enclosure. The most common has been to speed up all movements after the relays have set them in operation, on the principle that the duration of the arc must be reduced to a minimum. A reasonably high velocity after the separation of the contacts at the first zero point on the current wave, with a short break, has been aimed at in preference to a long break.

Another method, which incidentally also increases the velocity of the break, is to employ a number of breaks in series, but any increase beyond two will lead to complication in design and consequent weakness or increased expense to maintain the same standard of insulation in view of the additional parts.

A further method has attracted much attention. The arcing contacts are enclosed in a steel cylinder called an "explosion pot." It has been claimed that this design takes advantage of the explosion to speed up the break, and, as the worst of the impulse pressure is taken within the pot, the walls of the circuit breaker need only be strong enough to contain the oil.† Whilst this may be an excellent means of strengthening existing weak circuit breakers, it does not allow for accidents in the working of the explosion pot. At some time or other the arc or gas explosion may occur outside the pot, in which event the ultimate safeguard is the strong external enclosure. Then the solution will be more expensive and, in the long run, really no more efficient than a circuit breaker with rational arcing contacts.

The simplest construction of current-carrying and arcing contacts includes one or, at the most, two breaks, spring loading for increasing the natural acceleration due to gravity, and a large volume of oil. Incidentally the oil volume provides ample clearance for insulation, particularly along the insulating surfaces between the contacts and the top plate, and a good head of oil above the point of separation of the arcing contacts. The whole is enclosed in boiler-plate tanks and a steel top plate is attached, together with correspondingly strong studs or bolts and flameproof flanges. This construction has been applied to reduce the arc energy to an economic minimum and to provide sufficient strength of enclosure to withstand the impulse pressure arising therefrom.

A typical design of circuit breaker embodying the features advocated is shown in Figs. 14 and 15. This has been used on generating plant of 60 000 kW with 10 per cent reactance. The tank is capable of withstanding without permanent distortion a sustained hydraulic pressure test of 350 lb. per sq. in., which corresponds to an impulse pressure possibly 10 times greater.

Rated breaking capacity of circuit breakers.—Some advance has been made in recent years on an expression of the breaking capacity. The B.E.S.A. definition ‡ is :—" The breaking capacity of an oil immersed circuit breaker is the maximum kVA which the circuit

* Colenso power station.
† Hilliard (U.S.A.). See also Bernard Price: *Transactions of the First World Power Conference*, 1924.
‡ B.S.S. No. 116—1923.

breaker will break, under prescribed conditions, at stated intervals, a specified number of times. The value of the maximum kVA is the product of the rated working voltage in kilovolts, and the actual current at the time of separation of the contacts, multiplied by 1, 1·73 or 2 for single-phase, three-phase, or two-phase systems respectively." The specification explains fully that the current on a severe short-circuit will reach temporarily a high value but that " due much room for speculation as to what the kVA rating of any circuit breaker really means in relation to satisfactory service on a specific size of plant. Is the 10 000-kVA power station to have 60 000-kVA or 200 000-kVA circuit breakers ?

Performances of circuit breakers have had in the main to be gauged from experiences in places where they have been overloaded under short-circuit conditions. In such situations comparatively small circuit breakers

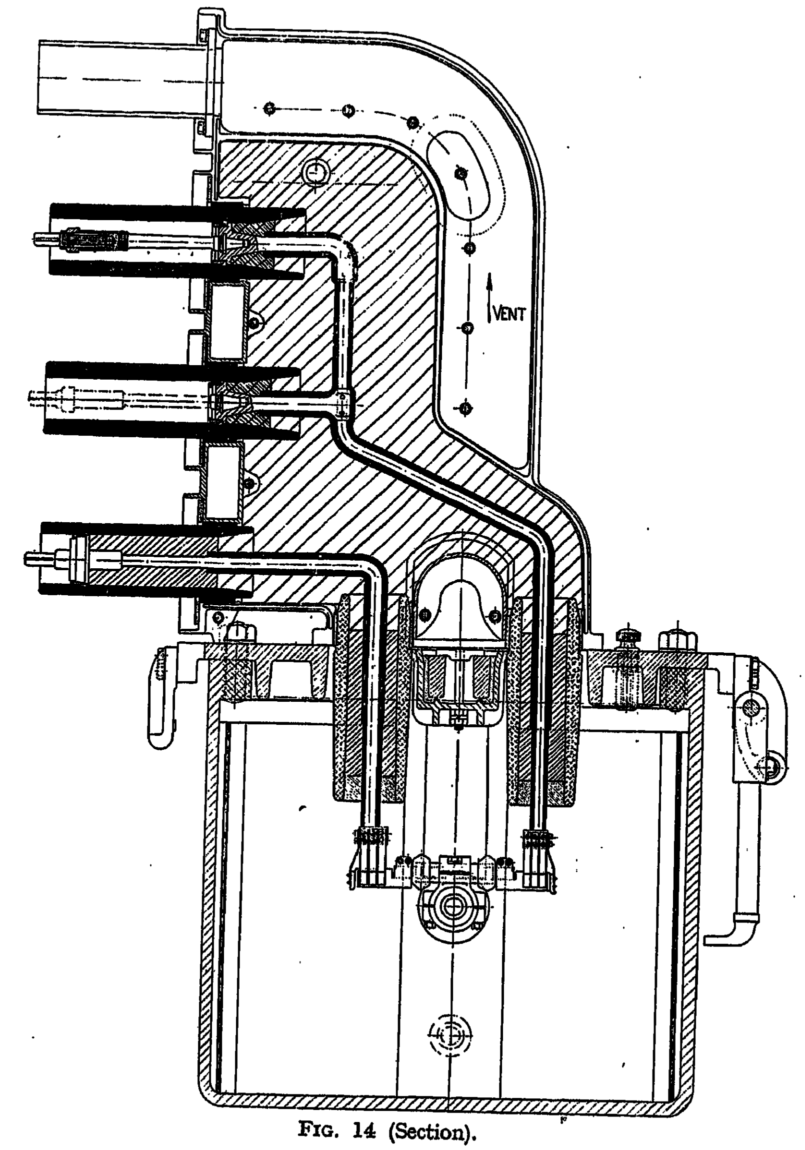

FIG. 14 (Section).

account " should be taken of reduction in the current to be broken as affected by the time characteristic of the circuit breaker and relays. As an example, with this easement a generator circuit breaker may be rated at six times the total kVA load of the generator (10 per cent reactance on short-circuit), although it is admitted that under a combination of the worst conditions on the same circuit as much as 20 times the current may have to be broken. Between these two values there is have satisfactorily cleared faults of much larger value than that for which they were originally intended, but when fixing commercial ratings due margin for safety had to be made to cover the unfavourable hazards also met with in practice. For example, a switch of the dimensions indicated in Fig. 16 has served at a colliery, which made rapid electrical developments, in places where the short-circuit was not less than 60 000 kVA. If commercial ratings were based solely upon such

experiences, the manufacturer, acting upon the B.E.S.A. specification, might advance this circuit breaker for use on plant of an aggregate full-load capacity and 10 per cent internal reactance of 10 000 kVA.

By way of comparison the corresponding sizes of actual commercial ratings in use to-day are indicated in Fig. 17. It will be seen that these larger circuit breakers range from 25 000 to 150 000 kVA breaking capacity.

According to whether the plant is to be one-sixth of

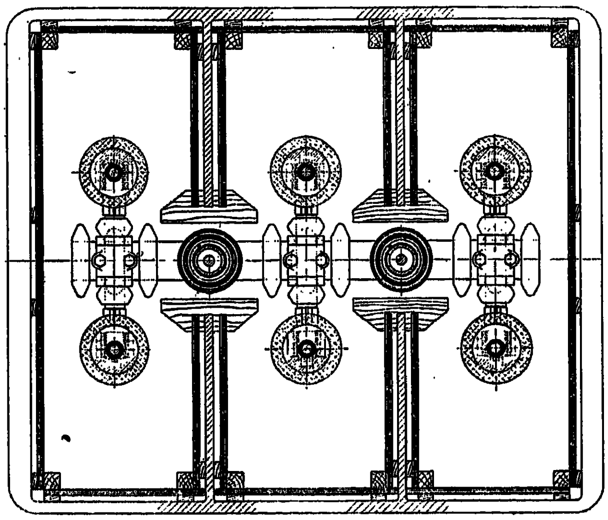

FIG. 15 (Plan).

this (as recommended by the B.E.S.A.) or one-tenth (as preferred by the author), these circuit breakers would be used on plant aggregating 4 166 to 25 000 kVA or 2 500 to 15 000 kVA respectively.

The introduction of reactance, whilst reducing the current and therefore the destructive mechanical forces on all parts of the system, does not necessarily reduce the arc energy with which the circuit breakers have to

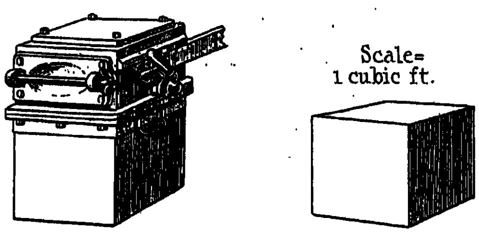

FIG. 16.

deal in clearing short-circuits from the system. In fact, in some cases the stress experienced on the circuit breaker has been actually greater due to the reactance, notwithstanding the reduced current value.

It has also to be borne in mind that the sparking contacts may separate at any part of the fault transient. For example, if the fault (it may be a high-resistance fault or a fault to earth culminating in a dead short-circuit) starts at A (Fig. 18), the sparking contacts may separate at any point from B onwards. At the worst,

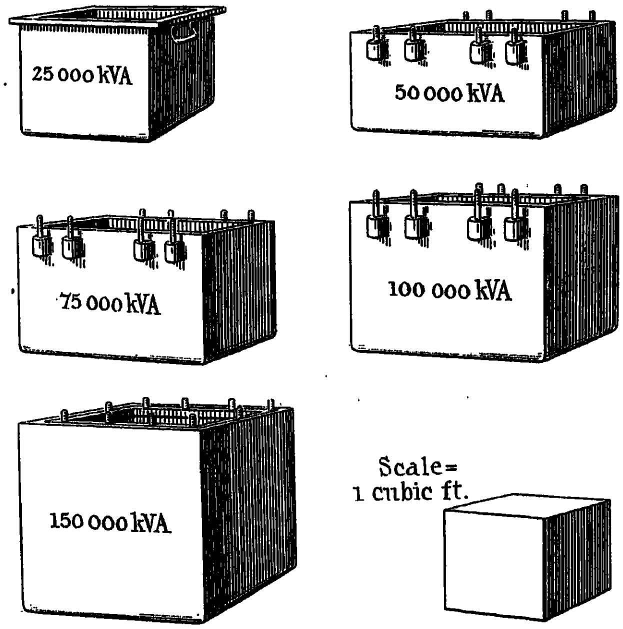

FIG. 17.

in rare cases it might be at C, when the breaking capacity is the maximum, viz. 20 times full load. If it is an instantaneous short-circuit the contacts would separate

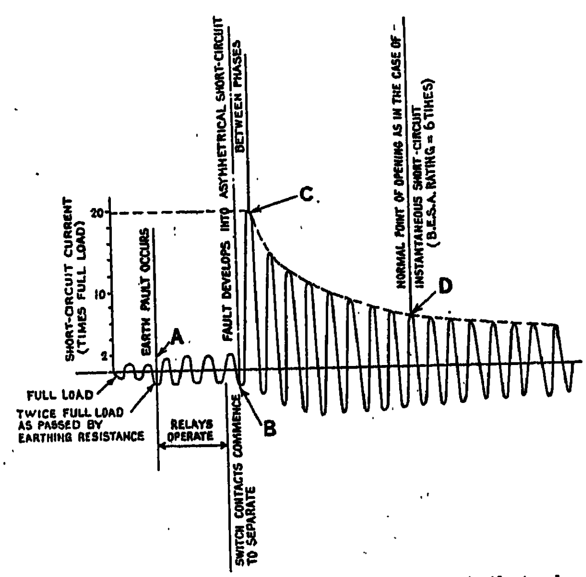

FIG. 18.—Curve illustrating maximum current that circuit breaker should clear.

in most cases about D, where the kVA on the B.E.S.A. basis would be six times full load.

In any case the circuit breaker must be designed to

withstand the mechanical forces and impulses given by the current at C. It should also break circuit at this stage at least without danger to persons or neighbouring plant, although it might in such exceptional circumstances require some attention before being put into service again. Moreover, the specification recommends that as the current to be broken "is limited by the reactances and resistances in circuit," the rating of the circuit breaker may be reduced in proportion. This seems to be in conflict with the experience that in circuits carrying equal current additional reactance increases the arc energy, and so at present the breaking capacity may not truly represent the work that the circuit breaker has to do in breaking the circuit.

Of course the way to rate any article is to base its performance upon some unalterable standard. It would therefore be a better guide, in stating the breaking-capacity rating of a switch, to qualify it by stating the basis in terms of generating-plant output and reactance on short-circuit.

burning of contacts, or other forms of permanent injury." Any circuit breaker should be capable of carrying the maximum "through" current possible in its situation on the system for at least 1 second in order to provide a margin for safety in the duration of a through short-circuit for ½ second.

For power station service a high "through" rating current is required of not less than 100 times the normal current-rating of the generator switchgear panels, assuming not more than 10 generators of 10 per cent reactance. At such ratings the conductors must all be so arranged that the magnetic forces improve the current-carrying capacity of the contact surfaces. This rating has sometimes been called the "thermal rating," but as there are other deforming causes than temperature, for instance strains on conductors due to magnetic causes, the thermal characteristic is not the only one and the term "through" rating would appear to be more expressive.

Charging resistances on circuit breaker contacts.—There is a considerable element of doubt as to the utility of charging resistances contained within circuit breakers and carried on the moving contact for the purpose of limiting the current-rush on switching-in power transformers and motor armatures. It is now generally recognized that their use for switching-in cables is unnecessary. All plant should be capable of withstanding the stress of switching without their use, as the stresses to which the plant may be subject are not always controlled by the charging resistance, since there are conditions of charge which occur in circumstances other than the closing of the individual circuits—for example, the re-establishment of the supply after a momentary cessation occurring during the clearance of a fault on another part of the system. Certainly the circuit breaker is greatly simplified by the elimination of the charging resistance.

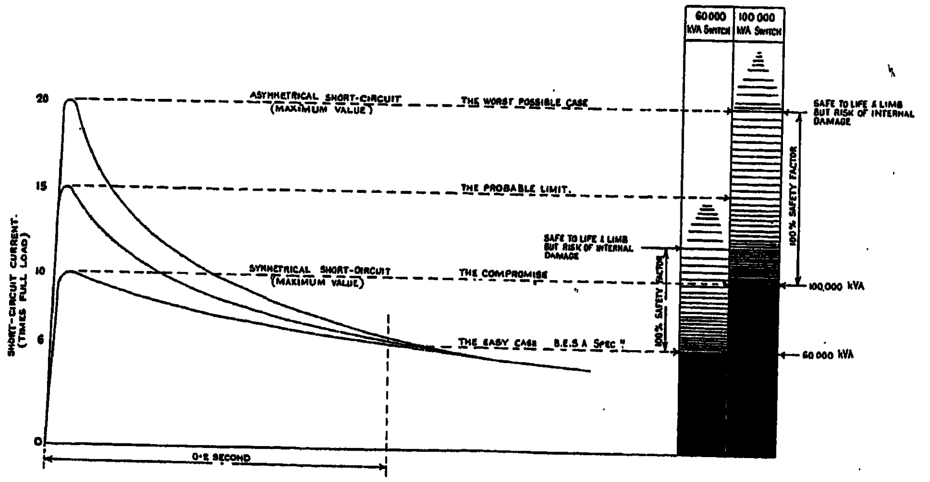

FIG. 19.

Shaded portion shows encroachment on safety factor; 10 000-kVA plant assumed.

A suggested compromise is to rate circuit breakers as being perfectly efficient at the maximum symmetrical current, viz. 10 times the aggregate full load, but admitting encroachment upon the design safety-factor at the exceptional asymmetrical current up to 20 times full load (see Fig. 19). If this were the understanding between the buyer and the maker it would only remain, in selecting the required size of breaker, to make allowance for any deviations from the standard circuit in inductance, resistance and capacitance, appertaining to the position and circumstances of the circuit on the system. A generator circuit with more inductance than the 10 per cent internal reactance on short-circuit may require greater breaking capacity, and a distant non-inductive circuit less than the standard, for equal short-circuit currents. The exact adjustment is a matter for experience and research.

"Through" rating of a circuit breaker.—The "through" rating of a circuit breaker may be defined as "the maximum current that the circuit breaker will carry during the transition period of a fault current without deformation of any parts of the circuit breaker,

LAYOUT.

Layout of busbars.—The simple layout for power station service, shown in Fig. 20, provides for parallel

running in sections, any of which may be completely isolated from or coupled to a common duplicate busbar. The dotted lines represent the outline of the switch-house building. The inside, open area provides light and an outlet for the vent pipes.

Reactances.—Reactance, if necessary, may be connected either in star fashion (Fig. 21) or in parallel with the busbar section switches (Fig. 22). There is but little to choose between these two systems from the point of view of the cost of a reactance for equal service. These diagrams lead one to suggest that on an all-solid system where the duplicate busbar is rarely, if ever, used, it might be made to serve the dual purpose of "hospital" busbar and reactance tie busbar, thus saving the initial and upkeep expense of the separate reactance plug-gear and busbar.

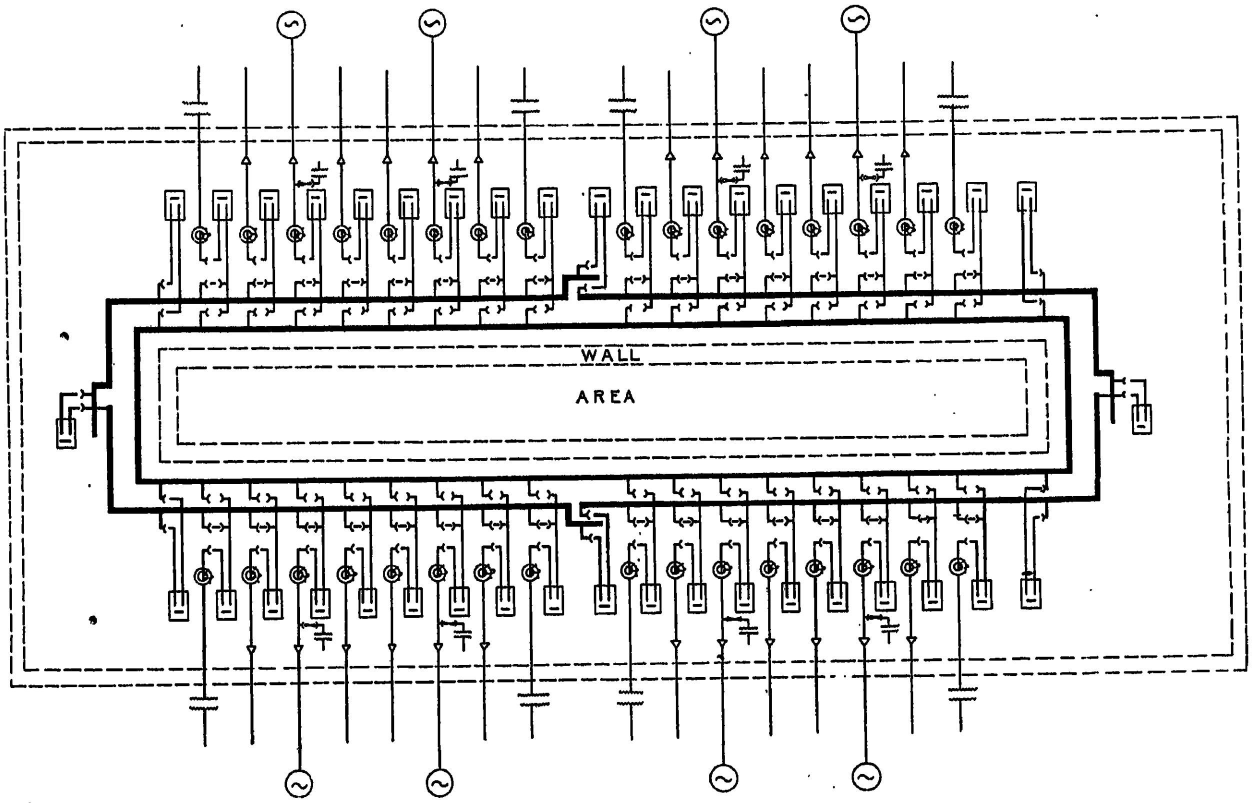

Fig. 20.

The use of a reactance is apt to complicate the layout of the gear and the operating conditions. For example, the effect of reactance between busbar sections may be nullified by an interconnection on the network of a ring main in parallel with the reactance.

Much care must be exercised in determining the values and location of reactances, otherwise the resultant complication due to voltage variation may be troublesome from an operating standpoint and militate against some of the advantages to be derived from the complete parallel running of the network on a large system.

Economy in layout.—It is preferable to employ, throughout the system, circuit breakers competent to act without artificial inductance, that is, other than that inherent in the design of the cables, transformers and generators. The economy in being able to lay out and run the network without having to think when, or when not, to put in reactances is an item which can be balanced against the possible extra initial cost of the switchgear. Moreover, as stated above, inductance in the fault circuit, although it reduces the fault current and the mechanical forces due to such currents, does not necessarily reduce to the same degree the energy dissipated in the arc and consequently the performance of the circuit breaker. This must not be overlooked when contemplating the use of reactances for the sole purpose of restricting the arc energy in circuit breakers when operating under short-circuit conditions. Single-phase faults to earth might be reduced to comparatively low values by the insertion of resistances between the neutral point of the generators and earth, but even in this case there is the risk of another earth fault occurring simultaneously on a different phase. This condition would be nearly as severe on the circuit breakers as an unlimited fault to earth.

Other Components.

Current transformers.—Considerations of shock risk must include the possibility of high secondary voltage due to an accidental opening of the secondary circuit. This condition also carries with it the risk of breakdown

due to excessive temperature caused by hysteresis in the iron core. Both these risks can be reduced, if not altogether eliminated, by suitable design of electrical characteristics. The impressed electromotive force should be strictly curtailed by reducing the number of primary turns to a minimum. The single-turn (bar type) primary has much in its favour, and, whenever possible, instruments should be designed to suit. In some cases it pays to sacrifice over-exacting accuracy to safety and convenience in maintenance and operation. A full-load secondary current of 5 amperes is preferable to one of 1 ampere because, as the secondary voltage varies inversely with the current, the difference might be that between discomfort and danger when touching with the hand the terminal of a relay at such a time that the secondary is open-circuited and a large primary "through" current is flowing. Delicate fault-settings of relays are sometimes attempted by the use of large current transformers, whereas coarser settings would give almost equivalent protection to the system with much greater security. The single-turn primary for current-transformer working with instruments on supply systems of 20 000 volts is very desirable. At 33 000 volts and over it is more so, because a primary winding

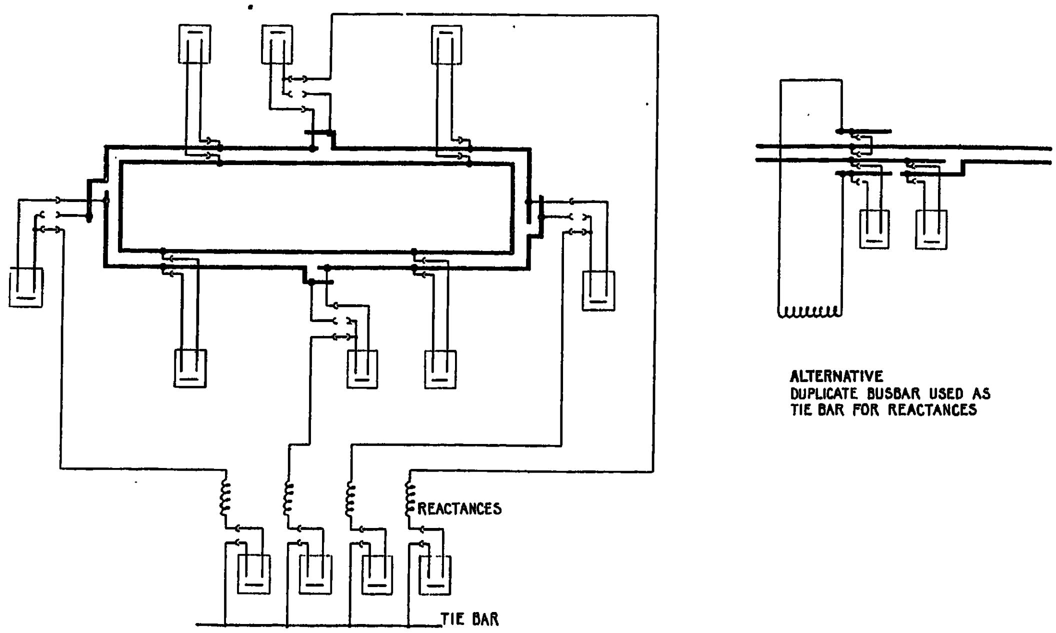

FIG. 21.

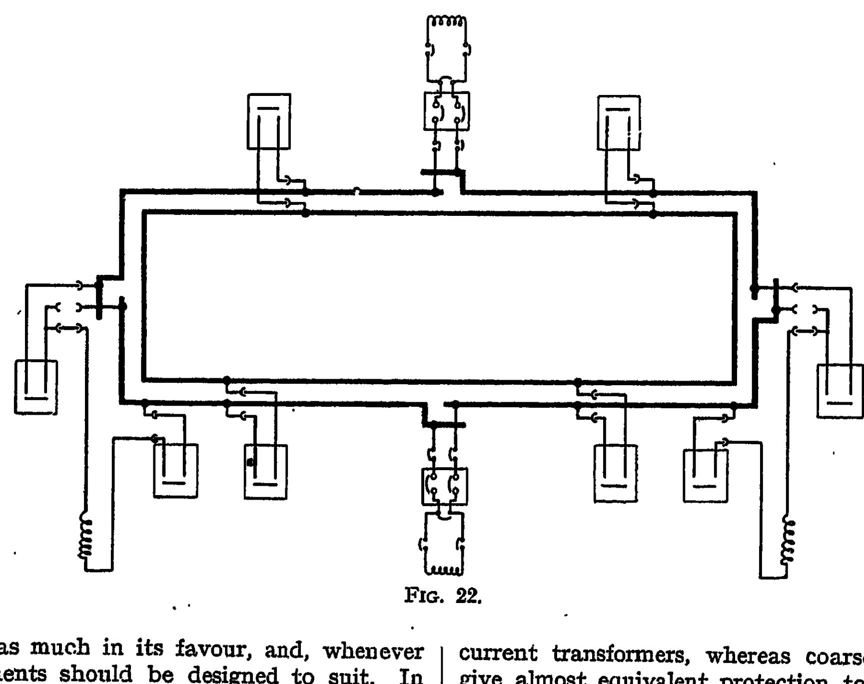

FIG. 22.

of two turns or more increases the dimensions and manufacturing difficulties altogether out of proportion to the difference in the number of turns. For instance, the single-turn transformer may have the primary in the form of a lead-covered cable or a copper bar with a solid insulator threaded through its core, whereas the transformer with two turns must have one convolution over the core. Unless a large difference is allowed in the cost or in the space occupied, the choice in insulation lies between a metal-clad conductor or a sound vitreous body like a straight porcelain bush and a flexible fibrous material moulded or wound on cloth or paper; this latter alternative must be very well done to be anything like so durable.

Insulation durability.—The author has found security in a high standard of pressure tests on individual parts and assembled gear. The failure of insulation on switchgear in service is so serious that even at an increased initial cost it is economical in the long run to have a large margin between the normal voltage and the breakdown voltage. It is, however, also essential that the test pressure shall be well below the breakdown voltage in order to safeguard against the possibility of over-straining the insulation in the process of pressure

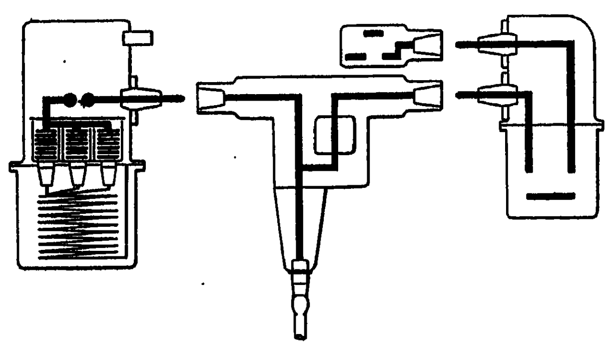

FIG. 23.

testing. Up to 20 000 volts a standard of design for each insulator to break down by flash-over at not less than 4 to 5, and by puncture at not less than 6 to 7, times the line voltage at normal frequency in a "type test" of 1 minute's duration, at its maximum working temperature, has allowed commercial pressure tests on assembled gear of 3 times the line voltage between phases and phases to earth for 1 minute. At voltages higher than 20 000, where on metal-clad gear the use of condenser-type bakelized paper is practised, the design should be made for the same standard of breakdown pressure, but, to reduce the risk of over-stressing, the pressure test might well be reduced by 10 per cent. For example, a good insulation on 33 000 volts is one that would break down by flash-over at not less than 120 000 volts, and puncture at not less than 180 000 volts. This should sustain no permanent injury when tested to 90 000 volts.

It must be borne in mind that the high-pressure test is not the only criterion. It is a measure of the initial strength but not necessarily a measure of its vitality. The latter must be judged by the result not only of the electrical but, in addition, the mechanical, microscopic and physical examination on "type tests."

Excess-pressure dischargers.—It is sometimes difficult to understand the need for the very expensive lightning arresters which are installed in other countries, as compared with the experience in this country. It is true that higher voltages are employed, but the insulation should be better able to withstand the excess-voltage conditions. It is probable that lightning has been made a scapegoat to explain away many failures which in reality have been due to inferior insulation at the start.

A high-frequency surge of excess voltage may be disposed of broadly under two methods: (1) to absorb it upon the line itself or (2) to allow it to discharge to earth. A direct lightning stroke must flash over the nearest insulators, but surges from atmospheric causes or by induction from lightning effects or switching operations are within the scope of protection. Where cables can be laid in series with the overhead lines, the result is achieved without any additional protective

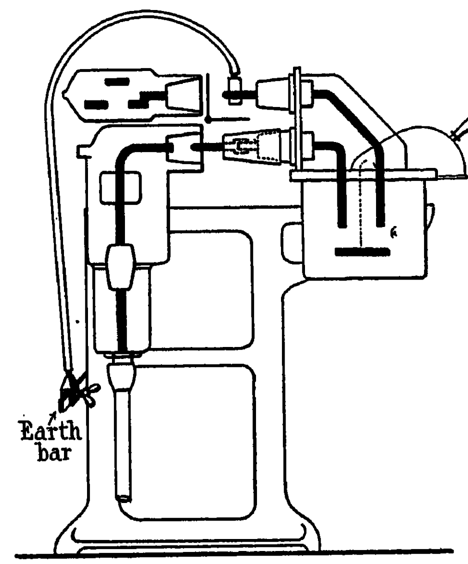

FIG. 24.

appliance. The excess voltage is absorbed in the capacity of the cable. This method, together with a high standard of insulation, satisfies the conditions prevailing in this country. The discharge method first involves the combination of gaps over which the discharge starts, and then devices to seal up the path and quench the discharge, or in some way prevent the following on of the power current. In one design on metal-clad lines the discharge is made over a number of narrow air-gaps formed between flat surfaces in a pile of copper discs, the flow of power current being limited by a resistance immersed in oil. The whole device is mounted in a metal-clad carriage which is plugged into the switchgear orifice (Fig. 23).

Safety to men working on the line.—The method of earthing at the end of a line on which men are going to work is indeed a matter of life and death not only to the men on the line but also to the operator who has to make the earthing connection. To him there is the risk of a conductor being "alive" by mischance. The wrong panel may be taken or a chance connection another way round forgotten. The flicking of a high-

tension conductor with a cable, in order to ascertain if it is dead, is on a par with pointing pistols or looking for a gas leakage with a naked light; and yet in many switchgears it is the only means available. Without exception the final closing of the earth connection should be done within an oil-filled enclosure, for example on the contact of a circuit breaker. Then if any mistake is made it will be no more serious than closing on a fault. Further, this may be limited to a single-phase fault to earth if a trial is made on one phase only at first. Fig. 24 shows an assembly of plug contacts, terminals, and earthing cable, which serves this object. In another design a hand-operated earthing contact is included as a component in the oil-immersed isolating switch; this is shown in Fig. 25. This figure also shows a convenient means of earthing automatically and simultaneously with the lowering of the switch tank.* This is vital when the lowering of a tank might otherwise expose a live conductor, or when there is any risk of the exposed conductor subsequently becoming dangerous to handle, for example, by electrostatic leakage across the oil between the contacts of an opened oil switch, by the inadvertent closing of another switch or by other mischance.

Indicating and interlocking.—Direct indication of "on," "off," "synchronizing," etc., placed on detail apparatus in a bold style, in a conspicuous position, and indication by coloured lamps serve a very useful purpose in the elimination of operating mistakes. A more complete method which has been adopted in several recent power stations is shown in Fig. 26, where discs give a semaphore type of indication on the control board. These discs are planned with the main connections like a single-line diagram, and are operated simultaneously with the switchgear components which they represent, by means of small electromagnets mounted on the back of the panel. The indicators are controlled by mechanical movements associated with interlocking devices to ensure a proper sequence of operation to avoid danger. The scope of this section is by no means limited to switchgear. For example, electric signalling and interlocking on railway tracks, if universally applied, might be the means of avoiding a wastage of life on a scale which must be very large compared with the number of mishaps on switchgear, for instance.

Economizing switchgear.—The cutting down of strength and qualities of designs and materials on important switchgear is doubtful economy. The cuts should be restricted to reducing the required number of functions, appliances, and constructional features. For example, an oil switch-fuse * combined with a transformer to form a small outdoor substation as shown in Fig. 27 takes the place of switchgear panels, transformer and connections in a building.

The single-switch substation scheme † reduces the number of switch panels required in the ring main (Fig. 28). At the same time it provides for the automatic isolation of a faulty section in the ring without discontinuing the supply to the other consumer. In this case the cable and power transformer are linked together in protection under the voltage-balance system by means of a "tee." The fuse arrangement acts also as a hand isolating-switch.

FAULT ISOLATION.

Discriminating protective systems.—The continuity of supply cannot be maintained during fault conditions unless devices are incorporated to pick out the faulty section or sections and to leave the sound sections undisturbed. In this country the problems of discriminating protection have had constant attention ever since the time when Leonard Andrews criticized the universal use of fuses. This development can be traced in the papers and discussions given in the Bibliography at the end of the paper.

Stability ratio.—The criterion of quality of any protective system is its stability ratio, i.e. the ratio between the maximum "straight through" current and the minimum fault-current setting that can be procured

* F. Coates and Mirrey.

* Gregory (Electrical Improvements, Ltd.).
† Beard (Electrical Improvements, Ltd.).

without any risk of inadvertent tripping after taking all the disturbing influences into consideration.

The growth of the fault current on the occurrence of a short-circuit is extremely rapid, and it is not possible to prevent it from reaching its maximum current value by making the protection sensitive. Even if it were practicable for the relay to have no electrical and mechanical inertia, there is still the comparatively long interval, say three or four periods, during which the circuit breaker is accomplishing its train of movements. It is therefore wrong to rely upon sensitiveness to limit the maximum current stress on the system.

What matters most is the acceleration of all moving parts right up to the separation of the contacts of the circuit breaker, the aim being to reduce to a minimum the period during which the fault is allowed to damage the system. It is not safe to depend upon limiting the amount of fault current by inserting resistance between the neutral point and earth. This can only help on the occurrence of a fault to earth, and no amount of scheming with protective gear will prevent the possibility of simultaneous earth faults occurring on different

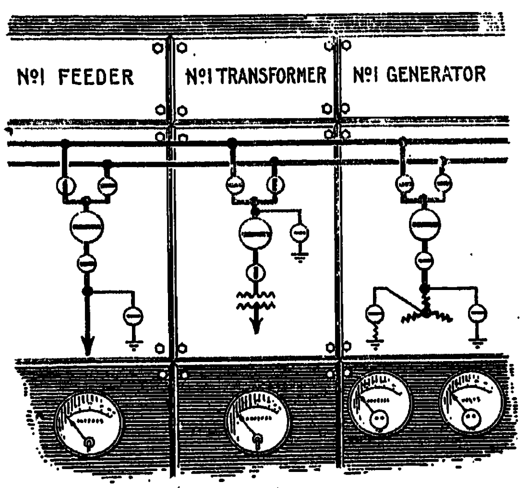

FIG. 26.

phases, maybe on different parts of the system. Every aspect, including relay settings, must therefore be subordinate to the maximum current possible on short-circuit between phases. In this light the value of the resistance connecting the neutral to earth is a matter for discussion. Certainly the stability of protective gear should not be sacrificed for the sake of ultra-sensitive relay settings, the need for which is solely due to the desire to cut down the amount of the earthing resistance. Rather save the entire cost of the earthing resistance and secure solidity by connecting the neutral direct to earth. For feeder protection this would permit the use of robust relays set like overload protection at 2–3 times full-load current, according to the size and position of the feeder. In the case of generator protection, in addition, the relation between the fault setting and the neutral earthing resistance also determines what proportion of the alternator winding is covered by the protection against single earth faults. The resistance may reduce, to a value below that at which the relay will function, the amount of current flowing into the fault in those parts of the winding nearest to the neutral point. If this were to happen, the fault would continue without disturbance until it developed into something more serious, or until it was observed

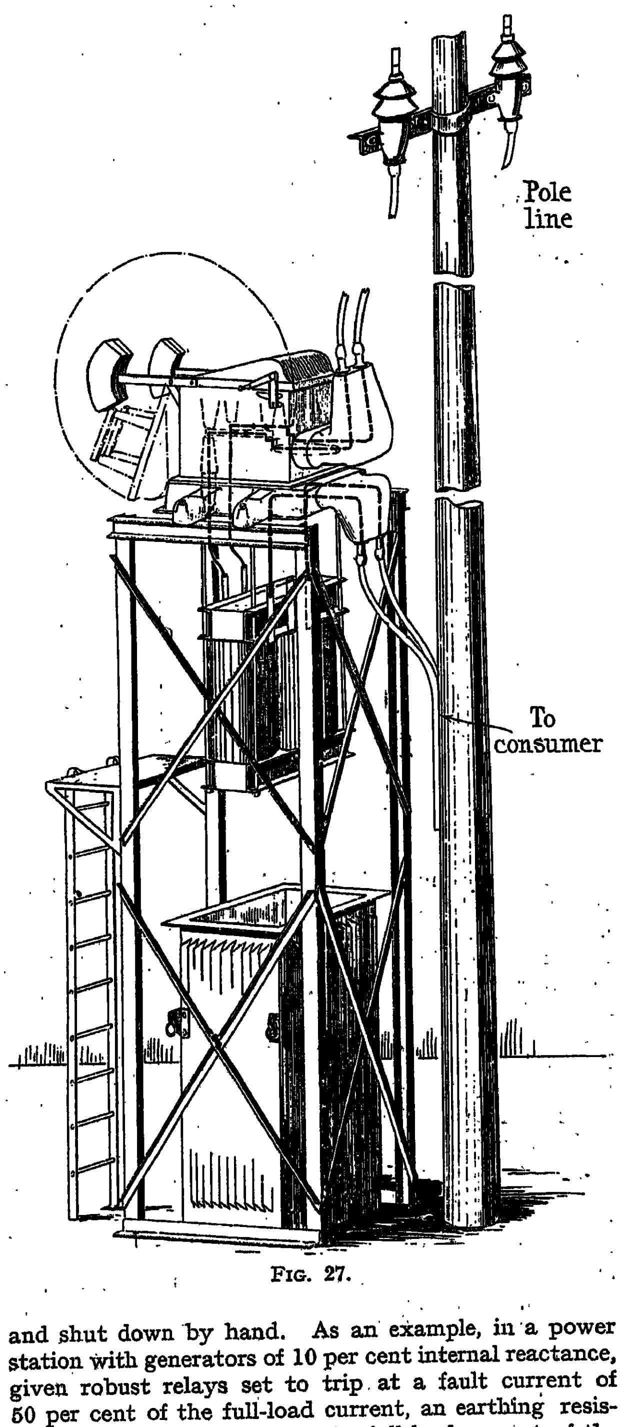

FIG. 27.

and shut down by hand. As an example, in a power station with generators of 10 per cent internal reactance, given robust relays set to trip at a fault current of 50 per cent of the full-load current, an earthing resistance which will allow twice the full-load current of the largest single generator to flow, and a stability ratio of not less than 40 : 1, there will be no inadvertent

tripping on any possible amount of "straight through" current. The whole of the stator winding will be covered for faults between phases, and 75 per cent of it for single earth faults. If more than this is required, either the relays must be made more sensitive or the ohmic resistance must be reduced. The former may be the more economical if the resistance must be retained, but the latter is better when considering comprehensively the protection of the whole supply system; and, if carried out to the full by the elimination of the resistance altogether, it would also be the most economical.

A robust relay such as is used in Merz-Price and split-conductor protection is one which has a simply constructed electromagnet to lift an armature, thus making contact and releasing a block contact which falls and serves the dual purpose of an additional circuit-closing contact and of an indication that the relay has operated. In practice a robust relay of this description may be set to trip at about 0·8 volt-ampere. A relay of this kind should not be subject to inadvertent tripping by any ordinary mechanical shock. Perhaps one of the best practical tests is to fix the relay to the base-plate of a turbine. If the vibration (which is the strongest form met with in a power station) does not trip it, it may be regarded as sufficiently immune from inadvertent mechanical tripping.

In contrast with the robust relay, sensitive relays have been used which can be set to trip at about 0·025 volt-ampere. This follows the line of a delicate instrument with a moving element rotating on pivots.*

Unbalancing influences.—Sensitive settings are jeopardized by several unbalancing influences. The capacity current in the pilot wire is one that is well known. Inaccuracies in the characteristics of transformers used in pairs "bucking" (one "bucking" against the other) may sometimes be due to careless assembly, but, in addition, phase-angle errors arise due to variation in the permeability of different batches of iron, and these errors cannot be entirely wiped out by mechanical skill and adjustment, however carefully the transformers are assembled.

Generally speaking, the current entering into a section is the same in phase and amplitude as that going out. This does not apply, however, in the case of oscillations in a cable carrying "straight through" current when the cable, acting as a condenser distributed throughout its length, is in series with heavy arcing. The cable, discharging over its whole length towards one end, passes more current at that end and sets up in the pilot-wire circuit an induced high-frequency transient which has proved to be sufficient to cause inadvertent tripping on long lines used for 33 000-volt and 66 000-volt transmission.

The influence on the pilot cable of direct induction between the cables themselves is unusual, but it has been encountered upon the same 66 000-volt system, so much so as to be the suspected cause of breakdown of the insulation of the pilot cable. This occurred on a single-cable three-phase system. Fortunately there are remedies for all of the unbalancing influences so far encountered, and these will be referred to in the following brief account of some of the forms of protection now in vogue.

Two-core pilot.—This system of Merz-Price protection has been devised as a means of reducing costs, and has been obtained by combining two of the earliest systems:

(*a*) The voltage balance, with transformers on two phases and 2-core pilot * (Fig. 29).
(*b*) The core balance leakage † (Fig. 30).

These combined give a system (Fig. 31) which is simple and is suitable for use with instantaneous relays of a robust character. For example, it may be used on ordinary feeder lines 2 miles long where the "straight through" current on short-circuit might be 10 000 amperes. The relay settings would be about 400 amperes for "between phase" faults and earth faults. Thus the stability ratio is 25 : 1. For longer lines the pilot capacity-current becomes effective and higher settings of the relays would be required in order to retain stability.

Balancing condensers.—To compensate for the unbalancing influence of the capacity current one of the earliest suggestions was the use of condensers.‡ This method has been experimentally applied, but in practice

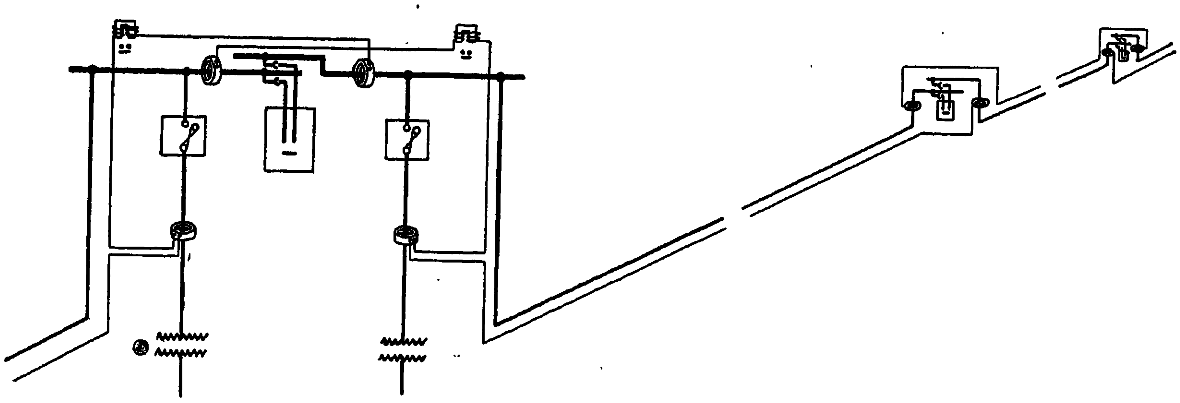

FIG. 28.

* Fawssett-Parry.

* 1904 Patent. † 1908 Patent. ‡ Whitcher.

in this country the compensated pilot found greater favour.*

Series relays.—As an alternative when the further stabilizing element is necessary, and when compensated pilot cables may not be used on account of additional expense, an arrangement with two relays in series has some points of interest.† One relay has a slight lag due to added inertia, but a sensitive setting; the other has a comparatively heavy setting but instantaneous action. The inertia relay deals with small and ordinary internal faults with a slight inverse time-limit, but is unmoved by the out-of-balance set up by heavy "straight through" currents. The instantaneous relay deals with the heavy internal fault currents that are of importance from the aspect of speedy release.

Diverter relay.‡—The above principle is carried a step further by the diverter relay system devised at an earlier date. This is illustrated in Fig. 32. In this case the relative action of the inertia relay and of the instantaneous relay respectively is similar except that the instantaneous relay does not trip the circuit breaker directly, but only makes the inertia relay more stable against the unbalancing influences by adding resistance

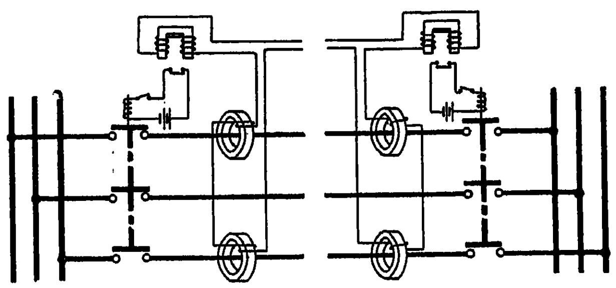

FIG. 29.

in circuit with the coil whilst the heavy "through" transient is passing. As compared with the preceding example, with a corresponding length of line the earth-fault setting may be reduced from 400 to 100, and the stability ratio increased from 25 : 1 to 100 : 1, notwithstanding the influence of the pilot capacity-current. By reducing the effect of this capacity current, which can be done by a simple modification as shown in Fig. 32A, the length of line may be increased to 10 miles with the same stability ratio.

Applied to feeder protection of long lines where unbalancing by oscillating currents is to be feared, the inertia relay coil may be by-passed by a non-inductive shunt resistance which will prevent the bulk of the high-frequency current from traversing the relay coil. This is really additional stability. Without the "by-pass" the inertia would be sufficient to tide over the short time during which it is possible for the transient to exist, assuming, of course, that the "through" fault will be properly cleared by its own relays.

Tuned relays.—A more positive method of elimination of the unbalancing influence of the oscillatory currents is a relay which can operate only with a flow of power current of or about the normal frequency of the system. A proposal * utilizing contacts mounted on reeds mechanically tuned to correspond to the natural frequency has shown promising results in its experimental stages.

Drainage coils.—The remedy for the vagabond induced voltage on the pilot wire is similar to that which has been applied to telephone circuits. Differentially-wound induction coils are connected to each phase of the pilot wire. These form a non-inductive path to earth for the induced current, but a highly inductive path for the normal currents which circulate in the pilot wire at the instant of a fault. These "drainage coils" have been tried and do not materially interfere with the fault tripping-values of the relays. The risks can be reduced to a minimum by good bonding at the joints in order to avoid the earth-return fault current taking a vagabond path. If it returns via the lead and bonding the resultant field of the outgoing and earth-return currents will be neutralized.

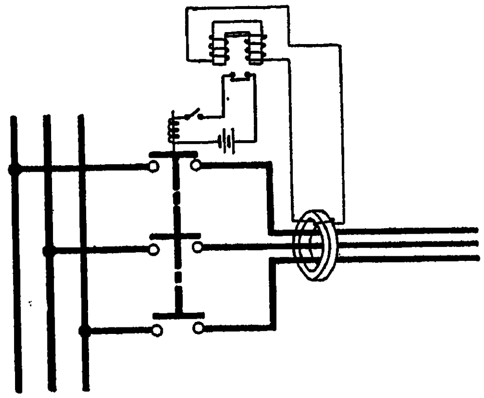

FIG. 30.

Extreme measures.—As a record, an aggregation of the foregoing on a 3-core pilot system is shown in Fig. 33. One side of the diagram shows the use of compensating condensers, and the other the compensation by pilot-wire sheath. Fortunately, the use of all the accessories is necessary only on very rare occasions.

Time-limit discrimination.—Relays with a definite time-limit action by pendulum or clock mechanism have still a place as positive discriminating devices for graded feeder and plant sections in series, whether in single line, tree or tee formation. Their scope is, however, restricted in those places where continuity of supply is all-important, and where in contrast the fundamental demand is for instantaneous action and parallel running, which includes the case of ring mains. The same limitation holds for excess-current time-limit relays with inverse time characteristics and with or without minimum definite time-settings.

Split-conductor system.—The split-conductor protection is exceptionally useful as a system involving practically no expense when two existing cables † can be used in parallel on one split-conductor switch. In fact, sometimes the entire cost of two switchgear panels can be saved (see Fig. 34).

Four-core protection.—A combination of Merz-Price

* Leeson. † Glasgow and Sheffield Corporations.

gear with the split-conductor system, known as the 4-core system,* is said to be the most economical in new cables from a cable-making standpoint (see Fig. 35).

Generator and transformer protection.—The stability of Merz-Price generator and transformer protection is also dependent upon the accurate magnetic balance of the current transformers and, as for feeder protection, in some cases there is the need for rendering it more secure by adding to the plain relay, pilot and transformer system some stabilizing feature such as the "bias" * or the "diverter" relay. With the latter the fault-setting may be reduced to 10 per cent, the stability ratio increased to 200 : 1, and, with the resistance to pass twice full load, 95 per cent of the winding will be protected, or, with the resistance reduced to full load, 90 per cent of the winding will be protected.

Generator field and auxiliary circuits.—The study of generator protection has included the possibility of a failing field. The best remedy is a thoroughly reliable air-break main field switch which will not inadvertently trip out, and efficient insulation, which latter is not difficult for the low voltages employed. The excitation of modern alternators is provided by their own exciter unit. Overload cut-outs are undesirable and unnecessary. Both poles are insulated so that a fault to earth, such as an accidental contact with a spanner on one pole, does no harm, and even this can be avoided by proper enclosure. Reverse-current relays controlled from the a.c. side are frequently inoperative on a failing field and their application is limited to a failure of the prime mover. Although recent designs are greatly improved, such relays cannot be considered desirable for alternator protection. In any case it is essential that they be fitted with a definite time-lag to prevent premature operation. In these circumstances it would appear to be unnecessary to introduce any failing-field tripping device, but if one is installed it should have a long, definite time-limit attachment. Here instantaneous action has no great significance from the point of view of limiting damage or disturbance to the continuity of supply. In fact, the rare occurrence of a failing field may safely be left to manual operation.

The further steps of closing the ventilating shaft and steam stop-valves are all to the good in limiting the possibility of the fire spreading inside a machine, but the automatic cutting-out of a fault should be effected so rapidly that a serious fire cannot start.

Generator auxiliaries are an important factor in the continuity of supply. The inadvertent closing down of auxiliary plant is frequently responsible for discontinuity. Infallibility of switchgear and connections will do much to prevent this annoying experience. For this reason it is important that the mechanism involved on the many circuits shall be very solid, notwithstanding that some of these circuits may be quite small and apparently insignificant. In large power stations the power behind the switch is considerable, and the ordinary service fuse equipment and low-tension switchboards are generally inadequate. There should be nothing in the nature of low-voltage releases, or anything that may be accidentally tripped out in cleaning operations. Fuse protection, provided the fuses are heavy enough to prevent premature blowing on occasional overloads, is permissible, but, as complete enclosure is essential, special measures are necessary to contain the forces of the explosion created by the blowing of a fuse on the occurrence of a short-circuit. Low-tension, metal-clad, oil-immersed fuses have been made for this purpose.

The other part of the problem of continuity concerns the layout of an alternative source of supply to the

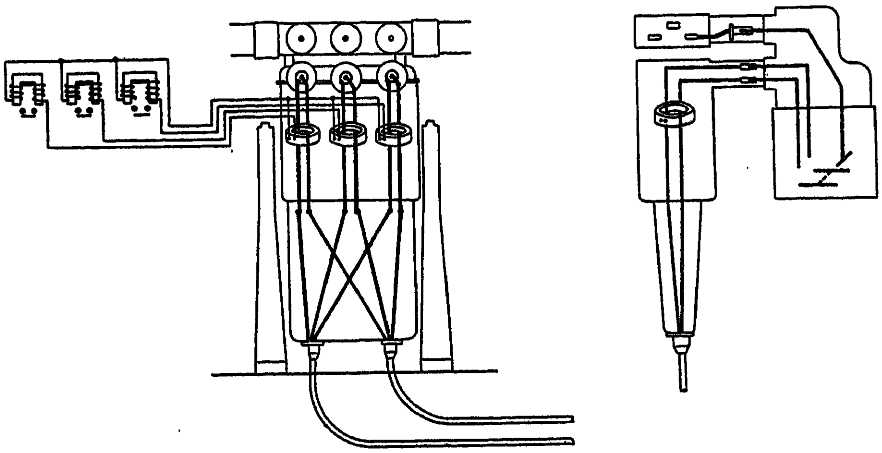

FIG. 34.

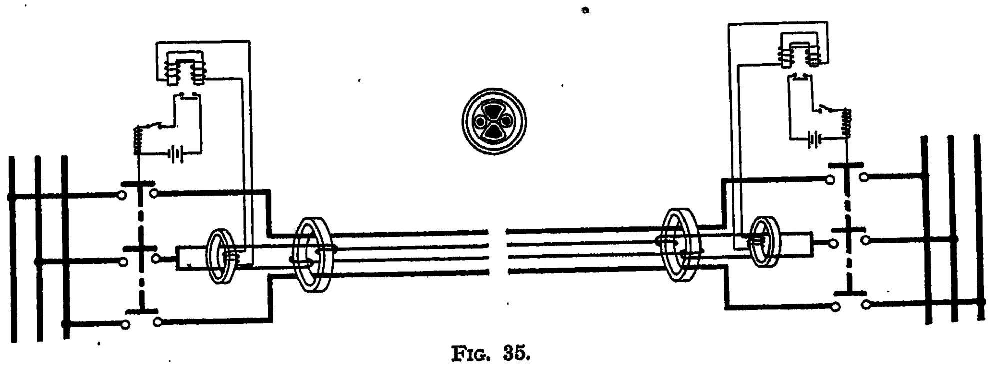

FIG. 35.

motors controlling the auxiliaries. One source may be a separate transformer attached electrically to the generator terminals on the unit system—i.e. it comes under control from the busbars through the same main circuit breaker as the generator—and the other a transformer supplied from the station busbars.

The plant must start up from the busbar transformer, and when the generator is running it may be changed over to the generator's unit transformer. The point of change-over from one system to another is a delicate and yet essential one. There is often a risk of the significance of this important detail being overlooked, as, for instance, in the transference of the requirements of a specification from one department to another. The importance of this equipment merits the best in design, and absolutely positive action; there must be no possibility of failure of operation. One switch must first break the whole auxiliary load, its contact being well clear, and simultaneously with that clearance the other switch contacts must close. The two switches must never make contact at the same moment, because the busbar transformer may at some time or other be taken off a section of busbar which is not in phase with the unit transformer.

Similar switchgear arrangements are suitable in those cases where the alternative supply to auxiliary plant is given by steam-driven house turbo-alternators. The layouts may differ in detail, but the principle represents the requirements for present-day practice.

Self-balance.—The phase-angle errors and unbalancing influences to which any two transformers in the same protective circuit are prone are eliminated by the use of a single iron core as in the system known as "self-balancing." * This core can be designed to slip over the lead of the main alternator cables and, in co-ordination with the design of the alternator frame, affords a good solution of the terminal question. Instead of bringing the terminals out underneath and out of sight as in the present practice, they might be given the prominence they deserve by being brought to the surface (see Fig. 36).

At the side of the protective transformer and terminal box is shown the usual emergency pillar containing the main field circuit breaker and a press-button release for the main oil circuit breaker and the field switch.

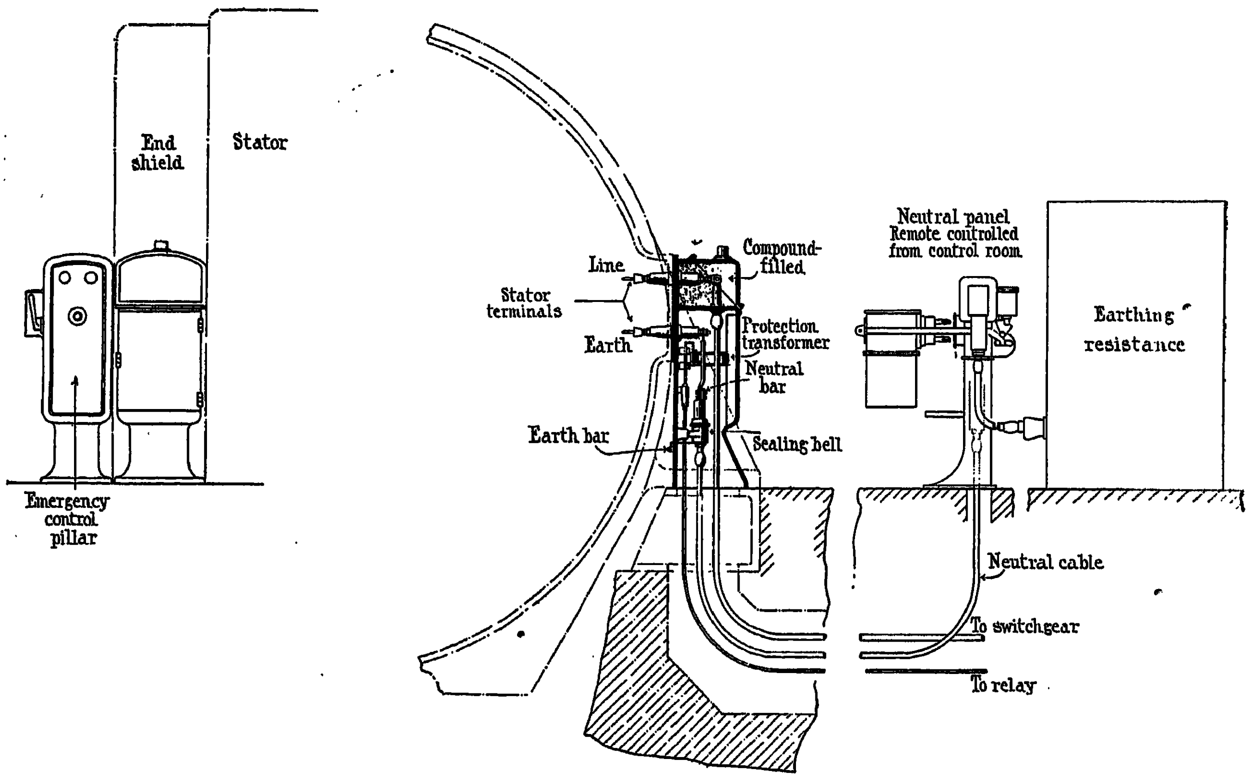

FIG. 36.

The diagrammatic scheme of connections, including protection, field control and interlock, is shown in Fig. 37.

The protection covers the stator windings, terminals, and the main cables to the switchgear. The relay contacts are arranged to open first the main stator circuit and, when that is accomplished, then the field and the neutral earthing circuits. The field may be closed by hand, but cannot be opened by hand while the stator is closed. The stator cannot be closed on an open field. An alternative is to allow the neutral earthing switch to open simultaneously with the main oil switch. The connections as shown in the diagram provide for this method.

Relay-tripping by hand for trial of mechanism from the control room opens the stator but not the field

* Beard (Electrical Improvements, Ltd.).

circuit. The emergency release on the engine-room pillar opens the main circuit and field circuit in sequence. The complete metal enclosure of all circuits, including the neutral, will be noted.

Interference with telephone lines.—The aid of protection against faults is evoked by the telephone and telegraph service in order to eliminate interference by currents induced from the main line during faults.* Currents at normal frequency of the line do not interfere so seriously with speech on telephones as those of abnormal frequency which may occur on transmission lines during arcing earth-faults.

S. Emergency control contactor located near alternator for opening main oil circuit breaker, followed at once by the main field circuit breaker and neutral earthing circuit breaker.
T. Remote-control switch for main oil circuit breaker.
u. Remote-control switch for neutral earthing circuit breaker.

The risk of shocks and fires from telephone and telegraph leads, occasioned by induced voltage, is one which must not be overlooked. In some places it has been found necessary to insulate telephone communication wires between substations as for high-tension service (3 000 volts), and to resort to the use of "drainage coils" of the type mentioned above in connection with pilot wires for protective gear.

The intensity of this form of interference depends upon the path taken by the return current from a fault. If the system can be arranged for the fault current to go and return along parallel paths in close proximity, the field of the outgoing conductor is neutralized by that of the return, and no currents would be induced in neighbouring cables. This requisite can best be obtained by completely enclosing all conductors in metal. This method, while providing an efficient bonding over all sections of the metal enclosure, reduces stray currents. Moreover, given an earthed neutral point, it tends to reduce to a minimum the possible duration of the high-resistance fault currents which set up the high-frequency oscillations. The duration of disturbances to speech can thereby be cut down to the short time taken by the protective gear to isolate the faults. Such interference would be unnoticeable to ordinary users of the telephone service.

To conclude, the variety of designs and possible causes of trouble on protective gear may create an impression of reluctance to depart from the simple overload devices, but it must not be overlooked that these overload devices are the greater offenders in inadvertent operation, and that the difficulties which

* S. C. BARTHOLOMEW: "Power Circuit Interference with Telegraphs and Telephones," *Journal I.E.E.*, 1924, vol. 62, p. 334.

have been faced are mainly those which have arisen out of ever-changing conditions of service, increased currents and voltages, and extension of the distances of transmission. There are innumerable instances of the simplest forms of balanced protection having given efficient operation ever since they were installed, some of them on a large supply system in 1906. Moreover, enormous benefit has been derived from them in the development of the large supply systems under the policy of universal interlinking and parallel running, with the consequent continuity of supply to all consumers.

Conclusions.

The requisites for safety and continuity are briefly as follows :—

(1) Universal metal-clad enclosure for :—

(*a*) The confinement of dangerous conductors;
(*b*) The preservation of insulation in compound and oil;
(*c*) The restraint of fire and arcs within a unit, and the impregnability of adjacent units; and
(*d*) The reduction of cleaning functions and other interference with conductors and insulators.

(2) A stable neutral point at earth potential, giving :—

(*a*) Durability of earthing and bonding;
(*b*) Stability on transient short-circuit "straight through" currents in sound sections, and instantaneous isolation of the faulty sections.

(3) Reliability in all operating mechanism, enhanced by periodical inspection and trial by hand-release of essential tripping movements.

(4) (*a*) Elimination of human error by security of interlocking, coupled with the indication of essential circuit connections.
(*b*) Strong flameproof enclosure for circuit-breaking elements.
(*c*) Reduction of destructive forces, if possible, but in any case the limitation of their duration to a minimum by all available measures.

The author begs to acknowledge that the paper is in the main the outcome of a long and close association in design and experience with the Operation, Testing and Construction Departments and the Consulting Engineers of the Newcastle-upon-Tyne Electric Supply Co., Ltd., and their allied Companies of the North-East Coast. In addition, he desires to acknowledge a large amount of assistance from members of the staff of Messrs. A. Reyrolle and Co., Ltd.

Discussion before the Institution, 22 January, 1925.

Mr. E. B. Wedmore: Many phases of the work which are indicated in the summary of the paper are now largely common practice. The adoption of the principles underlying the metal-clad construction is in a large measure due to the author's personal effort. I am not able, however, to agree with the author on every point. In certain respects he is carrying his ideas too far. I refer particularly to the omission of duplication in certain cases. He is not in favour of the duplication of switches. Although the electric supply industry is very well served by expert purchasers and maintenance engineers, the repair bill of the industry runs into millions of pounds per annum. Insulation failures alone account for half a million pounds a year. No manufacturer intentionally offers defective apparatus, but these figures show that there are still weaknesses to be overcome, and that we have not reached finality in design. We have switch failures to record every year. I think there are instances in which maintenance of supply and other considerations

do tend to the duplication of switches. One cannot afford in a station where the supply rests principally on two or three large generating units, to face the position, even for a comparatively short time, of two of those machines being out of action. It means that when one machine is shut down we are absolutely dependent upon individual switches to keep the second and third machines running. The provision of duplicate switches in such cases sometimes carries with it other advantages, e.g. simplicity of the whole scheme and its operation. Where the supply to a large substation depends upon a few large power transformers, the question again arises whether one could not duplicate switches to advantage where a duplicate busbar system is employed. The author favours the use of a single busbar in large generating stations, but I altogether disagree with him. The use of simplified gear in a small compass is part of the practice advocated, but if a breakdown occurs, the result will almost inevitably be very serious and prolonged. The use of single busbars has been discussed before and I have sought for some analogy to illuminate the issue. It is to be found in the anatomy of the animal creation, in designs which have been evolved through countless ages and withstood the test of time. We find the rule is that the external exposed organs are duplicated and the single organs are the protected, the partially enclosed and the totally enclosed. So far the argument is with the author, but closer examination shows important exceptions. We find the brain or principal nervous centre amongst the best protected but always completely duplicated, each half with its independent blood supply, and to make assurance doubly sure we have at the base of the brain the best protected spot of all, the circle of Willis, which is comparable with the ring busbar, one of the ideal forms of duplicating, so arranged that any section may be damaged without stopping the blood supply to either half of the brain from either main artery. The single busbar in the large generating station has been tried experimentally in this country and found wanting. I have followed with great interest what the author has to say on the subject of rupturing capacity of oil circuit breakers, a subject upon which a great deal will be said in the next few years. The Electrical Research Association is happily in the position of being able, with the co-operation of power station engineers, to carry out on the rupturing capacity of switches researches which are revolutionizing design. The extraordinary range of action that is given when one and the same switch is called upon to open one and the same circuit under identical external circuit conditions cannot be too clearly recognized by all buyers and users of switches. A given switch may open a circuit with hardly any indication that anything has happened, but on the next test the same switch may be blown to pieces. The amount of energy released on one and the same switch on one test may be very many times that released in the next test under similar external conditions. It has been said in the past that half a dozen tests should be made on a switch before any idea can be obtained of its safe rupturing-capacity rating, but I now doubt if that number is sufficient with present designs. I am, however, happy to say that we are in sight of formulæ which will enable us to establish on scientific principles the true rupturing capacity of an oil circuit breaker. Until that is done it is of very little use to split hairs on small margins on supposed factors of safety based on data now current. Diagrams of protective gear are puzzles which mean nothing at all to those who are not familiar with the details, and I shall not pursue the details now, but certain interesting facts emerge when the designs recently developed in protective switchgear are examined. The modern motor-car or flying machine could not have been built 20 years ago, because we had not the special materials and special machinery which are now available for their production. There is no reason, however, why the most highly developed protective gear of the present day should not have been manufactured 20 years ago. I put that point to a designer to-day, and his reply was to the effect that at that time the necessity and the economic value and importance of protective gear were not realized. We have got past that stage and there is now a recognized market for effective protective switchgear. Of the various designs produced, each one has been the "last word." This suggests that finality has not yet been reached, and anyone who will make himself familiar with the requirements as detailed in the papers cited in the author's bibliography, and will apply himself to the outstanding problems, may expect to make further advance. When the Hunter four-core system was evolved, I spent some weeks trying to improve on it with a single pilot in the middle of a cable. There are many ways in which it cannot be done, but it should be possible. At any rate, the next step will be something on those lines, and I suggest that those who are interested in the subject should pursue the idea.

Dr. C. C. Garrard: I should like to suggest that while the author's methods are no doubt excellent when the conditions are suitable, he goes too far when he maintains that they are the only methods. The author's clear exposition of the term "stability ratio" expresses in two words what would otherwise take a great deal of explanation. It is an all-important matter in protective gear. Applying it to a given case, if the short-circuit current be, say, 50 times the full load of the circuit, then the minimum fault setting one could have, given a stability ratio of 100, would be 50 per cent of full load. I would recommend that the B.E.S.A. Committee on Nomenclature should consider the standardization of this definition. Reading between the lines of the paper, it would appear to me that the author's scheme for dealing with a low stability ratio is to increase the fault setting. To my mind the proper solution of the stability problem is the adoption of the biasing principle. This can be done in a variety of ways. For example, mechanically or electrically in the relays, as in McColl's system, or by the use of a biasing transformer, as employed by FitzGerald. The diverter relay in Fig. 32 would be a form of biasing were it not for the fact that it puts in the bias in one step, the fault setting being altered suddenly at one particular value of the load by the

insertion of the resistance. The biasing principle in the systems I have mentioned is, however, effective over the whole range, its effect being to make the fault setting a constant percentage of the load flowing at the time. Thus the stability ratio is enormously increased. There can be no doubt that in the future this bias principle will be more and more applied. It can, of course, be used in conjunction with any system of pilot-wire or split-conductor protection. It might be thought from the heading of the paragraph on page 442 that the bias system can only be applied to generator and transformer protection. This is, of course, not so; it is of universal application. In passing I would add that the use of an "inertia" relay seems to be contrary to the spirit of the author's remarks elsewhere in favour of the instantaneous action of protective gear. I quite agree with his preference for the term "mistake-proof." What we have to guard against is an attendant operating without thinking. As long as his attention is drawn by some means to what he is doing, for example, by finding it impossible to open a link door without having first to open the oil-switch chamber door, this is generally, at least in power station work, as far as it is desirable to go. Complicated interlocks on power station boards, operated by skilled attendants, are in my view very undesirable. They can introduce a false assumption of security. I know of a case where a highly-skilled engineer was killed because he relied upon an interlock, and another case of the representative of a firm which specialized in interlocks having his arm burnt off in spite of all these precautions. Simplicity, ease of inspection and flexibility are vital in power station switchgear. It is certainly good practice to inspect periodically all connections and joints on important installations, and in my view it is desirable that this should be made possible. For large power houses I believe the fireproof subdivided system, developed from the original cellular gear of Ferranti, gives the most satisfactory all-round result. This certainly seems to be the trend of events in America, where the largest stations (such as Hell Gate) are now installing the isolated-phase system in which the three phases are in separate and distinct rooms. The advocates of the totally-enclosed compound-filled type claim, with justice, that this scheme is free from the danger of busbars being short-circuited by rats or mice. This is true. But cellular gear, as now constructed, is vermin-proof, and mica-insulated busbars and connections are an additional safeguard. In making these comments I wish to point out that I do not for one moment make any exclusive claims for the cellular construction. The totally enclosed scheme has many legitimate applications; I merely deny that it is the only right system. As regards the form of reactance mentioned on page 427, I should like to ask the author if he can give any figures as to the internal losses in the lead-covered cable type, as compared with the bare-wire type. I am inclined to think that they are rather large. On page 428 the author seems to deprecate the use of duplicate busbars in large power stations. I should hardly think he is serious in this, and I cannot conceive it possible that any large power station will be built without duplicate busbars. I think that the remarks in the paper regarding B.S.S. No. 116—1923 require some discussion. The general drift of the paper in this matter would seem to be that this specification rather leans towards a low standard. This is, however, to misunderstand the specification. In the appendixes of the specification, suggestions are given as regards the selection of oil circuit breakers. These are attacked by the author, and I think that his Fig. 19 is calculated to do a certain amount of harm to British reputation. The B.E.S.A. specification leaves it open to the purchaser to specify the factor of safety he requires. In order, however, to guide him in the rather complicated matter, the suggestions in the appendixes are given. It may be added that these suggestions have a large amount of practical experience behind them, and are to all intents and purposes the same as those adopted by the American Institute of Electrical Engineers. The real crux of this question is the rating as regards rupturing capacity given by the various makers to their switches. Generally this is in inverse ratio to the reputation of the maker. If the purchaser were sure that the maker's rating was a true one, he would not go very far wrong if he followed the specification. There is of course a great deal yet to be known about the question of breaking capacity. The author touches upon one, viz. the effect of reactance (page 434). It may be necessary in the future when specifying breaking capacity, to specify the power factor, but we are hardly in that position yet. The expression "through rating" of a circuit breaker used on page 434 seems to me to be the same as its rupturing capacity rating, and I should be glad to know whether this is so. I agree with the author's remarks in regard to "explosion pots" in oil switches, and I would also point out that with switches on 5 000-volt or 6 000-volt circuits it is necessary for the "pot" to embrace only the arcing contacts, not the main contacts. In my opinion it is the secondary explosions (in the air space above the oil) which have been the cause of most of the disasters with oil-break switches in the past. I doubt whether the explosion-pot construction helps in such cases. As regards the use of charging resistances in oil switches, these are very advantageous in transformer switches. There is generally a large rush of magnetizing current when switching-in a transformer; with a plain oil switch this not only affects the protective gear but is bad for the apparatus generally. It can be entirely obviated by a self-contained charging resistance mounted on the moving cross-bar of the switch. I disagree with the statement on page 438 that "without exception the final closing of the earth connection should be done within an oil-filled enclosure." When my own safety is in question I prefer an earth link which I can see is closed and in perfect contact with its jaw: personally I should never rely upon something I cannot see. I also must protest against the author's vibration test on the base-plate of the turbine (page 440). I think that the crane often affects the switchboard more than the turbine does. The necessity for the use of drainage coils, compensating condensers and the like, mentioned on page 441, shows

how complicated protective gear can become. I should like to know to what extent these are necessitated by the necessarily relatively high voltage on the pilot wires when using the balanced-voltage system. It seems to me that the circulating-current system for cable protection is free from many of these difficulties. I think that the author's remarks (p. 435) on the question of reactance coils must be accepted with caution. Reactance coils are an absolute necessity in large stations. They should, in my view, be installed so as definitely to limit the short-circuit current to a maximum value not exceeding, say, $\frac{3}{4}$ million kVA. This provides no difficulty even with the biggest possible plant.

Mr. T. C. Christianson: I gather that many operating engineers dislike interlocks for various reasons. There is a limit in practice to the amount of interlocking which can be applied to switchgear and other apparatus, and with very complete interlocking there are occasionally circumstances requiring some of the interlocks to be temporarily put out of action—in such circumstances special care is essential to avoid accidents. I think most engineers will agree that complete enclosure or inaccessibility of all live connections with plant of large capacity is highly desirable, and it should be noted that low-tension apparatus should be treated as carefully in this respect as high-tension apparatus. I know of at least one fatality resulting from arc burns following a short-circuit set up by the metal on a portable instrument on a 440-volt switchboard. Many engineers prefer, however, that the enclosure of switchgear and its accessories should be of the cubicle rather than the complete metal type. Cubicle-type switchgear has several merits which one feels will always appeal to many engineers. On page 430 the author mentions an entire switchgear being destroyed due to a fault, and the inference appears to be that this switchgear was of the cubicle type. I think it only fair to say that faults on metal-clad gear have occurred, and that while their effects have generally been concentrated, repairs and resumption of supply have taken a good deal of time. It must be recognized that the effects of faults when they do occur on the cubicle type of gear are in general more readily rectified than those on metal-clad gear. A change-over on duplicate busbar cubicle-type switchgear is quite simply and easily arranged for. The majority of engineers will agree with the author that one good circuit breaker, etc., is better than two of inferior quality, and that with metal-clad switchgear the necessity for a duplicate busbar for cleaning purposes scarcely arises. Even with the best design of apparatus, however, faults are possible; therefore one would naturally prefer to have duplicate busbars at vital points on the system, such as the main generating station, to permit—among other reasons—the supply to be resumed quickly from the hospital busbar after a fault on the main busbar. A further advantage of duplicate busbars at, say, the main generating station is to permit the practice of normally running some of the generators and feeders on one busbar, and other generators and feeders on the other busbar—separated when the capacity of running generators is large except through reactors *per se*, or through network feeders with their inherent impedance. I think that the author will agree that under both the above heads it would be a distinct advantage from an operating point of view to be able to effect the change-over from one busbar to the other in the shortest possible time. It is a fact that faults on metal-clad busbars have been of rare occurrence, but it is probably worth while to arrange (and pay) for the means to enable a rapid change-over to be made when such a fault may occur. Again, under the second heading mentioned above, some engineers are probably prepared to pay for the means of enabling circuits to be changed over—for adjustment of load, etc.—without interruption thereto. I think that the author has mentioned that in most cases feeders, etc., would be at least in duplicate—so permitting a short interruption of power supply through one feeder without interfering with the supply of power to any given location. It will be appreciated that simple but efficient interlocks can readily be applied to most of the change-over devices mentioned by the author in order (*a*) to prevent both busbars being connected simultaneously to any circuit under any conditions; (*b*) to prevent both busbars being connected simultaneously to any circuit except when the two busbars are paralleled through, say, a busbar coupler switch; and (*c*) to necessitate the circuit breaker being open before any operation can be performed on the isolating switches. I believe that some operating engineers would prefer to change over without interruption with or without interlocks, and that others would prefer definitely to interrupt the supply to each given circuit—even if only momentarily—for change-over purposes. It would appear to be mainly a question for operating engineers to determine their requirements in this regard, and we manufacturers hope that they will give us their views on the necessity or desirability of these various features, bearing in mind that what we may call the rapid change-over features are somewhat more costly than the others. Referring to Fig. 9, a further point in regard to the design shown therein is the simple means available for earthing either of the busbars or the cable by inserting earthed plugs in the appropriate sockets and closing the oil circuit breaker. It should be noted that the design—under Patent No. 217290—covers bottom sockets with through insulators for bottom plugs to connect the circuit breaker terminal to the cable or earth as required, as well as the two top sockets indicated in the figure. There is the further feature not discernible from the figure, viz. that the oil circuit breaker may be of the normally fixed type. Referring to Fig. 8, I consider it to be of prime importance with this design of change-over arrangements that (*a*) positive means should be provided to prevent both busbars being connected through plugs associated with any one circuit oil circuit breaker other than the busbar coupler, and (*b*) that a positive indication should be given as to which busbar is connected to the oil circuit breaker. The indicator should, therefore, be automatic and should not depend merely on the operator's memory at the time of change-over. The double oil circuit-

breaker layout would appear to be the best for duplicate busbar working, and its greater cost is probably justifiable in large and important stations. I think, however, that engineers adopting this scheme would prefer to have the busbars separated more than Fig. 10 would appear to indicate. It is probably good to recognize that many engineers have in the past objected to compound-filled metal-clad switchgear, largely because of the difficulties of changing current transformers, or of adding potential transformers to units not initially provided with sockets, etc., for these latter. These difficulties have now been practically eliminated by using a viscous oil (such as resin oil) or an oil-base compound of low melting-point for filling the chamber containing the above apparatus. It would be of interest to have the author's views on the commercial and technical feasibility of employing viscous oil, etc., for filling the busbar chambers of metal-clad switchgear for the various voltages commercially in use on this class of gear. A study of the various figures indicating metal-clad units shows that no potential transformers have been indicated. It will be appreciated that these can readily be fitted where required, and the design which permits safe

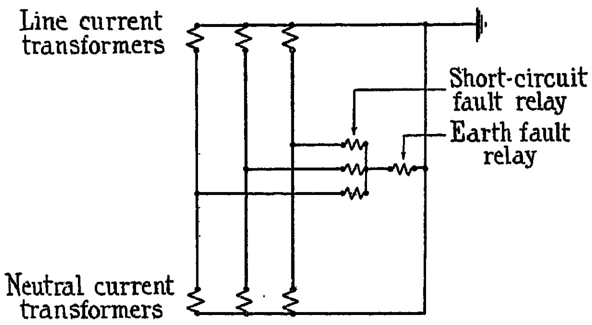

FIG. A.—Improved circulating-current protective system.

accessibility without interruption of supply to the main circuit is doubtless to be desired. Some users of metal-clad gear wish to be able to circulate current through the primaries of the current transformers for testing purposes, and to do this readily it is a simple matter to make temporary connections from a suitable local circuit through the cable and P.T. sockets. It is not clear at first sight from the author's remarks on pages 433 and 434 in regard to reactance increasing the arc energy why this should be so, and his explanation would doubtless be of interest. Referring to Figs. 14 and 15, the earthed metal divisions inside the tank can be used to greater advantage in eliminating the risks of arcing between phases and strengthening the tank if the top crosshead design of circuit breaker be adopted, as it is then possible to carry the metal divisions right across the tank. I consider that the breaking capacity of a switch or circuit breaker (mentioned on page 434) ought to be a definite figure to be stated by the maker or, preferably, by an independent testing authority. I do not appreciate the author's suggestion that the breaking capacity should be qualified by stating the basis in terms of generating plant output and reactance on short-circuit. This latter information is obviously required in estimating the short-circuit current possible, but it is not clear to me that it has anything to do with the ability of a given circuit breaker to rupture any stated power in kVA or kW. With reference to the term "stability ratio" used in the paper, should it be desired to protect more than 75 per cent of the stator winding for single earth faults without reducing the ohmic value of the earthing resistance, it is possible to do this by connecting an "earth fault" relay between the "short-circuit fault" relay star point and the current transformer star points (as indicated in Fig. A). It is true that this "earth fault" relay would require to have a setting to trip at a current less than 50 per cent of the full-load current to achieve the above protection, but it will be appreciated that such lower setting would not impair the stability ratio of the protective gear. A thoroughly sound relay can be supplied to operate with, say, $7\frac{1}{2}$ per cent of the full-load current of the generator, and this, connected as above, would give single earth fault protection on 96·25 per cent of the stator winding under the other conditions set out by the author. It will be appreciated that one of the "short-circuit fault" relays may be omitted if desired, when the "earth fault" relay is installed. This improved circulating-current protective system was, I understand, devised by one of the Metropolitan-Vickers engineers and is covered by Patent No. 144073.

Mr. P. Rosling: On page 437 the author mentions the effect on cables of a direct lightning stroke or surge. He says: "The excess voltage is absorbed in the capacity of the cable. This method, together with a high standard of insulation, satisfies the conditions prevailing in this country." It is quite true that this may save the transformer and the gear but it is not fair to the cables to make them surge arresters. If the matter is studied only from the point of view of the induced charges from lightning, which do not take place very frequently, probably no damage occurs to the cable, but if the cable is subjected to frequent surges due to switching, or other causes, trouble may arise, the crucial point being the number of times the pressure is applied before the cable will break down. On studying the question with the electronic theory of matter in our minds we see that the molecules or atoms are composed of varying numbers of electrons which presumably are arranged in varying groups depending on the element which they form. These electrons are possibly vibrating in unison with the molecules (the periodicity depending upon the temperature), and also probably moving, or able to move, in their own particular atom at a speed approximating to that of light. We know that if we bring a collection of electrons in the form of a metal bar at a high temperature near another collection of electrons in the form of paper vibrating at a lower frequency, the vibration of the molecules in the bar will transmit energy through the ether to the molecules in the paper, increasing their vibrations until the electrons in the molecules of paper rearrange themselves into the groups of electrons peculiar to carbon, hydrogen and oxygen, etc. The electrostatic field and the periodicity of vibration are

in some way connected, as we know that should the electrons be in a state of strain due to an electrostatic field, the electrons in the molecules of the paper are affected by a lower temperature, i.e. a lower rate of vibration of the molecules in the hot body, and if the state of strain is very intense the electrons in the molecules of paper are affected even when the periodicity of both sets of molecules is similar. Further, there is a possibility that if electric current is caused by the passage of electrons along the conductor, these current electrons may conceivably, as they travel at a speed approximating to that of light, jolt the groups of electrons in the molecule of the dielectric which are under intense electrostatic strain and split them up into the groups representing the elements. It is well known that in many cases of slow growth where there is apparently no law to govern the direction of the growth, as for instance in the marking on a window-pane where moisture is congealed by cold, or the growth of coral in Southern seas, the growth takes a tree-like or fern-like formation, and in examining cables after high-pressure breakdown tests, certain tree-like or fern-like marks have been found, which makes it seem possible that the intense pressure due to the peak of each alternation of the charging current has caused the electrons in the molecules of paper to split up into groups proper to the particular atoms in the molecules, and this process, having once started, has possibly localized the stress, and has continued, showing a slow growth in the tree-like marking. I would suggest that where high-tension cables have broken down for no obvious cause, the users would be well advised to put in some apparatus to act as a discharge for any high-pressure surge, say, 25–30 per cent over the working pressure.

Mr. H. Trencham: As regards most of the fundamental principles enunciated in the paper I am in accord with the author, but there are a few points on which I must join issue with him. I think that the single busbar does not provide a sufficient margin of safety. A duplicate busbar has quite a number of useful functions in connection with the operation of electrical systems, and I think that it is likely to remain. The explosion pot as a means of rupturing heavy fault currents has been mentioned, but the fact that the very first oil circuit breakers used in heavy power stations were of the explosion-pot type is rather lost sight of. There are a very large number of those breakers in use to-day, and a large proportion of them have been in service for many years. The principle of their operation is probably not completely understood, but there are sufficient data available to enable one to say that the ability of the breaker to interrupt heavy short-circuits is not a velocity phenomenon alone, and it is also peculiar that the heavier the current in this breaker the quicker the interruptions are likely to be. Moreover, the characteristic of the interruptions is very much more regular than in the other type of breaker. Another point to which I should like to refer is the rating of the circuit breakers. I think that the author has somewhat confused the actual rating of the breaker and its selection. I do not think that there can be any question that the British Engineering Standards Association intended the usual expression "kVA rating" to mean a definite number of kVA. It would be better if the rating could be expressed in terms of energy, but that is impossible. When kVA or amperes are taken as a basis, voltage must come into the question, and, as the power factor will influence the ease or otherwise of breaking, one has to assume that the very worst power factor must be taken into account, so that to express it in general terms of kVA is quite a rational proceeding. If we accept that as the rating the breaker must, in order to fulfil that rating, be able to pass a test which will give those conditions, and it is very unfortunate for the industry, particularly in this country, that very little real testing apparatus has been available. I think that one of the essential things for the switchgear industry to attend to now is to see that investigations are made with short-circuits much more comparable with those which occur in large power systems. The application of an oil circuit breaker depends on many more variables than are concerned in the action of the oil breaker itself—and those are very numerous in themselves—but to try to introduce the additional variables of the generating and distributing system into the breaker rating is a suggestion in the wrong direction. I believe that to employ bias in protective gear is the correct practice in providing for the stability of apparatus. If the relays are to be kept sufficiently delicate to function with a small amount of energy they will be liable to interruption if they have to deal with two contending forces which it is desired to balance against each other. Sound practice indicates the necessity of bringing to the relays only those tripping currents which are necessary for their correct functioning.

Lieut.-Col. K. Edgcumbe: The author suggests (rather diffidently, I am glad to see) that if economy is essential it might be gained by cutting out the earthing resistance, but I am more than doubtful as to the wisdom of this. I believe that under normal conditions about 90 per cent of all faults start as earth faults, but I imagine that with the author's arrangements 99 per cent of the faults would start as earths. In fact, I gather that this is one of his chief objects, and therefore I should have thought that he, of all people, would have insisted on the installation of an earthing resistance. The tendency of the present day to employ single-core cables in place of multicore cables—particularly for the higher voltages—serves also to emphasize the importance of earthing through a limiting resistance. The author suggests that for induced lightning discharges a length of cable should form a satisfactory discharge path. It cannot, however, do so in the case of internally produced surges, so that some form of surge gap seems to be essential.

[The author's reply to this discussion will be found on page 464.]

North-Western Centre, at Manchester, 17 February, 1925.

Mr. S. Ferguson: The need for compound-filled switchgear has arisen owing to the growth of power systems. Every extension of the high-tension distribution system has brought with it at least a proportionate number of additional faults, every extension of the generating plant has increased the severity of these faults, and the interruption of increasing values of short-circuit power has magnified the effects of voltage surges which, of course, vary directly as the value of current broken. The air clearances required to give adequate protection have increased and with cellular gear it has become practically impossible to allow the clearances which are really necessary. It is on record that flash-overs 6 in. long have occurred even on 6 600-volt systems. With compound or oil dielectric the clearances can be reduced to one-fifth and hence it is very evident that a complete compound- or oil-filled unit can be accommodated in much less space than a comparable cellular installation. Furthermore, oil and compound have a much higher dielectric spark lag against high-frequency voltages. This is a very important advantage when considering the protection of switchgear against high-frequency surges. The author has not overstated the advantages of metal-clad gear. It affords protection against dust, dirt, vermin and moisture, and explosions in the switchgear structure are eliminated as there are no air spaces in which explosive gases can collect. The maximum protection to the life of the operator is assured. It would be as well for engineers to face facts. Some time ago I analysed the Factory Inspector's reports covering a period of four years and found that 50 per cent of the accidents were due to operators dealing with switchgear which was supposed to be dead but which in fact was actually alive. Only a fortnight ago the Chief Mining Inspector's report appeared in the Press and showed that practically 50 per cent of the accidents occurred on switchgear. These facts clearly show that some form of metal-clad filled switchgear is very desirable, as it minimizes the fire risk and any damage is localized. Above everything else this type of gear is manufactured and shipped as factory-built units. I am very much in favour of standardization. At the present time the cost of switchgear is too high and this is mainly due to the multiplicity of types which are perpetuated. Metal-clad filled gear will, I believe, meet all requirements and I sincerely hope that sooner or later it will be standardized. In this connection I think that the Institution is behind the American Institute, in that there are no committees which analyse progress during the year and issue annual reports. In the American Institute there are sectional committees each of which deals purely with one section of electrical plant. For instance there is a power station committee, a protective devices committee and many others. The members consist of manufacturers and operating engineers and there is the closest co-operation. I consider that it is high time a lead was given to operating engineers on the question of switchgear if the enormous waste which is going on at the present time is to be eliminated. The objections to the earlier forms of this gear were the lack of accessibility of instrument transformers and busbars and the method of busbar selection by the change-over of plugs. The first objection has been overcome by oil filling. This is a recent innovation which has only just been put into commercial use. The outward appearance of the gear is unaltered. The second objection has been remedied by the substitution of oil-immersed selector switches or double breakers. We are frequently told that the demand for metal-clad filled switchgear is the outcome of fashion, but I think that this is an erroneous idea. There are definite reasons which have prompted numerous manufacturers in this country to spend thousands of pounds on patterns, jigs and tools for the production of this class of gear. I agree with the author when he says that the settings of protective gear are frequently too light, at the sacrifice of stability. This brings the important point that such leakage protective devices often open the short-circuit before the fault has been fully developed, and it is necessary to close the breaker two or three times before the fault can be dealt with. This makes it possible for the breaker to rupture the short-circuit power at its peak value, as the author has shown. He states that duplication should be governed by the liability to break down, and refers to immunity from breakdown. I cannot share his optimism, because duplication is governed, or should be governed, by the consequences of failure, that is, the difference it makes to the consumers who will be affected and the length of time the supply will be discontinued. There is no plant which is immune from failure and there never will be so long as it is operated by imperfect human beings. The busbars in a central station are the most immune from failure, and yet I consider that there is the greatest necessity for their duplication because of the consequences involved in a breakdown. We duplicate our transformers and feeders and I consider that it is very essential to duplicate the busbars also. The author suggests that it is preferable or more economical to increase the initial expenditure in obtaining quality and strength of parts rather than to duplicate such parts. This is not in agreement with the policy adopted towards the rest of the system and I do not see why it should be carried out on switchgear. Generators and cables insulated for 11 000 volts on a 6 600-volt system are no substitute for spare plant. I quite agree with the author that one good circuit breaker is better than two of inferior quality, provided that the inferior breakers are not able to cope with the short-circuit power, but then no breaker that cannot deal with the maximum short-circuit power should be installed in a central station. There are certain advantages attending the use of duplicate breakers and these should not be forgotten. Spare breakers are certainly useful because an attendant can ruin a breaker by closing too frequently on a fault or at too short an interval between unit-operating cycles. American manufacturers and operating engineers have arrived at an

agreement with regard to the duty cycle. The agreement provides that four operating cycles instead of two (the British standard duty) and with no time delay between cycles will reduce the breaking capacity to 30 per cent of the rated value. In other words, if the operator is going to close the breaker four times in succession without hesitation then it is necessary to install a breaker having a rated breaking capacity $3\frac{1}{3}$ times that which would otherwise be required. With regard to duplicate busbars, the author states that it is only on a few occasions during the life of the plant that the duplication of busbars may prove advantageous. He infers that it is economical to dispense with duplication. I entirely disagree because I consider that duplicate busbars are the most essential apparatus in a central station scheme. To give only a few of the uses, they provide facilities for boosting the voltage on any particular feeder, they provide means for receiving a supply from an interconnected generating station without running in parallel, and they enable non-adjacent busbar sections to be paralleled at light loads. If there is only one purpose to which duplicate busbars can be put, that is, to provide means for carrying out extensions without interruption of the supply, then I consider that there is a sufficient warrant for the duplication of busbars. The value of duplicate busbars is very much reduced if one has not the necessary facilities for making full use of them, and in this connection the method of busbar selection is important. The author advocates the change-over of busbars whilst the circuit is dead. Certainly much switchgear could be saved on our systems if it were permissible to interrupt the supply and change over the connections by hand. In my opinion this is the crudest method imaginable. When this method had to be considered a few years ago I dismissed it as impossible and agreed that nothing but oil selector switches or double breakers could be considered suitable. In the event of a busbar breakdown it is imperative that the supply should be resumed as quickly as possible, but the change-over of plugs does not allow of a speedy resumption. The advantage conferred by the use of double breakers is that the operator has complete control from his desk by means of push-buttons and there is no need to deputize another person to enter the high-tension room for the purpose of busbar selection. A separate busbar coupler is not necessary when double breakers are provided. In the case of a particularly heavy fault it is useful to have a spare breaker which can be used immediately. In an address at the International Conference, Paris, Mr. P. V. Hunter said that no serious proposals had been made to provide for automatically changing over from one busbar to the other in the event of a busbar fault. This is quite feasible with double breakers and it is possible to change over automatically in about 0·8 second. In that time I do not think that any of the synchronous machinery will fall out of step. The author is very unfortunate in his reference to Stepney and Neepsend at the foot of page 428, because the charge engineer who operated the plant at Stepney stated,* after saying that the gear was in good order: "The only criticism I have to offer is in connection with the method of putting dead the busbars when required for alterations, additions, overhauls, etc." Manufacturers ought to study the published experiences of operating engineers. With regard to Neepsend, in a discussion at Sheffield in connection with the plans for a new power station, particular interest was centred on the method of transfer of circuits from one busbar to the other without breaking load as it was wished to work some of the feeders at a different voltage from the rest. With regard to Fig. 13, the current densities given for safe ratings seem too high and I do not think that we should recommend current densities of the order of 1 600 amperes per sq. in. for current ratings of 500 amperes, especially when the British Engineering Standards Association are considering a limit of 1 000 amperes per sq. in. regardless of the temperature-rise. The author's reference to current-limiting reactors is very brief but I judge from his remarks that he is not too sure whether they are necessary. I think that the short-circuit power on a system should be limited to somewhere near 750 000 kVA by means of busbar reactors. If one calculates the enormous forces which are brought into play by short-circuits of the above magnitude I think it will be agreed that reactors should be employed not only to reduce the size of switchgear but also to protect the whole of the system. Taking the case of a 6 600-volt system in which 750 000-kVA breakers are used, the loading of the busbars at the peak of the short-circuit would be about 1·45 tons per foot run, for a 12 in. spacing of the busbars. If the supports are placed at every 2 ft. along the busbars, then the force exerted on each support would be 2·9 tons. In the case of a short-circuit of $1\frac{1}{2}$ million kVA under the same conditions the force exerted on each support would be 11·5 tons. Breakers can be built to deal with any short-circuit power but the effect of electromagnetic forces is experienced before any breaker can open. Furthermore, if the short-circuit power is not limited, the effect of surges becomes more serious. The author refers to the effect of reactance on the duty of oil breakers. I do not agree that the introduction of reactance imposes a heavier duty on oil breakers, except in outlying substations. The worst short-circuit is one at the busbars in a central station, and here the addition of 10 per cent external reactance to the 10 per cent inherent reactance will only alter the phase angle of the short-circuit current by about 3 degrees, so that the duty on the breaker in its worst location is very little increased. I agree with the author's suggestion that breakers should be selected to meet the peak of the short-circuit instead of on the B.E.S.A. basis of 6 times the aggregate plant capacity. This would give a higher factor of safety but it would add about 66 per cent to the cost of switchgear because the cost is almost directly proportional to the breaking capacity. The whole question resolves itself into this: "Is the purchaser prepared to pay extra for the increased factor of safety?" I think that the present method of stating the breaking capacity in short-circuit kVA is perfectly satisfactory and that the author's suggestion of stating the breaking capacity rating in terms of generating plant output and reactance would be a retrograde

* *Electrical Power Engineer*, January 1922.

step, as this method obtained 10 or 12 years ago. His reference to the "through" rating for circuit breakers is very opportune and I agree that such a rating is necessary, say for 1 sec. and 5 secs. This is common practice in the United States but it is rarely specified in this country. In my opinion, breakers fitted with charging resistances should be used for power transformers because I think that these resistances serve a useful purpose in reducing switching surges. On page 435 reference is made to the use of the hospital bar as a reactance tie busbar. I do not think that it should be used for this purpose as it has many other functions to perform. In selecting breakers, I do not agree with the author's suggestion that external reactance should not be taken into account in calculating the short-circuit current, as this would add enormously to the cost of switchgear. The short-circuit kVA of a 200 000-kVA station can be reduced to 650 000 kVA by means of busbar reactance. In this case apparently the author would recommend the installation of breakers rated at 2 million kVA and this would treble the cost of the switchgear. No reactance is shown between the hospital bar and the tie bar in Fig. 21. I think that it is current practice to include this and I presume that its omission was not intentional. In connection with bakelized paper condenser bushings referred to on page 437, I consider that the 1-minute test is not all that could be desired. Many bushings will stand up to the test pressure for 1 minute, but it is always the time factor which determines the reliability of the bushing. It would be much better to apply a lower test pressure for half an hour. In the design of condenser bushings for metal-clad gear it is not possible to make the male and female bushings for the plug-and-socket portion on the orthodox condenser principle, because the outer condenser layer of the male bushing is at earth potential and the inner condenser layer of the female bushing is at the line potential, so that, when the two engage, the arrangement of the condenser layers has to be arranged to suit these conditions and, in consequence, perfect grading cannot be obtained. The final design has to be a compromise between a bushing with high flash-over pressure and a comparatively low puncture pressure, and vice versa. With regard to the ring-main scheme of protection shown in Fig. 28, I should like to ask if this scheme has been put into extensive commercial use. All engineers are looking for cheaper switchgear for ring-main substations, but the scheme shown in Fig. 28 appears to be defective in that the transformers themselves are not protected. The switch fuses are apparently relied upon for protection of the high-tension side of the consumers' transformers. I cannot see how this will be satisfactory, because a short-circuit on the transformer terminals will be just as severe as one on the ring main. It is very desirable that a scheme of this sort should be available if only the above defect could be remedied. The author infers that the neutral point of a high-tension system should be solidly connected to earth. I do not think that this would be wise, because the shocks to the system would be far too great. In his conclusions he states as one of the requisites for safety and continuity, "a stable neutral point at earth potential." Does he really mean "dead" earthing? Further, I think that he could have included the draw-out feature in his list of requisites, because it is very important from the point of view of protection of the life of the operator.

Mr. T. W. Ross: Regarding the protection of generators, on page 439 the author recommends relay settings of 50 per cent, and an earthing resistance of a value which would pass twice full-load current at the voltage between phase and neutral. Such a combination would give protection to 75 per cent of the generator winding against faults to earth, and a stability ratio of 40 : 1 when using a relay which takes 0·8 VA. We went into this question some years ago and found that we obtained a much greater stability ratio when using a relay having a very much higher impedance than the relay mentioned, even with settings as low as 15 per cent of normal. As a matter of fact we can obtain a stability ratio of 70 : 1 with a relay set for 15 per cent of normal. This gives protection to 85 per cent of the machine windings with an earthing resistance proportioned to pass normal full-load current. The reason for this improvement is that the higher impedance of the relay tends to force any out-of-balance current, which may exist on heavy loads or external short-circuits, through the other alternative circuits formed by the current transformer secondary windings. By a slight modification of the connections a still lower setting can be obtained for earth faults without decreasing the stability ratio, and this method is used when the earthing resistance is not designed to pass sufficient current to give 85 per cent protection. This modification provides for one element of the relay to operate on earth faults only, and the other two elements take care of short-circuits between phases. I agree with the author that the value of the earthing resistance is very often too high, but the operating engineers in this country insist on a high earthing resistance which of course necessitates lower relay settings than are desirable. In this connection we very often find that when we have to supply a generator which is controlled by switchgear of another make, the protective gear does not give sufficient protection and lower relay settings are necessary. A difficulty arises here, as unless the gear is well designed and carefully manufactured, insufficient stability results. With regard to the protection of feeders, I agree with the author that the tendency is to have relay settings which are too low. To my mind the protective gear for feeders is most useful in maintaining a continuity of supply and not so much in preventing damage to cables. If, therefore, this object can be realized with relay settings comparatively large, there is no object in impairing the stability of the system with low settings. In the past, and even to-day, certain engineers when purchasing switchgear or protective gear place too much importance on the sensitivity of relays or protective systems. The system of inertia relays described by the author is very ingenious, and I would suggest that if relays having a slight inverse time-limit characteristic were used on balanced protective schemes very many of the troubles due to abnormal transient conditions would be overcome. Such relays could also be shunted by non-inductive resistances to provide a by-pass for high-

frequency capacity currents which may exist in the main cables due to surges. The author mentions time-lag devices for use as discriminative protection on feeders. Such protection is certainly not ideal, but one is very often faced with the necessity of an alternative to the expensive instantaneous balanced protective gear which requires special cables or pilot cables, and something of this nature then has to be resorted to. It is a well-known fact that a short-circuit will soon cause synchronous machinery to drop out of step, and it is here that time-lag devices have their limitations. Some years ago there was a referendum of the operating engineers in America in order to come to some agreement as to the length of time for which it was possible to hold a short-circuit, and it was then decided to allow a maximum time-lag of 2 secs. It is therefore apparent that this maximum time of 2 secs. must be split up into fractions of a second if several circuit breakers are in series. This means an accurate type of relay which will discriminate with different time settings of a fraction of a second. A very good type of relay for this purpose is an induction relay having inverse time-lag characteristics and so designed that for heavy overloads the time-lag becomes approximately of a definite value. Such relays can be obtained with a maximum time-lag of not more than 2 secs. on short-circuit and this can be split up into 4 or 5 equal parts for switches in series. If, in addition to overload settings, directional features are added, protection can be obtained for ring mains, parallel feeders and supply networks. This form of protection is very largely used in America and on the Continent. I agree with the author that reverse-power relays are practically useless for the protection of generators. Some engineers contend that they should be added to take care of a failure of the prime mover, and it is possible by suitable connection to use such relays to protect against failure of the generator field, but on the whole I think that it is best to leave them out. I was interested in the lantern slide which shows an emergency trip situated near the machine. I consider that this is a very necessary feature where the machine may be some distance from the control board or in fact may be in another room. The engine driver would then have some control over the machine in the event of trouble with the prime mover, and this is much better than reverse-power relays. I cannot urge too strongly the need for rapid isolation of a faulty generator and in this connection I do not agree with the author that the tripping of the automatic field switch should take place after the main switch has opened. We made a number of tests to prove that it was preferable to trip both switches simultaneously, and we believe that it is necessary to do so. This was fully discussed in Mr. Kuyser's paper * before the Institution. I do not understand Fig. 37, as I cannot see why the automatic field switch should not be operated as a routine test. In regard to the balancing of protective transformers I should like to know whether the author experiences any difficulty in maintaining a balance on the transformers when they are eventually mounted in the cast-iron housing. We find that it is difficult to get a perfect balance when the protective transformers are supplied by other makers to fit in our ironclad gear. This is, of course, frequently necessary when the switchgear at both ends of a feeder is not of the same make. I am sure that metal-clad gears will have a great future, but a note of warning which I would give to operating engineers is that simplicity is essential to success. We have been used to what we call facilities in the open-type gear of the past, but these facilities are perhaps not so easy to obtain in the metal-clad gear. I believe, however, that the other advantages much outweigh the loss of what is very often an unnecessary feature.

* *Journal I.E.E.*, 1921, vol. 60, p. 176.

Mr. H. A. Ratcliff: The author refers to the risks to continuity of supply arising from the unnecessarily sensitive settings of protective relays, and there is no doubt that within reasonable limits the higher the settings the greater the stability of a system. Modern plant should be capable of withstanding momentarily very considerable overloads. Metal-clad reactances appear to possess some distinct advantages, and they are a natural corollary to metal-clad switchgear, but their use involves some incidental difficulties. The effective earthing of the metal sheathing—usually lead—is a matter of considerable importance, but the best method of effecting it is by no means obvious, since provision must also be made to prevent troubles arising from the comparatively high pressures which may be induced in the metal sheath. It is essential that reactances should be absolutely reliable, since they are intended as the final safeguard in the event of severe short-circuits occurring on a system, and therefore it hardly appears desirable to adopt a form of construction which possesses all the inherent weaknesses of cable, further accentuated by the severe conditions arising from electromagnetic forces and induced E.M.F.'s of considerable magnitude. Although I am in agreement with much of what the author says on the subject of duplicate busbars and change-over facilities, I am nevertheless of the opinion that he rather underrates their advantages. In connection with substation operation more particularly, there are occasions when it is very convenient and even desirable to be able to change a circuit over from one source of supply to another without interrupting it. The separation of the phases in e.h.t. metal-clad switchgear appears to be a matter of very great importance, and without such separation it is by no means evident that metal-clad gear would be in any way superior to cellular gear in the event of an internal short-circuit occurring between phases. In fact the resulting conditions in the case of metal-clad gear might be the more severe owing to the incidental dangers arising from the destructive distillation of the compound filling. The analogy with three-core cable is hardly applicable, since cables are invariably protected by automatic devices, whereas the protection of busbars is unusual and frequently impossible. The reference to the use of explosion pots on the contacts of circuit breakers is very opportune. If explosion pots are all that is claimed for them, and they are used as an additional line of defence, well and good, but if they are merely fitted in order that inferior and mechanically weaker tanks may be employed, then the principle cannot be too strongly condemned. I am in agreement with the author's views on the B.E.S.A. method of

determining the necessary breaking capacity of oil switches. In the case of switches employed on large interconnected generating and transmitting systems there appears to be little, if any, justification for the B.E.S.A. method of computing the switch ratings. In this connection it would appear that actual switch ratings are very elastic, and consequently a switch may have its rated breaking capacity increased from 150 000 to 250 000 kVA within a period of a few days, presumably on the strength of its observed behaviour under known operating conditions. The whole subject of switch ratings, however, still calls for full and careful investigation and standardization. Charging resistances incorporated in the construction of circuit-breaker moving contacts are most unmechanical, and therefore undesirable; but unfortunately experience has shown that they are at times necessary in order to protect the end-turns of machine stator windings where no other form of protection is available, and also more usually to prevent the inadvertent operation of protective gear of the balanced-current type. It is probable that with modern plant having the end windings properly reinforced, and with thoroughly stable protective and overload devices having reasonably high settings, charging contact resistances are not really necessary. The author's remarks on the subject of reactances are very apposite as there is no doubt that the indiscriminate employment of reactances may be easily overdone. Reactances should be employed not so much for the purpose of permitting the use of switches having a smaller rupturing capacity than would otherwise be necessary, as for preventing enormous concentrations of energy in the event of short-circuits occurring in, or in the immediate vicinity of, generating stations, and also for minimizing the effects of such drastic disturbances by enabling the pressure on other portions of the system to be maintained above the value at which synchronous plant falls out of step. Reference to current transformers of the single primary turn or bar type was inevitable in a paper of this description; within their limitations there is much to be said for them, and they possess undoubted advantages, but it is essential to recognize their limitations. The single-turn type of current transformer is most desirable for use on e.h.t. circuits, but unfortunately these are usually just the circuits for which it is least suitable owing to the comparatively low values of the primary currents. As a general rule, current transformers of this type may be used with advantage for ammeters and overload relays, but except on heavy-current circuits they are useless for watt-hour meters, and unreliable for protective gear of the balanced-current type. Core-balance methods of protection, where possible, afford a reliable means of overcoming the inherent defects of single-turn current transformers in this respect. The value of so-called high-frequency surge arresters is, to say the least, open to question, and certainly on an underground transmission system the cables themselves form the best possible high-frequency surge arresters. The danger attaching to the use of oil-immersed isolating switches is not perhaps always recognized as it should be, and therefore the author's reference to the subject is particularly appropriate. I cannot agree with the author that there should be no resistance at all in the connection between the neutral point of a high-tension system and earth, since every earth fault would then amount to a short-circuit with all the usual incidental effects. Moreover, the resulting damage at the fault would be very much greater, and the effects of the heavy earth currents might be most serious in other respects. The essential requirement of the neutral earth connection is that its resistance should be sufficiently low to ensure the reliable operation of the various fault protective devices on the system. I am in complete agreement with most of the author's remarks in regard to cable protective gear, and observe with interest that he now fully appreciates the importance of the transient capacity currents in the main cables, quite apart from the effects of the capacity currents in the pilot conductors. The non-inductive shunting of protective relays has been adopted with a considerable measure of success on the Manchester 33 000-volt system. The protective scheme illustrated in Fig. 32 is very ingenious and should be quite effective; but the discriminative bias by means of relays possessing different time characteristics is undoubtedly the weak feature. The real value of the quick-acting relays probably lies in the fact that they constitute a permanent load on the current transformers, with the result that the pressure applied to the pilot cables is reduced, and if transformers of the closed-core type are employed, the lower saturation in the cores due to the secondary load enables the transformers to be balanced more accurately. The objections to the Hunter four-core system of cable protection are the apparent unbalanced capacities of the three phases to earth and the necessity of making all joints core to core, since in practice this is extremely difficult and in some cases almost impossible.

Mr. D. R. Davies: After several unfortunate experiences and shut-downs, due to overrated and out-of-date cellular gear, some operating engineers are now looking hopefully to the metal-clad type. The author speaks feelingly of the troubles peculiar to open-type gear, and it would add considerably to the value of his paper if he would also record the troubles experienced with metal-clad gear. The manufacturer rarely has a free hand in obtaining sufficient space for his switchgear, and it is not right to condemn cellular gear because of troubles experienced with a layout squeezed into an existing building. I know of three disastrous fires which have occurred in switch rooms during the past 12 months, and it is rather significant that all of them were equipped with Continental switchgear. Interlocks are very simple and cheap for metal-clad gear of the draw-out type, but they become very complicated on designs having oil-immersed selector switches similar to those shown in Figs. 7 and 25. It is no easy job, for example, to design simple interlocks which will ensure that all contacts within an oil-immersed busbar selector switch are dead before the removal of the tank. Interlocks on large cellular layouts are also fairly expensive, because when required it becomes essential to operate all isolators and selectors by a remote mechanical drive. Perhaps the best feature of metal-clad gear is the ease with which the circuit breaker

can be withdrawn in case of emergency from one circuit and plugged into another. In fact, American manufacturers are now supplying breakers for cell mounting built on a carriage in order to incorporate this feature. Whatever may be our individual views on the necessity for changing over the breaker from one busbar to another without interrupting the supply, the fact remains that this is possible with cellular gear and further does not involve additional complications in the layout, or incur additional expense. The majority of supply undertakings requiring metal-clad gear do not regard the necessity for changing over on load as important, and in the few cases where the purchaser insists in this feature he must be prepared to pay more for the metal-clad type. It is safe to say that 90 per cent of the supply undertakings in this country would be prepared to accept metal-clad gear which would not permit changing over from one busbar to another on load. The manufacturer is not therefore justified in increasing the cost of a design which is almost universally acceptable. It occurs to me that the class of operator who would open an isolator on load and cause a large station to be shut down three times in one year is just as likely to forget to change over all the plugs on the metal-clad gear shown in Figs. 8 and 14. This may result in the accidental coupling of busbars, and I think therefore that an oil switch as shown in Fig. 14 should be provided with an interlock which prevents the switch being racked home on the bars with the plugs incorrectly inserted. Of the schemes submitted by the author for changing over on load, that shown in Fig. 10 using two breakers is the best but is expensive and requires double the floor space. The author's idea that it is better to spend money on one good breaker instead of two of inferior quality would not be very convincing to an engineer who regarded continuity of supply as his main object. The factor of safety of the oil circuit breaker should obviously be the same no matter which scheme is adopted, so that if an operating engineer decided that one breaker would give him the desired flexibility he would hardly be justified in buying a rating exceeding his requirements simply on the score of increased security. If the author's point of view is correct it would be better on a 6 600-volt system to lay one 11 000-volt cable for a feeder instead of running two 6 600-volt cables in parallel, in order to obtain a greater factor of safety on the cable insulation. For two reasons it is not good practice to put two switches into one tank as shown in Fig. 11, viz. (1) when the switch on the right opens, the inner arc is blown to the left across the centre contact, and when the switch on the left opens, its inner arc is also blown across the centre contact, and (2) the tank is always eccentrically placed in relation to the arcs from which the explosion is initiated, and the interruption of a severe fault may cause the tank to be displaced sideways. I should like to ask the author whether he regards the design of breaker shown in Fig. 7, which has a single horizontal break, as being superior to one having two vertical breaks in series. The single horizontal arc is formed substantially parallel with the surface of the oil, and on a heavy fault one would reasonably expect the magnetic field to blow the arc upwards with such violence that it would extend beyond the oil-level in the tank, whereas in the conventional double-break switch as both arcs are drawn down deeper into the oil this must reduce the risk of flame emission. Moreover, using the same depth of tank it would be possible with a two-break switch to double the head of oil above the arc, which would not only reduce the risk of flame protrusion but also provide better facilities for cooling the liberated gas before reaching the oil-level. It would be interesting to know whether the construction shown in Fig. 7 has given satisfaction in service and, further, if this particular design of breaker has actually interrupted faults of any magnitude without showing signs of distress. The number of double-break switches which are meeting their guarantees are so numerous that responsible engineers and manufacturers should regard any distinct departure with diffidence. Moreover, different ratings of the double-break type were tested at Baltimore and proved their suitability for dealing with large amounts of power. The testing facilities at the disposal of the British switchgear manufacturer are far too limited. Even the fortunate ones, who also make large machines, can only rely upon a maximum of 200 000 kVA being available when it is desired to test out a circuit breaker. We are therefore forced, when considering the possible performance of the circuit breaker on a large system, to rely upon the data obtained from field tests carried out in America. I fully appreciate the excellent work done by the British Electrical and Allied Industries Research Association, but however convincing their final recommendations may be, we shall still lack the testing facilities necessary for proving the possibilities of the super-station circuit breaker, until the supply undertakings in this country realize the mutual advantages of co-operation with the manufacturer. The author shows very clearly in Fig. 18 the various values of current which a breaker may have to interrupt on short-circuit. The chances of a fault developing and reaching its maximum value at the exact moment at which the arc-tips separate are very remote. For example, if the arc-tips were to separate 0·02 second later than the point C in Fig. 18, the current to be broken would be 14 instead of 20 times full load. I think, therefore, that the author is perhaps unconsciously providing an excuse for a weak breaker failing to do its duty. There seems to be a tendency, both by some manufacturers and also by supply undertakings, to take the British Standard Specifications too literally. My experience has indicated that the various clearances, lengths of insulators, etc., recommended are, as stated in the Specification, minimum values. The breaking capacity of a circuit breaker has no reference to any particular system and the breaker is sold by the manufacturer for a specified current and voltage. The effect of reactance or power factor, or its probable position in any particular system, should all be considered carefully by the designing engineer before deciding on its short-circuit rating. Sometimes a purchaser does not state in his specification the breaking capacity required, but gives instead the plant capacity of the station and leaves the manufacturer to offer a breaker which he considers suitable for the conditions. In these circumstances it is necessary

for the manufacturer to state in his tender the assumptions made in arriving at the short-circuit current to be interrupted. Otherwise the buyer may assume that the circuit breaker is capable of dealing with any value of the short-circuit current. Whether a circuit breaker will withstand the repulsive forces due to "through" currents of the order of 100 000 amperes or more, depends mainly on the design of moving contact used. The insulators surrounding the stems are analogous to cantilevers with a distributed load, and apart from their inherent strength to resist the repulsion it is safer to use a brush, which effectively locks the ends of the stationary contacts together, in order to prevent deflection. One type of moving contact which is capable of locking the ends of the stationary contacts together, and also increases the bedding pressures of contact as the current increases, is the "Y" brush, shown in Fig. B herewith. This brush was developed in the

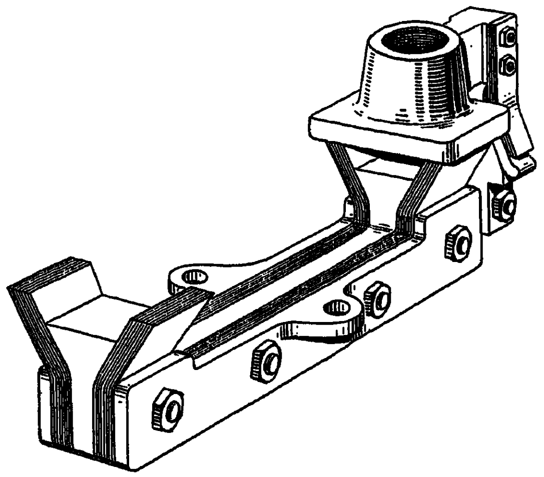

FIG. B.

United States by one of the leading manufacturers and, after exhaustive tests had proved other types unsuitable for withstanding the passage of large "through" currents, completely justified the claims made by the designers. At that time American engineers were considering the advisability of rating oil circuit breakers on the 5-shot basis. To meet such a rating the breaker would be required to interrupt its guaranteed short-circuit current five times in succession and then be in a condition to carry its rated load continuously. Subsequently, breakers fitted with the "Y" brush were tested at Baltimore and interrupted arc currents of the order of 20 000 amperes (R.M.S.) at 13 000 volts seven times in succession. Even on the last shot the current transferred from the main path to the shunt path through the arcing contacts without causing pitting or welding on the brush face. It is doubtful whether such a performance would be realized with finger contacts as used for the switch shown in Fig. 14. Although finger contacts increase the bedding pressure on the moving element with increase in current, this increase in pressure is not sufficient to lock the ends of the stationary insulators together and prevent them splaying outwards as the "Y" brush does. I should like to mention incidentally that the repulsive forces are always greater in an oil circuit breaker than those calculated by means of the usual formulæ, because in deriving the well-known expressions no allowance is made for the increase in flux due to the presence of the tank. In certain cases where a circuit breaker is fitted with a rectangular or elliptical tank, the throw-off force may be as much as 50 per cent more than would be obtained by neglecting the presence of the surrounding iron. I am surprised to note from Fig. 14 that the author advocates the use for metal-clad gear of what are apparently porcelain insulators. These insulators are liable to crack when filling the hoods with hot compound, and such cracks are very difficult to detect, even with a high-pressure test. Further, if a porcelain becomes badly chipped or cracked in service, the complete hood must be returned to the manufacturer to have the damaged insulator replaced. Bakelite insulators have the great advantage of not being brittle, and although of course they are liable to surface damage by careless attendance, this can be repaired on site with far less inconvenience and expense to the purchaser. However much care is taken in producing a reliable potential transformer, and whatever test the manufacturer is prepared to subject his product to, operating engineers will always insist on the provision of fuses on the high-tension side. I believe I am correct in assuming that the metal-clad gear in Fig. 7 accommodates the potential transformer and its fuses in the oil-immersed feeder isolator tank. Consequently, it is necessary to open the oil circuit breakers at each end of the feeder, or, in the case of a generator, cause a complete shut-down before the transformer or its fuse is rendered accessible. This arrangement is so inconvenient that I think operating engineers are justified in demanding metal-clad gear, which enables inspection of the potential transformer and makes re-wiring of the fuses possible without causing interruption to the supply.

Mr. P. B. Hall: I quite agree with the author that the term "foolproof" which is sometimes applied to electrical apparatus is a misnomer, but it is extremely difficult to make apparatus so mistake-proof at commercial prices that it cannot be deliberately abused or used incorrectly. On page 426 the author advocates all-metal enclosure for all electrical apparatus, even up to lighting fittings. This is very good theoretically but is not very practicable, and in any case would be too expensive for the vast majority of installations. On page 427 he refers to the "development of metal-enclosed switchgear," but I do not agree with his assumption that the air-insulated types, or in other words the cubicle and truck types, are a "half-way measure." As regards these and their "safety factor" (which is the main point), the act of withdrawing the truck from its container in most cases isolates right back to the busbars, due to the intervention of shutters, while cubicles, at any rate so far as my firm are concerned, are always interlocked so that the contacts back to the busbars are dead before the door of the cubicle can be opened. As regards such interlocking, about nine months ago I was in a new power station which had a large installation of high-tension switch cubicles without an interlock anywhere, so that once

anyone was in the switch room he could at any time open the door of a high-tension cubicle and walk inside. This I consider to be bad practice. There are advantages and disadvantages in filling in busbar chambers solid with compound, but I consider that the disadvantages frequently outweigh the advantages, and there is a great deal to be said for the greater accessibility of the cubicle or truck type of gear for very high capacities and voltages in the event of faults, and in this connection I think that the words "the distinct inaccessibility of every conductor" which the author claims for the compound-filled gear are rather an unfortunate expression. Referring to the "metal-clad switchgear construction" mentioned at the foot of page 427, the author gives three types of isolation, namely, horizontal, upward and downward types. In the downward type of isolator—with which the author credits my firm—the live socket contacts in the isolating chamber are also deeply recessed just as they are on the horizontal type to which the author refers, and the isolating jaws before insertion into the isolating contacts are passed through slots in an insulated shield. In the illustrations of the three classes of the horizontal, upward and downward isolation, which the author shows in Figs. 4, 5 and 6, and which he says are diagrammatical of classes only, Fig. 6 shows the downward type referred to above. He also shows each type having the busbar chambers filled with compound, but I certainly do not agree with him when he says (see page 427) that these metal-clad types of switchgear are generally of the solid type—if by this he means having compound-filled busbar chambers. In spite of all the tests made on such alternators as are available, a great deal still requires to be done in respect to fixing the kVA breaking capacity of switches for commercial use. Although I agree with the author's remarks in regard to insulation troubles on page 437, unfortunately the trouble is that whilst most of us are continually improving insulation, and thereby as a rule incidentally adding to our costs, the user generally objects to pay more for the gear.

Mr. A. Bannister (*communicated*): While the growth of metal-clad switchgear has no doubt been fostered by the extreme "safety first" attitude adopted in this country towards anything electrical, it can also be claimed that the space limitations imposed upon switchgear designers by those responsible for station layouts have also been a factor in promoting this growth. For years past, the switchgear engineer and designer has been endeavouring to squeeze, as it were, a quart into the pint pot allowed to him. Metal-clad switchgear, whether of the truck, steel cubicle or armour-clad type, is the result, as this gear includes the maximum of safety with a minimum space requirement. It has its limits, however, and for voltages over 35 000 it is very doubtful whether metal-clad gear is possible until our knowledge of solid dielectrics and the voltage stresses therein under operating conditions is increased. For some time to come, open-type gear relying mainly on air and porcelain for insulation will be used above this limit. After all, these two insulators are the cheapest available and probably those about which most information is available. While the tendency has been for switchgear to move towards metal-clad types, it is interesting to note a movement in the opposite direction; this is in the case of reactors where the oil-immersed iron-core reactor has been largely superseded by the open-type concrete reactors, and here again space requirement has been one of the deciding factors. I cannot agree with the author's implication that the duplication of parts is governed by the liability to failure. While in some cases this may be correct, there are other cases where the question of duplication is decided by the operating conditions or requirements of the system layout not connected with any possible failure of apparatus. For example, I am aware of one large power station where the testing arrangements were such that the provision of duplicate busbars was practically necessary to enable machine tests to be carried out. Where duplicate busbars are provided, the question of circuit change-over without interruption of supply has to be considered. The author considers this to be an imaginary necessity in the majority of cases, but here again I suggest that this requirement depends on layout and conditions. While duplicate supply to outlying substations may be usual on large interconnected systems, it is probably exceptional for the general run of smaller systems in this country, and in the latter cases, if continuity of supply is to be maintained, some change-over device without circuit interruption is essential on the outgoing feeder circuits. The arrangement shown in Fig. 11 is not a very satisfactory one as the central main contact is in an unsuitable position. Apparently the main contact of one switch becomes the arcing contact of the other, an arrangement that is hardly to be recommended. On page 429 it is apparently hinted that there are cases when a busbar coupler switch is not required. This can only occur when the busbars are paralleled through the isolators or similar devices. When this is not possible a coupler switch is essential, especially if duplicate supplies are given to substations, otherwise there is the possibility of paralleling bars out of synchronism through substation connections. We cannot safely say that any particular type of apparatus is free from insulation failure. If such a failure occurs the duration of any arc formed will depend on the position of the fault or the sensitiveness of the protective gear. If the failure is outside the protected zone one is inclined to the view that the arc is likely to continue for a long period and that more damage would result to metal-clad compound-filled units than to the other types, due to the positive metal-to-metal circuit and the inflammable and conducting nature of the vaporized compound and metal. If complete separation of the phases in different floors or buildings does not prevent phase-to-phase faults, as stated, it can hardly be expected that metal-clad switchgear with its close spacings will be free from similar troubles. The subject of circuit-breaker rating and design is worthy of a paper to itself. While there are still many points to be learnt about breaker operation under fault conditions, several known points are often overlooked by users and designers. While agreeing with the author that failures have been due to mechanical weakness, these have more probably been caused by secondary explosions

and not by the immediate results of the rupture of the circuit. Records of short-circuit tests carried out a few years ago, where powers up to 500 000 kVA were interrupted, showed that the pressures recorded near the contacts varied between 100 and 150 lb./sq. in., but when a secondary explosion occurred a value of over 600 lb./sq. in. was reached. Dr. Garrard in a recent article showed the danger of these secondary explosions and pointed out that not only is the resulting pressure 3-4 times that due to arc energy but this higher pressure is generated in a much shorter time, thus rendering it doubly dangerous. In one case while the arcing period was 0·02 sec. the pressure due to a secondary explosion reached its maximum in 0·004 sec., 0·014 sec. after the rupture of the circuit. It is the latter effect that should be remembered, and the object of the designer should be to design the breaker so that when interrupting its rated short-circuit kVA there should be no possibility of the mixture of gases above oil-level being fired by the arc of rupture. Mention is made of speeding up the velocity of the contacts to reduce arc energy, but it is often overlooked that the throw-off forces due to electromagnetic repulsion resulting from large fault currents are generally far in excess of any mechanical loading of the moving element, and these will probably decide the speed of break under fault conditions. Mechanical loading should only be used to give quick operation under normal conditions. A single tank with steel phase barriers tends to increase the mechanical strength of the breaker, but care should be taken to ensure that the tank is equally strong in all directions. The design illustrated in Figs. 14 and 15 appears to be weak to some extent both electrically and mechanically, owing to the fact that the phase barriers are not continuous through the tank. I am pleased to note that the author deprecates the use of charging resistances. They are a constant source of irritation to designers and it often appears to be overlooked by users that these resistances increase the impedance of the breaker during fault conditions. As their thermal capacity is small they are likely to cause trouble in such cases. On the subject of rupturing capacity (see pages 432 and 433) the author is surely confusing the actual rupturing capacity of a breaker with the rupturing capacity required of the breaker when used on a particular system. This confusion is apparently due to the fact that rupturing capacity is being talked of in terms of plant capacity, a practice which is not to be recommended. As far as we can tell at present, the short-circuit rupturing capacity of a breaker is a fixed value in amperes under prescribed conditions. The proposed American standard specification recognizes this and states the breaking capacity to be a certain number of amperes at a definite voltage. The B.E.S.A. specification combines the same current figure with the rated voltage of the breaker and the circuit constant to give a kVA value, a figure from which an attempt is being made to rate the breaker in terms of plant capacity. With this fixed rating, the question of the size of breaker to install on a given system is one for the operating engineer, who must balance the possible risks against costs. He can either install a breaker rated to interrupt the fault current at D (Fig. 18) and chance its failure to do so should it operate at the point C, or pay the additional cost for breakers rated to interrupt the larger current. If the first alternative is taken, the design of the breakers must be such that they will withstand the mechanical forces due to the current at C. As in practically all cases the application of breakers is based on the lines indicated in the appendix to B.S.S. No. 116, present-day breakers are designed to meet this requirement. The confusion of actual rupturing capacity with the application of breakers for a given plant capacity suggests that the question of the duty cycle of oil circuit breakers is not clear; it would therefore appear desirable to have a more definite statement on this point than Clause 52. The suggested American standard specification would form a very good basis upon which to start. Dealing with other components, very probably most engineers will agree that the bar-primary current transformer is the best type to install on large systems, but many operating engineers still require manufacturers to attempt to reconcile small current-capacity designs of this type with B.E.S.A. specification requirements for ratio and phase-angle errors. Excess-pressure dischargers present a problem on compound-filled metal-clad units if required, but these are usually omitted on cable systems. Arresters for overhead lines should be placed outside the station as they are practically part of the line equipment. The use of cable as a type of condenser arrester may be satisfactory in this country where lightning storms are infrequent and not severe, but such a device could hardly be considered efficient for the severe lightning conditions in other countries. Incidentally one would like to hear the cable maker's comments on this practice. The arrangement illustrated in Fig. 27 is a very cheap scheme for controlling the high-pressure side of a small transformer, but it would be interesting to know what happens when a fuse has to be replaced in wet weather. Although the lid may be replaced in a short period the water that would enter the case would seriously reduce the electric strength of the oil. In the various schemes of protective gear no mention appears to have been made of the modification of the Merz-Price circulating-current system patented some four years ago. This modification consists of the connection of a relay between the usual relays and the earth lead of the circulating-current system. This scheme permits of a coarse setting for the phase relays and, with a standard leakage relay, approximately 95 per cent of the winding is protected against earth faults. In conclusion, the simplification of protective schemes seems to be desirable as the variations of the balanced principle are becoming numerous with a gradual increase in the number of parts required.

Mr. S. R. Mellonie (*communicated*): The most singular feature of the paper is the omission of any reference to potential transformers. The title certainly covers these components, and it may be asserted without fear of contradiction that more trouble is caused by the breakdown of potential transformers than of current transformers, to which considerable space is devoted. The rupturing capacity of the fuses used to protect the h.t. side of these instrument transformers is round

about 2 000 kVA, being somewhat higher for the carbon-tetrachloride fuse with spring-accelerated break, and less for the dust-filled fibre-tube type on lower voltages. The expulsion type of fuse has an intermediate rupturing capacity and a distinct advantage over both, inasmuch as re-wiring is a simple matter. The location of this type demands careful consideration, however, as flame is expelled during the operation. These figures emphasize the necessity of providing current-limiting devices to enable the fuses to deal with faults to earth or between phases. Resistances are available in the form of a composition rod with a carbon-silicon base, and would appear to be an attractive proposition. Unfortunately these are not reliable, tests showing erratic variations in resistance after service.* These rods are also very brittle, and instances are on record where the cost of replacement due to breakage is unduly high. Such difficulties have led to the development of wire-wound resistances for this service, and quite simple designs have proved successful under "dead short-circuit" tests. On systems up to 37 kV the value of the ohmic resistance as determined by the limitation of the fuse is always so low that the question of interference with the regulation of the transformer does not arise. A rating of 0·1 sec. has been found quite suitable and during the test the wire glows red, the temperature being between 600 and 800° C. To obtain the requisite thermal capacity, the current density for a given material is limited, and this fixes a minimum length of wire for a given voltage, irrespective of the diameter of the wire. Another point deserving more attention is the size of wire used for the primary windings of potential transformers. Many designers use No. 40 S.W.G. (0·0048 in. dia.) wire, and it is open to question if this can be justified as an engineering proposition. The slight increase in cost and bulk of a transformer using, say, 0·01 in. dia. wire would be more than compensated by the increased reliability. The specification and adoption of 0·01 in. or 0·02 in. dia. wires as a minimum would seem to be desirable. Several cases have occurred where elaborate and expensive protective systems have failed to function due to the trip coil being open-circuited, and this is a serious matter. In all these cases the coils were wound with wire less than 0·01 in. dia. The majority of modern oil circuit breakers are tripped by the excitation of separately supplied trip-coils, and this method has several advantages. The coil does not normally carry current and so consumes no energy. Owing to the short time rating a small coil gives the necessary blow to release the mechanism. It does not, however, fail to safety. This desirable characteristic can easily be obtained by the use of tripping mechanism with a no-volt feature, the various protective relays being arranged to open a coil circuit which releases a weight or catch to trip the switch. This method is not in favour at present and has several disadvantages, but possesses the distinct virtue that any failure becomes obvious.

* Compare curves published by Steinmetz.

[The author's reply to this discussion will be found on page 464.]

South Midland Centre, at Birmingham, 18 February, 1925.

Mr. W. Wilson: I am in agreement with the correctness of the "stability ratio" for estimating the value of protective gear. This implies that, first, the gear must be stable for all external short-circuits that can pass through the equipment, up to, or even exceeding if necessary, 20 times the normal value of the load. When this condition has been fulfilled, the sensitiveness of the operation for fault currents must be as great as can possibly be obtained by the designer. The author appears to deprecate the use of fine fault settings as being unnecessary for efficient protection, and from the figures quoted in the case of feeders, viz. 2 to 3 times normal full-load value, it would seem that a very low standard in this respect is advocated, and I think that a few words upon this point will not be out of place. If the case of transformer protection be first considered, it is not difficult to ascertain the degree of sensitiveness for this type of apparatus, and to demonstrate that it should be a very high one. First, there is the condition that the relays must not be operated by "through" currents of about the order specified, i.e. about 20 times normal full load. Secondly, the other limit is determined by the magnetizing current of the transformer, which at no load and light loadings is the preponderating current passing into the transformer. Since it does not pass out again, it behaves exactly as a leak would do, so far as the protective gear is concerned, and the protective equipment must be so designed that this current is not capable of causing operation. Now the magnetizing current for a modern transformer is in the vicinity of 5 per cent, and thus the lower limit of fault setting is obtained. There is a very strong reason why the sensitiveness should be fixed at this limit if it can possibly be managed, as transformer faults in nine cases out of ten begin as leaks between adjacent turns of the same phase. Such faults upset the balance very slightly, and, with relays that are unable to trip at this small degree of unbalance, the fault has to continue burning the insulation until it has reached sufficiently large proportions to cause operation. The continued destruction of the windings of so important a piece of power equipment as a transformer is an event to be avoided to the utmost extent, since it not only increases the element of danger to life and property but also much increases the length of time over which the apparatus is out of commission for repairs. Thus the characteristic of the ideal protective relay can be deduced. It constitutes a curve which is only slightly above the minimum of 5 per cent at no load, remains approximately horizontal until normal load has been passed, and thereafter trends upwards at a sufficient rate to be above the instability point at all degrees of overload. This characteristic, as far as I know, can only be obtained in its ideal form by a biased relay provided with a correct counterweight. By virtue of the bias the sensitiveness

of the relay is decreased, as the load rises, by the automatic restraint imposed by the biasing arrangement, and thus stability at overloads is obtained. By virtue of the counterweight the fault setting is raised as much as is desired at no load and light loadings in order to bring the curve sufficiently above the magnetizing-current point to prevent operation. Dealing now with alternators, it is evident that the finest setting consistent with stability is appropriate in this case also, for the modern turbo-alternator possesses all the elements of a blast furnace except the means of ignition. Once the latter has been effectively provided, and failing adequate protective devices, a period of only about 10 seconds is required to bring about the entire destruction of the machine windings. Manual methods are thus useless for isolating the machine, and not only is automatic protection essential but it must be as sensitive as possible in order to reduce the amount of energy that can be concentrated in the destruction of a portion of the windings without being able to trip the relay. Even if the setting of the relay be as low as 20 per cent it will be seen that in the case of a 10 000-kW alternator it is still possible for destructive energy of over 600 kW per phase to be employed in setting fire to the insulation without any protection being given. The case for a sensitive setting is equally strong with regard to feeder protection. The author has assumed that cable faults always come on suddenly, and that a sensitive fault setting is unnecessary. This, I think, is not quite an accurate description of what actually takes place. It is true that when mechanical damage occurs to a cable the fault usually comes on suddenly, although even this depends upon the extent of the damage. It is quite otherwise, however, with regard to electrical faults, which include those that may be caused by overheating the cable, by overstressing the insulation in some way, or by faulty manufacture. In any of these cases the fault originates as a weak spot in the insulation, and is actually a high-resistance leak which gradually develops into a complete breakdown. It is a fact that by the use of sufficiently sensitive relays such a fault can usually be detected several hours before the breakdown occurs. Not only therefore is it possible, by the use of sensitive relays, to remove the faulty section before any extra damage is done, but the severe shock to the system which occurs when a complete breakdown is experienced is also prevented. I think that these facts will show that the advantages attending the use of a sensitive protective scheme, possessing stability at the same time, are very real ones. I was much interested in the "diverter" relay, shown in Fig. 32, for decreasing the sensitiveness at overloads. It would appear, however, that the restraint added by this relay is of a rough description as compared with that given by the biasing principle, which is able to apportion the restraining effect exactly to that required at each value of the load. In addition, I consider it very undesirable that when a single relay is capable of doing the work, two of these should be employed. The use of unnecessary relays and electrical contacts in power station apparatus should, I think, be avoided at all possible cost. The second point which I propose to raise concerns the reference to the split-conductor system on page 441, where the author states that this system is exceptionally useful where two existing cables can be used in parallel on one split-conductor switch. I am not of this opinion, since although a certain economy in switchgear is possible by adopting this system, it involves the waste of an entire cable. The characteristic of the split-conductor system is that when one of the systems breaks down it cuts off both. Now the great value of having duplicate transmitting equipment is just that one unit is left to carry the current when the other fails. In such a case the parallel-feeder system offers more advantages. In the first place it only cuts out the faulty feeder; secondly, it may be endowed with a bias, and hence it may possess the advantages as regards sensitiveness and stability that have been referred to above; and, thirdly, the protective gear and the switchgear are very little more elaborate than those required for a single split-conductor equipment. Hence there is no question in my mind that the split-conductor system should not be used where two fully-insulated cables are available. The only case in which it can be considered competitive is when there are two paths for the current provided which are insufficiently insulated from each other to withstand the full working voltage, such as is the case in the specially designed split-conductor cables.

Mr. F. Forrest: It is now the standard practice in large generating stations, both in this country, and abroad, to provide duplicate pumps and auxiliaries in connection with the main units, although it will be generally conceded that such things as circulating water pumps are among the most reliable pieces of apparatus in the station. It therefore does not seem logical to install single main switches for the alternators, as shown by the author in Fig. 20, especially as these switches are complicated pieces of mechanism and are likely to be subjected to very severe stresses. I suggest that the duplication of the main oil switches is essential in large generating stations. It is not always the case that a big switch is out of service due to an internal explosion, or due to its failure to break on heavy short-circuit, but as often as not such a switch fails due to some minor defect in connection with the switch-operating circuits, or to the operating mechanism. Such defects cannot always be located and rectified immediately, and until they are rectified the main turbo-alternator is compulsorily out of service. The author's argument that one good circuit breaker is better than two of inferior quality is sound, but I think that he will admit that one good circuit breaker is not so good as two good circuit breakers. One of the problems which supply undertakings have constantly to solve, is how best to protect the oil switches which were installed in the generating stations years ago, and which were then of ample breaking capacity, but which are now, owing to the increased plant, no longer able to break satisfactorily the increased short-circuit current. The most satisfactory method is to install current-limiting reactances in series with these switches, either by subdividing the busbars by busbar reactances or by installing sub-busbars to which such switches are connected, and to place reactances between the sub-busbars and the main busbars. So much trouble

has been experienced due to the fracturing of the porcelain switch insulators that users have been seeking another form of insulator which will have a certain degree of elasticity. Bakelite is being extensively used for this purpose, and so far is proving very satisfactory. Where porcelain must be used an internal bush of micanite or other insulating material should be employed, so that the circuit is not earthed if the porcelain breaks or cracks. The failures of oil switches may be divided into two classes:—(A) Those which occur before the switch commences to operate, and (B) those which occur while the switch is operating. In (A) we have breakages of insulators due to stresses set up by the passage of heavy currents. The repulsion of the moving main or arcing contact is due to the same reason, and because of their incorrect shape, whilst in (B) are included internal explosions due to the explosion in the oil tank caused by the arc firing the gas under pressure. The author, who is responsible for the design of switchgear which is probably unequalled anywhere, has paid very great attention to these possibilities, but I am surprised that he has not dealt more fully with the necessity of giving all oil switches the highest possible velocity at the point of break. In Birmingham we specify a velocity of 5 ft. per sec. at the point where the sparking contacts are separated, and we are able to obtain, from most of the leading manufacturers, switches capable of breaking with this rapidity. I believe that this velocity could be still further increased with advantage, and I should be glad to have the author's views on this important point.

Mr. Christopher Jones: The author has for long advocated the consistent enclosure of all conductors and insulators, including a continuous earthed metal core throughout the whole supply system, from the generators to the load, and even to lighting fittings, and with these views I fully concur. He refers on page 426 to the earth circuit to the metal cover of all portable plant and appliances being continued through an earth conductor in the flexible cables. The recommendation to surround the outer insulation of the flexible cable, i.e. trailing cable with an earthed sheath of copper braiding in addition to the compulsory earth conductor, thus continuing the metal cover over flexible cables also, is a good one. I have gone carefully into this question in connection with a large number of electrical coal cutters under my charge and I am replacing the ordinary 4-core C.T.S. cable with the class of cable referred to in the paper. On page 426 the author, in dealing with alternators, etc., refers to the entire framework being earthed to avoid the risk of shock to attendants, and states that more often than not the proper finishing off to the metal enclosure has been neglected at a most critical place, namely at the terminal ends of the stator windings. I have quite recently had to condemn such methods in connection with a 1 500-kW turbo-alternator where 3 000-volt rubber tails were in view and accessible, with the weakness pointed out by the author. The plant was supplied to comply with the Home Office Mining Regulations, but it does not under the above conditions. The question of the standardization of terminal cable-sealing boxes has been mentioned, and very rightly so. Mining electrical engineers are alive to this and have been so for the past 10 years. It is high time that manufacturers supplied such equipment as a standard for works and collieries. Ninety-nine per cent of makers of electrical motors are not alive to the requirements of Mining and Factory Regulations. Apart from the fact that the regulations call for such practice it is in the interests of safety to install plant that is electrically and mechanically efficient. Quite recently I had occasion to purchase single-phase, 440-volt motors. These were supplied with an ordinary large tumbler switch fixed to the motor case, the cover of which was not earthed, although the motors were required to be placed in a damp butcher's warehouse. The manufacturer's branch office were informed that the switch on the motor did not comply with the Factory Regulations and that they must supply the proper article. As no notice was taken of this I wrote pointing out the seriousness of supplying apparatus in this manner. The reply was to the effect that it was an oversight at the works and that I was to return the machines. I was told later, however, that the firm had sent out thousands of motors in this manner and that I was the first to complain. The author refers to the less attention and maintenance required for ironclad gear, apart from the saving in initial outlay for housing. This housing question has been overlooked in the past when switchgear costs were under consideration. For rural supply districts with small substations, the capital outlay on houses or substation buildings has to be seriously considered. I have had leakage protective devices installed on all low-tension feeders for the past 12 years, and these have proved to be highly satisfactory. At a recent meeting of the Electrical Power Engineers Association, when the subject of electric supply in Hong Kong was being discussed, special reference was made to the amount of trouble obtained with open-type gear, and it was held that the only solution would be the solid type of gear mentioned in the paper. Reference is also made in the paper to indicating and interlocking devices being conspicuously labelled, and to the advisability of coloured lamps being used. In a high-tension cubicle of the non-draw-out type recently delivered the lamps were so arranged that to replace broken or defective bulbs the alternator would have to be shut down, as the attendant had to reach across bare high-tension busbars. The system shown in Fig. 26 is to be commended. The earthing arrangement shown in Fig. 25 is also a very desirable feature, from the point of view of safety. A d.c. 550-volt switchboard which I had occasion to inspect for a colliery was supposed to comply with all the Home Office Regulations, but I was surprised to find open-type bare busbars placed on top of the board, which was in a power house where an overhead travelling crane was used. The circuit breaker and isolating link handles were not earthed, nor were the metal covers of meters.

[**Dr. C. C. Garrard** also took part in the discussion at Birmingham. The substance of his remarks will be found on page 447 in connection with the discussion before the Institution.]

Mr. A. M. Taylor (*communicated*): With regard to

the separation of phases referred to on page 430, while agreeing in the main with the author's remark that "should an internal fault occur, the arc cannot be long or sustained," and the deductions which follow, I think that this ought to be qualified by some statement as to the limitations of the power passing through. It would appear that, although perhaps no serious "burn-throughs" have been obtained up to the present between any of the conductors and bends leading into the Reyrolle type of switch, it is largely a matter of the power going through the circuit before the outer metal sheathing will be burst through with a sufficiently large hole to permit of the arc repelling itself into the surrounding space. I know of a case where single-phase voltage, backed up by only a trifling kVA capacity, burnt large holes in a paper-insulated cable in which the lead sheathing was 3 inches in diameter. In another case a large hole had been burnt in a three-core cable of some 3½ in. diameter, although the arc was smothered by being buried in the street. In the latter case it is true that there was 10 000 kVA of capacity behind the arc. What would have been the result had 50 000 kVA been behind the arc, and if there had been no surrounding earth to quench the flame? This latter case would correspond somewhat to the bends and hoods of the metal-enclosed parts of the switchgear. Subject, however, to this qualification, I believe that the author's remarks as to the advantage of enclosing each phase with a continuous metal sheathing are perfectly correct. Where it is possible for an arc to get long enough and open enough (as possibly in the case cited by the author) for sufficient resistance to be incorporated to keep the current below the operating point at which the relays are set, there would appear to be great difficulty in preventing a disaster such as that mentioned on page 430. Referring to the author's statement on page 426 that "carried to a logical conclusion, overhead lines would be replaced by underground cables," I agree that this is the ideal case, but, as he says, the cost is excessive. Two years ago I advocated a wholly underground system operating at 150 000 volts,* but I found that engineers' minds were so obsessed by the tremendous difference in cost between overhead lines and underground lines that for long transmission they condemned underground schemes offhand, being unaware that if underground transmission could be carried out in sufficient "blocks" of power, at the voltages which I proposed, and if the cables could be laid alongside the railways, there would not be so much difference between the costs of underground and overhead transmission. However, the next best thing to running the trunk transmission lines entirely underground is to run underground those parts that are in the towns, or that approach the switching stations, and to change from bare conductors to lead-covered cable at a height of not less than, say, 30 ft. above ground (i.e. on the mast itself) and to have no bare conductors entering switching buildings. This is what I am now recommending. By such arrangements the awful catastrophe by which seven men in America were burnt to death in doing switching work on the Niagara lines would be avoided—not to mention the very serious dislocation of supply which this must have entailed. The author gives on page 446 as one of the requisites for safety and continuity: "A stable neutral point at earth potential," and again he says on page 439: "Rather save . . . by connecting the neutral direct to earth." Although it is true that in America there are many installations in which, on the high-tension side of the step-up transformers, the neutral is earthed directly, I believe that, at any rate on 33 000-volt systems in this country, and with underground cables, it will not be advisable to do this. I have recently made careful investigations into the possibilities of resonance being set up in such circuits by the "triple harmonics" (left unsuppressed in spite of the delta winding of the primary) set up by the transformers themselves, where single-phase transformers are used, and I was surprised to find the exceedingly valuable damping-out effect performed by the earthing resistance. Without this, resonance effects would, on a 10 000-kVA transmission system at 33 000 volts, become quite serious when the total length of cable became much over 20 miles, and as on some big systems there are sometimes two cables in parallel (giving 20 miles of cable over a 10-mile route), I think it would be a great mistake to cut out the resistance entirely from the earthing connection. At the same time, in the particular case which I investigated, the earthing resistance was so very much higher than sufficient merely to check resonance that possibly sufficient "stability" could be provided to meet the author's suggestions substantially, without inviting the introduction of triple-frequency resonance where at present none exists. It is a matter of the careful investigation of each individual circuit and of its group of transformers, i.e. each circuit must be dealt with on its merits. (I may add that the investigation is rather involved and should not be undertaken by a tyro.) Of course these remarks will not apply to the earthing of the generating system—at any rate not to the same extent—though even here it may be inadvisable to cut out all the resistance.

* *Journal I.E.E.*, 1923, vol. 61, p. 220.

The Author's Reply to the Discussions Before the Institution and at Birmingham and Manchester.

Mr. H. W. Clothier (*in reply*): I have noted as a trend in the discussion that there is an apprehension of failure in details, which seems to promote the idea that in a power station or substation one must be able to "get at" this or that part of the apparatus. I must say that on the other hand I look to the time, arising out of the haze and endeavour of the last 30 years, when operators will no longer need to be on the constant qui vive. We shall dispose of our troubles with bad insulation, with fittings which come loose, with relays which trip when they should not, and with the hundred and one other things which have gone wrong, by the

simple and common-sense process of learning from past experience how to design in a way which will avoid defects in every minute detail. These little annoyances, trifling in themselves but far-reaching in their effect, should not in future pester and endanger that broader expansion in the utilization of electric service which should be our future aim in this country. Many of these details may be overcome by using conductors and insulators buried in compound or oil; in which case they need be no more accessible than the conductors and insulation of a well-conducted cable laid solid in the ground. I can imagine how busy those people would be who are always wanting to look at the joints on their conductors and the surfaces of their insulators, if their methods for switchgear had been allowed for transmission, and bare conductors had been laid in ducts in the ground or mounted on walls, just as they nowadays want to fix the busbars in their power stations. And yet, as I look at the issue, there is no more reason for having access to the busbars and connections thereto than to the main conductors. In fact, perfection of busbars is easier to attain, as this covers only a small part of the system, whereas any improvement of the cables must spread over the whole network. I admit that there is still room for research in the improvement of insulation and I agree that insulation failures, on certain classes of apparatus and with certain materials, may be a heavy charge on the installation. Until such research as may be possible in the future brings the art of insulation to a state of scientific perfection, my appeal is to carry a safe margin. My experience, as recorded in the paper, is that a reasonable factor of safety, such as is common in engineering construction, will give protection from insulation failure, provided that the materials are suitably preserved and kept out of the reach of any intruding foreign matter. With our present knowledge of insulators, and with a good safety factor, the industry can obtain security now, although I admit that after more extensive research it may be attained more economically. But, notwithstanding the possibilities of research, the preservation of insulation in oils and compounds, on which much experience is now available, cannot be disregarded. After all, one of the dangers is the poor and unreliable insulation provided by air, and this, I fear, no amount of research will cure.

On account of insulation failures, Mr. Wedmore has a leaning towards the duplication of circuit breakers. What one has to guard against is the interruption of supply due to such failures. I suggest that to have two circuit breakers instead of one does not reduce the risk of such failure. On the contrary, this risk is increased, as there must be more insulators, the failure of any one of which in service may result in a busbar fault. If the anticipation of failure of insulators and switches is really the controlling factor of the switchgear layout, then the best policy is to cut down the number of them and utilize the consequent saving in cost to improve the quality of those which remain. Mr. Wedmore says that duplication carries with it " simplicity of the whole scheme and its operations." Multiplicity does not generally lead to simplicity, nor does it in the case of switchgear. It may be simpler to use two oil circuit breakers to change over from one busbar to another than to draw out a circuit breaker and change over the plugs, but with all circuit breakers it is necessary to provide isolation on both sides; and so if the isolating switches also are operated there are actually more operations in changing over with duplicate circuit breakers than with a single circuit breaker and ordinary selector switches. To secure efficiency of operation by duplication, the circuit breakers should be of the draw-out type. If the advantage of the draw-out type is admitted, then the consideration arises that on the single-circuit-breaker-per-panel type of gear one spare circuit breaker in each station will serve all the purposes of duplication. It would seem that duplication is, after all, only justified as a means of substitution for a broken-down part, in which case certainly one good circuit breaker is better than two made for the same total cost, because it must reduce the risk of this part needing substitution. A failure of the circuit breaker means a shut-down of the station, or at least a section of it. In such an event the breaker can be withdrawn and replaced in a few minutes without a flurried series of operations. A failure on the connections to the breaker from the busbar also means a shut-down, and it is as likely as not to be on a conductor, which prevents the particular circuit from being put into commission immediately whether there is duplication or not.

Several speakers have referred to American practice. It does not follow that what suits American control is necessarily the right example for this country, but in connection with circuit breakers it is opportune to note from a recent Report of the American Institute that the manufacturers of oil circuit breakers are making " herculean efforts " to secure satisfactory oil circuit breakers of sufficient interrupting capacity. The elimination of the isolating-switch troubles is also being sought after. This is evident from the same Report, which continues: " in one of the newest large central stations practically no disconnecting switches are used for disconnecting the oil circuit breakers from the bus or line. The disconnection of the breakers is accomplished by lowering them below their normal position, thus breaking the connections and isolating the breakers." This practice in America is also confirmed by Mr. Davies, who states that it is perhaps the best feature of metal-clad gear.

Whilst American stations are in general larger than anything attempted yet in this country, the system of distribution by feeders starred out is possibly no more searching on the switchgear than such systems as that of the North-East Coast where many power stations having an aggregate of 300 000 kW are all linked together in one mesh of ring mains, separated only into sections after the occurrence of a serious fault. It is on this large testing ground for bringing out the weak points that the principles described in the paper have been tried out. So although agreeing, as Mr. Wedmore wisely says, that there is no finality in design, at the same time it would be an indictment of lost opportunity if something very definite and useful did not come out of the experience, something which, to say the least, will bear its mark on future practice in this country, if not in other countries also.

Several speakers have also referred to the duplication

of busbars in a way which seems to point to a misreading of the paper. Two reasons justifying the retention of duplicate busbars on switchgear in important situations, such as power stations and large distributing centres, are recorded on page 428. Maybe this misunderstanding has been brought about by the discussion of the process of changing over from one busbar to another, which is another subject. Notwithstanding Mr. Ferguson's objection, I feel that the consensus of opinion is in favour of disconnecting any circuit from the busbar before changing over from one busbar to another. Other contributors confirm that, when dealing with large amounts of power, it is not safe to attempt the rapid juggling of circuits. Nor is it at all necessary on a system that has been laid out to maintain continuity to all consumers. To effect this object any circuit may be opened at any time, as happens automatically on the occurrence of faults, without causing cessation of supply through alternative circuits.

Another general subject on which there appears on the part of some speakers to be a misreading, is the breaking capacity of circuit breakers and the interpretation of B.E.S.A. recommendations. Mr. Wedmore says that it is of very little use to split hairs on "small margins on supposed factors of safety now current." We are in sight of "formulæ established on scientific principles." The prospects of "revolutionizing designs" must be waited for with intense respect from such an authoritative statement. As one who has taken a part in helping to bring about the tests and in the supply of material for investigation, I am not permitted to discuss the outcome, but until the tests have been carried out upon a much larger scale (that is, with larger power behind the short-circuit) I cannot think that the discoveries up to the present justify the brushing aside of such vital questions as factors of safety which practical demonstrations under service conditions (often failures) have evolved in certain established designs. These are not to be shaken by merely the promises of formulæ to come.

Mr. Ratcliff draws attention to the elastic nature of statements about breaking-capacity ratings; and this, coming as the declared opinion of a large user, notwithstanding the existence for two years of the British Standard Specification, indicates a state of affairs which calls for some explanation.

Dr. Garrard fears that my approach to the subject will harm British reputation. British reputation is not made by the B.E.S.A. but by the results of the work produced under the direction of their recommendations. Dr. Garrard says that the breaking capacity of the switch must generally be in "inverse ratio to the reputation of the maker." Surely, if that be so, it is in the interest of the whole country to declare a better standard. Anyhow it should be definite. If it is to be what is known as the B.E.S.A. rating (six times the aggregate kVA), then a factor of safety of at least 200 per cent is required. If it is taken at 10 times, a factor of safety of 100 per cent is better. These safety factors would meet the worst conditions illustrated in Fig. 19. Dr. Garrard goes so far as to admit that it may be necessary to specify the power factor. It is only a step further also to state the factor of safety which is to be the objective in the design.

In the attention given to switchgear construction the discussion on protective systems has taken a secondary place. I think it has been generally admitted that a better standard of stability is required, and that on the whole it is not working in the right direction to cut down the amounts of fault-current settings. Even the sensitive systems of generator protection which once were given to operate on fault currents of 7·5 per cent of full load are admitted to be more reliable if raised to 15 per cent of full load. On feeder protective systems the working of current transformers over the point of saturation is likely to introduce difficulties in the standardization of a common design of current transformer for all purposes, including feeders with tees as shown in Fig. 28 (single switch substation). The multi-airgap current transformer having a straight-line characteristic up to 10 000 amperes, on the other hand, has prospects as a standard which will suit most conditions and situations that arise in general transmission practice.

As to voltage-surge arresters for protection against lightning and atmospheric voltage disturbances, Mr. Rosling points out that whilst insulation may stand momentary stresses, each instance may by cumulative action tend to an ultimate localized puncture, and Colonel Edgcumbe seems to confirm the opinion that it is unfair to the cable to expect it to perform a function which should be part of the switchgear's duty. The practical difficulty is to find any surge-arresting device which is capable of reducing the excess stress by any really effective proportion. The large shunting action of the cable itself is the reason for this. For adequate protection any artificial discharge resistance would have to be of such a low value that serious trouble would be experienced, in view of the heavy power current which would follow through it. The suggestion has been made that there would be undue stress at the point of juncture between the overhead line and the cable. Of course at this situation all sharp corners and small clearances must be avoided, but from the theoretical consideration of this subject the cable acts as a shunted condenser, in which case, although the voltage stresses are admittedly greater at one end than at the other, no voltage-reflection effect takes place at the point of juncture but, in fact, an actual tapering down of the surge voltage immediately commences due to the flattening effect of capacitance of the initial portion of the cable. There is no abrupt voltage-wave distortion at this point, the cable acting as an ideal condenser for this purpose. In addition to the tapered flattening effect, a cable will have, due to sheath and dielectric losses, a heavy dissipative effect on the energy of the surge. The necessary precautions are, first, to use an appropriate length of cable in order to provide sufficient capacitative shunting action, and also to ensure that any surge passes through an appreciable length of heavily damped circuit in order to prevent severe voltage reflections occurring between the line and the inductance of the plant—in most cases a length of 200 yards or so is adequate. Secondly, to ensure a sufficient safety factor in the insulation, in the cable and inside and outside the dividing box. This safety factor is in any case necessary to withstand surges which occur in normal system operations. In this connection the

duration of the atmospheric disturbance when severe stresses do occur is extremely short, whereas the stresses occasioned by normal system operations, while appreciably lower, have longer duration. To have a large cable network and to earth the neutral point through a sufficiently low resistance are the most efficient safeguards against internal voltage stresses. There may be some combination of circumstances where, as cited by Colonel Edgcumbe, an apparent improvement has been secured, but, in general, artificial surge protective apparatus can only make a small proportional reduction in the stress, whereas, on the other hand, they may themselves set up cumulative oscillations which annul any advantages to be derived from them. To avoid this, if any apparatus is used it should be of a series damping nature of the Campos, Thornton, or Grant type, rather than of a discharge nature like the horn gap, or similar device which permits a sustained discharge through a resistance. The problem of arresters, buffer charging resistances for transformers, and similar examples of extraneous apparatus which sometimes find a place, cannot be finally disposed of by this discussion, but the tenor of the discussion leads me to suggest that with a little more attention to the subject the use of them may be abandoned eventually. Such devices do not always enter the lists when the need comes for action, and on that consideration alone the true safeguard is to make plant capable of withstanding short-circuits and an adequate pressure test without risk of incipient injury or flash-over; it should then be independent of those protective devices of doubtful efficiency.

Dr. Garrard's proposal to improve cell-type switchgear by making it vermin proof, and to cover the busbars and connections with mica insulation, is certainly a step in the direction of the more complete enclosure obtained by the all metal-clad gear, but the switch houses of large power stations with cell gear, such as Hell Gate in America which he has cited as an example, have become so unwieldy as compared with the metal-clad form that it is questionable whether the practice will survive unless, indeed, Dr. Garrard can make his insulation covering so complete as to allow great reduction in the space now occupied. It is opportune here to note the comments of Mr. Gregory on this subject. Notwithstanding the extra space entailed by the duplication of circuit breakers, the recently published experiences at Calumet (also of the cell type with separation of phases in isolated parts of the building) go to show that, despite the large dimensions and apparently elaborate precautions for isolation, it is still possible for the effects of faults to spread over panels on several circuits and even from one phase building to another.

It has been stated in the discusssion that the effects of a breakdown on cell gear are more readily repaired than upon metal-clad gear. This depends, of course, upon the extent of the damage, but in any case what matters most is the time taken to get the supply restored after a breakdown. Much of the time is frequently taken in getting the maintenance engineer to the spot, which is the same in both cases. Where time is saved is in clearing away the results of the breakdown, and in the cell gear this almost invariably extends to adjacent panels which, if not actually distorted or burnt, have to be cleaned and overhauled. On the other hand the metal-clad damage is confined to one unit; and the insulators and conductors of the others, thanks to the invulnerable enclosure, remain intact and ready for continued service. Indeed, in some cases which would put the counterpart in cell gear out of service, the supply would not be interrupted at all through the metal-clad gear.

Having now dealt in a general way with the main criticisms it remains to reply to detail comments and questions.

Mr. Wedmore says that a modern motor-car or flying machine would not have been built 20 years ago, but he asks why should not the protective gear of the present day have been manufactured 20 years ago? I think it was. It was at that time that the balanced systems of protection were developed on the North-East Coast, and metal-clad designs were made only a year or so later. At that time the necessity had been realized, at least in that part of the country. The single pilot in the middle of the cable is no doubt attractive, but I fear that it would require another revolution of the balanced systems. At present the single-wire pilot would be subject to interference by induced currents, and, moreover, it has never been accepted as good practice to enclose the protecting pilot in one cable with the main conductors, because a fault on the cable might bring the high-tension voltage on to the low-tension relay system. If the pilot were used as a high-tension connection, which its insulation might justify, there would need to be a potential transformer at the ends. Potential transformers on protective gear have up to now been tabooed. The Kuyser system of generator protection has not progressed, I think, mainly on this account.

Dr. Garrard agrees with me that some form of standardization of terms is required in order to express the stability of protective gear. Mr. Leeson's comments on this subject will need to be taken into consideration. A good margin between the test-room results, or promises of performance, and the "service setting" is necessary to ensure stability under service conditions which cannot be reproduced artificially, and hence my preference for raising the fault settings. Some form of proving house also is an urgent need. The proving should include a record on the maximum "through" current possible without inadvertent operation. It is not yet clear that there are no unbalancing influences within the biased relays, or that the unbalancing in the primary circuits —for instance, during arcing earths—will not give an unexpected instability in the system of feeder protection mentioned by Dr. Garrard. This may account for the comparatively slow development of this system. The diverter relay, on the other hand, acts as a person would if given sufficient time; that is, at a stage in the magnitude of the "through" current it resets, as it were, the tripping relay, giving it greater stability. Its correctness is not dependent upon a balance between the restraining and operation currents on two different iron cores of the relays, which is additional to the balance required between the cores of two different current transformers.

Dr. Garrard's two incidents of injury to men appear to indicate some imperfect construction of interlocking

devices. To my mind the argument points to the need, not to dispense with interlocks, but to improve them.

As to internal losses in the lead-covered reactance coils, it is the practice to divide the lead sheathing into sections each of which is separately earthed. So the losses are practically resolved into I^2R losses, and owing to the smaller sections of copper which are used on the open type these losses are less on the cable type. The following is one comparison recently made in connection with an actual specification :—

33 000-volt 11 per cent 220 kVA rated reactor :—
Open type, 11 kW approx. at full load
Metal-clad type, 8·5 kW approx. at full load.

These figures are based on commercial ratings as obtained from manufacturers, and a truer comparison may be necessary by considering to what extent the copper section of the open-type reactance could be increased on the cost basis.

The "through" rating of a circuit breaker is not exactly the same as its breaking capacity. The circuit breaker should be capable of carrying the maximum current that can pass through it for a longer period than that when normally operating at its maximum breaking-capacity rating. As Mr. Ferguson suggests, the time for "through" ratings should be stated at 1 second and 5 seconds if the American practice is to be taken as a guide.

Dr. Garrard would not rely upon something which he cannot see. He fears that a closed oil switch might not be making contact. The object in the closing of the earth circuit within an oil switch is to make the earth contact in safety to the person actually making the earth. It is not to be supposed that a man would be expected to touch a cable outside before ensuring that the cable is dead by driving a pick through it or by some other such precaution.

Mr. Lovell also refers to this earthing device and suggests that it might cause a three-phase fault which might not operate the protective gear. The practice is to earth one phase at a time, in which case the amount of fault current would be limited by the resistance between the location and the neutral point.

I note the objection to the proposed vibration test on relays and agree that some more perfect example of the "jerks or shocks" to which a relay may be subjected on a switchboard is necessary. Some form of accepted standard device is required, which again would be an instrument to be used by some future Proving House. I think the complication of devices on protective systems is not due to voltage balance any more than it would under similar conditions be due to current balance. In fact the pilot-wire voltage may be higher with current balancing on long lines by reason of the voltage-drop. I question the utility of circuit breakers of 750 000 kVA breaking capacity with the "biggest possible plant," even with a liberal use of reactances, but I think that their use will depend upon the power factor at which the rating is fixed. Circuit breakers of 1 500 000 kVA rating are specified in this country where the aggregate plant is 150 000 to 200 000 kVA. In stations in the future of 600 000 kVA which are spoken of, I think Dr. Garrard's limit is likely to be on the small side.

Mr. Christianson's comments on interlocking also suggest to me that better attention should be given to this subject in the future. With the railway system of interlocking, would one countenance the temporary putting out of action of important interlocks, thereby endangering life ? I think not ; and switchgear, to be perfect, should be no less safe. He seems to hover between open cell gear (" cubicle " type) and the metal-clad, preferring, if breakdown occurs, to repair the former. He must humour the old love whilst he takes the new love home. I agree with Mr. Christianson that complete enclosure or inaccessibility is also essential on low-tension switchgear, and that the question about the design of change-over is a matter for operating engineers. In due course these subjects will settle themselves by force of general practice. It is as well that simple plans be adopted, because, contrary to Mr. Christianson's expectations, I do not find the engineers very willing to pay for the special arrangements sometimes called for by peculiar idiosyncrasies in demands. I agree that the rapid change-over features are more costly to produce, and in view of the risks involved it is to be expected that the course of events will follow the lines which are the most economical. If the rapid change-over must be made I agree with Mr. Christianson in his choice of the two-oil-circuit-breaker method. It is liberal of him to make this choice despite his own design with front plugs and the earthing features embodied therein. There is no need to separate the busbars more than shown in Fig. 10, as these are compound filled and the metal-clad enclosure is to all intents and purposes invulnerable. Therefore busbars may be close together like armoured cables on racks.

Among many other interesting statements, Mr. Christianson asks for my views on the commercial and technical feasibility of employing viscous oil for busbar chambers. I think it may be necessary to resort to oil filling for some conditions of high current values and high voltage, but compound has certain advantages which would always claim from me a preference.

I am of the opinion that notwithstanding the addition of the extra coil on the relay similar to that adopted for overload and leakage relays, there are risks in attempting settings as low as 7·5 per cent of the generator full-load current. I do not consider the risk to be worth the gain of covering a little more of the alternator winding, which, being near the earthed neutral, should never be in danger of breakdown to earth provided there is sound insulation between turns and reasonably low earthing resistances are used. The system using a coil between the starred point of the relays and a common starred point of the transformers may not be altogether free from unbalancing influences due to external phase faults, and the earth coil will be liable to operate only to a slightly less degree than the phase coils. In this connection Mr. Ross, I think, agrees with me in preferring 15 per cent with the sensitive leakage coil. With diverter relays 10 per cent gives equivalent stability.

I think that Mr. Trencham is begging the question a little when he says that the very first oil circuit breakers used in heavy power stations were of the explosion-pot type. The explosion-pot type, as the term is now understood, is that invented by Mr. Hilliard and advocated by

Mr. Bernard Price, which consists of extra pots surrounding the contacts and contained within another oil chamber in the form of the ordinary switch tank. The first large power station in this country to use oil circuit breakers was Deptford, and the second was Bankside and in these cases the pots were of glass and porcelain respectively. The well-known American General Electric switches were a later introduction, and they have undoubtedly given excellent service on cell-type switchgear. The object of this type is to retain the oil within the pot, but in the type referred to in the paper the pots are used to generate a pressure within, which assists to expel the plunger at a high velocity through a clearing hole at the bottom. I admit that the arc is started within the pots in both cases, but in other respects it seems to me that in construction and principle of action the two methods are separable in classification. I agree with Mr. Trencham that additional variables must not be introduced into the standard rating of circuit breakers. My whole desire is to have a standard based upon invariable quantities that will be understood. This is not a confusion with selection but a fundamental matter of measurement.

The points of Mr. Ferguson's valuable contribution are of three kinds: he agrees, he disagrees, and he misinterprets. He agrees with all the main principles; in fact, his entry into the production of metal-clad switchgear during the last few years has contributed not a little to the present prominence of the metal-clad principle. The points in which he disagrees relate chiefly to constructional details. These include compound-filled transformer enclosures and busbar change-over plugs. His innovation just put into use includes the immersion of these parts in oil, a practice which in one form or another has been applied for several years. One design embodying both these features is actually shown in the paper (Figs. 7 and 25), but there must be discrimination in such details, and in the majority of cases for ordinary service the simpler forms shown in Figs. 4 and 8 adequately meet the requirements. As a general rule compound filling is to be preferred; it dispenses with the possibilities of oil leakage, and the explosion and fire risks are less; moreover, the compound gives a support to busbars and other conductors, helping them to withstand the large stresses on "through" short-circuits referred to by Mr. Ferguson. He expects, in the event of a busbar breakdown, to change over automatically from one busbar to another in 0·8 second by the use of duplicate oil-switch movements. I think it would be a surprising achievement in a large power station (and even without a "separate coupler" to parallel the busbars first) to change over the generators and the load in this time. I suggest that operating engineers in the power station and switch house would not view this project with equanimity. I think they would be happier to know that the effort was being directed towards so making the switchgear that busbar faults do not happen necessitating this rapid change-over.

The general objection to duplication of oil switches which is discussed above, applies here also with the added disadvantage in Mr. Ferguson's arrangement that the connections from both busbars are brought down into one common circuit-breaking chamber. The dangers of this method are also discussed by Mr. Davies and Mr. Mold, with both of whom I agree on this point. Other contributors to the discussion on this question have referred to serious accidents in changing over and seem to confirm the opinion expressed in the paper that, for ordinary service, it is preferable to rack out the circuit breakers and incidentally to make sure that there are no hasty operations in effecting a change-over. The alternative is to have entirely separate circuit breakers. The question is: does the need justify the expense? I suggest that the consensus of opinion is to be found in Mr. Davies's statement that 90 per cent of the supply undertakings would accept the simple plan which, in Mr. Ferguson's judgment, is the "crudest method imaginable." Mr. Ferguson refers to a statement of an operating engineer at Stepney and a discussion at Sheffield. The fact is that in both these places the arrangement (Fig. 8) has been in use for about 15 years and all extensions, including recent ones, have contained the same principle. It is strange that the first intimation of any dissatisfaction should come to me from Mr. Ferguson. True, as also emphasized by other speakers, including Mr. Townley, the operating engineers' experiences must have first consideration. The need for efficiency includes the reduction of the number of operations to a minimum, and that would seem to be an explanation of the existence and development on a very large scale of the simpler plan. If the change-over had to be frequently made, the alternative of duplicate oil switches would be more necessary, but in most places where the layout permits of opening any circuit as required, the spare busbar on metal-clad gear is rarely, if ever, used. Certainly in the case of Sheffield the spare busbar has only been used twice since 1913—both times for extension purposes. It has been frequently demonstrated that a circuit can be changed over in less than 3 minutes, which is the routine period at Sheffield to wait before reclosing a breaker after opening on a fault. The idea of needing rapid change-over devices is a relic of the days before alternators were run in synchronism. As to Fig. 28, the fuse is suitable protection for the transformer if properly enclosed. In the event of the fuse failing and itself developing into a fault upon the link, it is cleared by the action of discriminating protection and the circuit breakers at both ends of the line.

Among the items which have been misread, Mr. Ferguson, in common with other speakers, takes the paper to infer that duplicate busbars should be dispensed with in a central station scheme. The paper shows duplicate busbars in all such cases and even gives two reasons (items 1 and 2, page 428) for their retention on metal-clad gear. The main inference in respect to busbars is that it is necessary to remove the risks attending the change-over from one busbar to another and that, by suitable layout of equipment and safety factor in design, the need for the frequent trial of this risky operation can be eliminated. They are seldom included in general practice on substations, which is in favour of the simpler sectioning of busbars. Mr. Ferguson also appears to read into my paper a proposal to cut out the use of reactances altogether, whereas the paper merely draws

attention to the necessity of exercising care in determining the values and location of reactances. Moreover, the paper does not propose to neglect to take external reactance " into account in calculating the short-circuit current."

The suggestion in selecting the rating of circuit breakers is not the method which obtained 10 to 12 years ago. The rating as defined at present is accepted, but with the addition of a standard of quantity which at present is missing in regard to both power factor and factor of safety. Stability of the neutral point is best secured by " dead earthing " the neutral, but this is only recommended in the paper as being preferable to using a resistance which is too small. The compromise is, as recommended in the paper, an earthing resistance which will allow twice the full-load current of the generating plant to pass through it. The forces given as the loading of busbars at the peak of the short-circuit current appear to be high, but in the absence of a standard understanding as to the meaning of the size of plant corresponding to a 750 000 kVA breaker, it is difficult to check Mr. Ferguson's figures. If the circuit breakers are rated on B.E.S.A. recommendations, the plant would have an aggregate capacity of one-sixth; that is, it would be 125 000 kVA with 10 per cent internal reactance, or, say, 250 000 kVA with 10 per cent additional reactance. The corresponding short-circuit at the maximum of the transient would then be 2 500 000 kVA, and I suggest that in stations like this a 1 500 000-kVA circuit breaker would be more suitable. It is stated in the paper that a generator circuit with more inductance than 10 per cent internal reactance may require on short-circuit greater breaking capacity that that recommended in the same clause as a standard (page 434). Mr. Ferguson does not agree with this on the ground that an addition of 10 per cent external reactance will only alter the phase angle of the short-circuit current by about 3 degrees. This may be perfectly correct, and a difference of 3 degrees does not materially increase the arc energy, but there may be circumstances in the layout of reactance where the added external reactance amounts to very much more than 10 per cent, and it is in such cases that an adjustment in the switch rating would be necessary in order to compensate for the added arc energy due to very bad power factor, as there is evidence to show that beyond 85 degrees the arc energy increases very heavily. On the other hand the arc energy of a circuit of 45 degrees would appear to be about $33\frac{1}{3}$ per cent less. As recommended in the paper, it is of importance that the relationship between the arc energy and the power factor shall be accurately determined and taken into account when selecting the suitable rating of circuit breakers for their relative positions on the system, having regard to the natural and added artificial reactance in circuit. This, I think, also replies to Mr. Christianson's question, in which he says it is not clear to him that the plant output and reactance on short-circuit has anything to do with the ability of a given circuit breaker to rupture any stated power in kilovolt-amperes or kilowatts. The fact that it is not clear to Mr. Christianson shows that the full effects of artificial reactance require further elucidation by the collation and publication of research data on the subject. In one experience the addition of 30 per cent reactance to a short-circuit proved that a switch, which had a breaking capacity more than sufficient for the short-circuit without the reactance, showed distinct signs of distress on the same circuit with added reactance, although the current was proportionately reduced.

It is gratifying to find that Mr. Ratcliff is in the main in agreement with the views expressed in the paper. His experience on a high-voltage cable system is unique and of extreme importance to the art of protection. I think that his explanation of the use of reactances, not so much for permitting the use of switches having smaller breaking capacities as for preventing enormous concentration of energy, is particularly apt. I am sorry, however, that his experience with cables leads him to prefer the open type of reactance. Possibly this is a correct view for reactances on 33 000-volt systems at the present time, but when cables at this voltage have the same standard of reliability as 6 000–20 000-volt cables, then I hope he will revise his opinion. The metal-clad reactances are in use at the lower voltages and, as stated above in reply to Dr. Garrard, the losses need be no greater than with the open type.

The hazards of compound-filled busbar chambers are less than the counterpart of cellular gear, and the risks of short-circuits are correspondingly less, as there can be no interference with the insulation once the chambers have been filled in. On the other hand, if the remote possibility of a short-circuit did happen, the damage would be restricted to the particular chamber, whereas the experience with open-type conductors as recorded by other speakers is that the trouble almost invariably spreads from panel to panel, usually with disastrous results to the structure and causing extended discontinuity of supply. It must be remembered that the long arcs on short-circuits cannot be maintained on metal-clad gear owing to the comparatively close proximity of the conductors and earthed metal, and whilst there are many instances on record of serious explosions destroying switchgear buildings which have contained open-type switchgear, there are none known to have occurred to buildings enclosing metal-clad gear, nor is there any instance on record to my knowledge where injury has been done to adjacent panels. In the comparison of busbar design with cables it must be borne in mind that the clearances allowed in the case of the busbar permit a considerably larger margin of safety on insulation, and so there is every reason to expect that metal-clad busbars will be immune from breakdown. Hence, although busbar protection is by no means impossible, it has rarely been considered necessary.

I think it is hardly safe to depend upon the charging resistances in switches to protect the end turns of machine stator windings, as, although the charging resistance does reduce the heavy current transient on switching-in at or near zero voltage, it must be borne in mind that the abnormal stress may also occur at other times than on closing the stator circuit by its own switch. However, the consensus of opinion appears to be in agreement with Mr. Ratcliff, that charging resistances are desirable

in certain cases for machines on account of the moral effect of quietness in starting up. It is useful to record here that on the North-East Coast they are not used for switching-in static transformers, preference being given to suitable bracing of the transformer windings to enable them to withstand the heavy current transient stresses to which they are sometimes subjected. These stresses in any case are less than they must be capable of withstanding under "through" short-circuit conditions. Whilst the single-turn type of current transformer may be unreliable for protective gear of the balanced-current type, it is worthy of note that the converse is the case on voltage-balance systems of protection.

The point to note in regard to Mr. Ratcliff's remarks about discrimination by means of relays possessing different time characteristics in the diverter system is that the time difference is merely that obtained by reducing the inertia of a high-speed relay, the time difference of 0·05 second being all that is necessary, and being secured by speeding up the diverter relay to operate in 0·015 second. The operating mechanism of the switch acting under the smallest fault condition commences in 0·065 second, and still retains what has been called instantaneous action, which, though not strictly correct, is sufficiently so for practical purposes. It will be seen that there is a safety factor between the operation of these relays of 4 to 1, which is a security for stability.

I am glad to see that Mr. Ross supports my views on protective gear, particularly with respect to earthing-resistance values and the use of inertia to form, as it were, anti-surge relays. No trouble is experienced in balancing protective gear transformers when in their chambers, provided adequate clearances are allowed. I agree that it is desirable to open the field switch by means of the relay whether under fault condition or by hand, but the alternator manufacturers usually object to the latter as routine testing, on the ground that the rotor is unnecessarily stressed. Equivalent tests are obtained by means of the emergency switch or the relay after the turbine is tripped on the steam side.

Mr. Davies asks for a record of troubles in metal-clad gear. Most experience has been obtained in mechanical failures where the short-circuit kVA of the system has outgrown the original breaking capacity of the circuit breaker. In such cases faults have proved the necessity for stronger mechanical construction, which has led to the use of steel tanks and top plates securely bolted together. The failures through insulation are insignificant and have usually been traced to definite causes. The salient features are the localization of damage to the chamber in which the fault occurs. The suggestion that the horizontal break shown in Fig. 7 may be dangerous, in that the arc can be blown above the oil, is erroneous. The actual break takes place in the centre of the tank and under an ample head of oil (20 in.). The figure is diagrammatic and is perhaps misleading in this respect. Further, too great a head of oil may not be advantageous.

I agree with Mr. Davies as to the advantages of co-operation between supply undertakings and manufacturers. The only safe and sure way of arriving at a suitable short-circuit kVA-rating for a circuit breaker is from performances under actual service conditions, and I have always relied upon ratings obtained in this way in preference to purely theoretical considerations. As previously referred to, it is this experience with breaking-capacity performance that has led up to the comments and recommendations given in the paper for selecting a circuit breaker the performance of which will be perfectly satisfactory, both on the average and on the rare occasion. It is not always fully appreciated that British Standard Specifications refer to minimum values, and Fig. 10 was intended to show how only the easy case has been legislated for. I think that Mr. Davies is advocating a very dangerous policy if he relies upon any special design of movable contact to provide the necessary rigidity for the stationary contacts by forming a "lock" between their extremities. In the first place, I fail to see how this so-called "lock" is intended to be produced except in the form of a friction grip between the surfaces of the brushes and contact blocks. This merely constitutes a restraint, which can hardly be likened to a "lock." In any case, such a restraint will only be present during "through" short-circuits, and as it is equally important to make the stationary contacts immune from mechanical damage when the switch is opening under a short-circuit, I prefer to make these portions inherently strong enough to withstand the stresses to which they are subjected. In situations where insulation might be liable to possible surface damage by burning, certain advantages are offered by the use of a vitreous material such as porcelain. The risk of cracking during compound-filling can be eliminated if precautions are taken to prevent any appreciable difference in temperature between the two materials. I agree that a high-pressure test is not the best means of determining whether cracks are present, and I prefer to adopt alternative means. I presume that Mr. Davies refers to bakelized paper insulation, and this certainly has its own sphere of usefulness. One of its chief advantages lies in the control of the dielectric stress by means of condenser layers, and I have found its use in this way to be most effective, especially on the higher voltages. Although it is very easy to provide separate accommodation for potential transformers and fuses, the chief reason for not doing so is one of economics. I think that it is better to spend the money on the construction of a sounder and more robust potential transformer and embody it in the isolator chamber which is of liberal dimensions, as this makes for simplicity in the equipment. A further distinct advantage is that by using single-phase transformers, interconnection between phases is avoided, thus providing maximum security. Experience up to date does not record a single failure of a potential transformer mounted in enclosures as depicted in Fig. 7. This, I think, justifies the policy advocated and I have found it meets with general approval.

I note Mr. Hall's general agreement with metal-clad principles, but he apparently prefers the half-way measure excluding compound filling. I think that this is permissible in the smaller ratings and for low voltages, provided the clearances are suitably adjusted.

In reply to Mr. Bannister, I do not recognize any limitations for metal-clad gear for voltages above

35 000, but we are dependent upon the further development of high-voltage cable design and I do not anticipate that any difficulties will arise in providing satisfactory metal-clad designs for any voltage. I do not agree that air is necessarily a cheap form of insulation, as it has variable characteristics which entail large margins on the necessary clearances in order to cover the hazards which it introduces in comparison with solid dielectrics. With reference to phase-to-phase faults occurring in separated-phase types of construction, the possibility of simultaneous earth faults occurring should not be overlooked. Reference has already been made to this in my reply to Dr. Garrard. Breaking capacity also has already been dealt with. With reference to the replacement of fuses in wet weather, the lid is not kept open for any length of time, and light building constructions have been used over the fuses. Something in the nature of an umbrella is really all that is required on the few occasions when it may be necessary to open the lid in heavy rain.

I agree with Mr. Mellonie as to the importance of stability in the design of potential transformers and fuses, and would strongly support his recommendation for minimum sections of fuse wires and windings. The potential transformer, however, has seldom been used on protective systems and never on the balanced systems of protection, and although trouble with such a transformer is annoying it does not endanger the continuity of supply, provided it is correctly used. Its failure does not endanger the operators and hence it has not been given in the paper the same importance as current transformers. I agree with Mr. Mellonie's objection to the use of carbon-composition resistances. Attempts have been made, and are likely to be very successful, to combine the required resistance with the fuse itself, thus obviating the introduction of any additional piece of apparatus into the potential-transformer circuit. The problem is to use a fuse wire sufficiently liberally rated to avoid risk of injury due to mechanical weakness, and when this size and strength is obtained the fuse on the high-tension side of the potential transformer must not be expected to do more than clear faults on the high-tension winding—in other words, to protect the system from the transformer rather than to protect the transformer itself from overloads or short-circuits on the secondary. It is certainly of primary importance for all trip coils to be rated with a good safety factor. The no-volt trip-coil feature, however, is one which has not made for reliability of supply. On the other hand, the principal objection is the risk of it causing inadvertent tripping. This consideration would not lead one to expect much from an extended use of no-volt coils arranged to be open-circuited by relays on the several protective systems. The inadvertent operation of switches is sometimes more to be feared than the failure of a switch to trip when it ought to trip, and Mr. Mellonie's virtue in exposing failures might become irksome. Adequate periodic inspection of tripping mechanisms is advocated in preference.

Mr. Forrest's remarks are of great interest to me and I have already dealt with his criticisms relating to the duplication of circuit breakers. The adequate protection of circuit breakers which are unable to deal with fault currents owing to the increase in generating plant is a problem with which we are frequently faced, and the use of reactance in these circuits must be controlled to a large extent by local conditions. It is often preferable and more economical to replace the switchgear, utilizing the old gear in a more remote situation, on account of difficulties in voltage regulation. Experience has now taught us to allow a more reasonable margin in breaking capacity when determining the size of breakers for a new situation than was the case 10 to 15 years ago. Much attention has been given to the important problem of determining the most efficient speed of break in a circuit breaker. As Dr. Garrard mentioned, it is the subject of research at the present time and is one of those points on which further elucidation is pending. In the meantime, economic limits giving satisfactory results in practical service may be taken as between 5 and 10 feet per second.

Mr. Wilson would be treading on insecure ground in relying too much upon the ultra-sensitive setting of

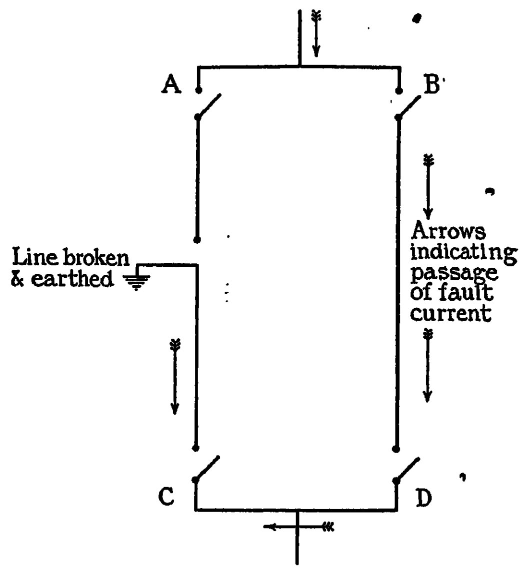

FIG. C.

relays. He makes no mention of how his light settings would behave on transformer protection, for instance, where a heavy magnetizing current-rush must be dealt with. Moreover, his advocacy of light fault-settings is contrary to his preference for parallel-feeder systems of protection, in which the fault-settings must exceed the normal load currents in order to prevent inadvertent operating of a switch at one end when opening by hand a circuit breaker at the other; and, even so, there are incidents in parallel-feeder protection where the sound cable is cut out instead of the faulty one. For example, in the event of an open circuit making a fault to earth on one side of the break only, as shown in Fig. C, the fault current will pass down the healthy line and switch B will trip out, leaving A closed, thus isolating the sound feeder and leaving the unearthed end of the faulty line alive. Mr. Wilson disapproves of using two existing cables on one split-conductor switch, on the ground that it involves the waste of an entire cable. This alleged

waste only appertains when one of the cables has broken down, in which case it is out of service anyhow. In those cases where there is no suitable alternative supply the sound line may still be used by the addition of isolating switches on each cable and the substitution of the split-conductor protection by a heavy overload setting.

Mr. Jones endorses the main points of the paper, and it must be admitted that the effect of the demands for safety in mines has had an all-important bearing upon the general improvement in switchgear construction throughout the whole electric supply industry, and it is opportune that one having so much practical experience should emphasize some of the significant exceptions which have come to his notice.

Mr. Taylor also refers to the possibility of an arc burning through the metal sheathing of switchgear, in accordance with his experience on cables. This point has already been touched upon. In the first place, owing to the elimination of foreign interference, the metal enclosure reduces the risk of internal failure. In the second place, the framework of the switchgear being of metal must make a good earth; and if it were possible for the arc to be maintained to earth there is very little risk of it not carrying sufficient current to operate some neighbouring overload release and thereby isolate the affected area. And thirdly, the metal enclosure of neighbouring sections of the gear renders it practically immune from injury, so that the fault is localized. Mr. Taylor's investigation into the use of metal-covered cables for very high-voltage service is on a par with the developments now proceeding on switchgear for corresponding voltages. His experiences also in regard to the damping effects of earthing resistances must have a bearing on the future policy, and I am glad he confirms that the damping effect will not be impaired by using the comparatively low ohmic value of the earthing resistances which are required to improve the stability of the neutral point and the protective gear.

In conclusion, it is gratifying to notice the marked change which has come about in the general acceptance of the metal-clad principles, particularly in the discussions at the Local Centres. My thanks are accorded to many speakers who have been kind enough to attribute this to my own personal endeavours, which after long years of opposition have actually led the principal opponents to acquire for themselves designs of the same type. However, it would be more correct to attribute it to a school of engineers, including users, who have from time to time furnished the results of experiences and designs and thus created the demands which have built up the practice at present characteristic in the largest power station equipment in this country.

DISCUSSION ON

"AUTOMATIC AND SEMI-AUTOMATIC MERCURY-VAPOUR RECTIFIER SUBSTATIONS."*

WESTERN CENTRE, AT CARDIFF, 1 DECEMBER, 1924.

Mr. J. W. Burr: After reading the paper, I am more than ever convinced of the desirability of the 50-period supply. All the author's troubles seem to arise from the fact that the supply in parts of his area is at 25 periods. There seems to be no difficulty in dealing with the distribution problems by means of static transformers. If, for any reason, there is a bad voltage-drop on a line running out from the substation, there is no difficulty in installing an automatic voltage regulator near the desired point to suit the particular drop. In regard to traction supply, I have yet to be convinced that it is desirable to install mercury rectifiers instead of an automatic rotary-converter substation. The author's substation appears to be very large. At Swansea the substations are about 20 ft. square, and by means of static transformers we are able to supply a demand at any individual substation up to 500 kW. Compared with the author's substations, this means a considerable saving.

Mr. W. J. Bache: Do the bulbs give any indication that they are approaching the end of their life? With regard to the provision of spares, I gather that it would be only necessary to have one set, instead of having a complete stand-by as in the case, say, of a 500-kW rotary substation. Where a severe short-circuit in a traction substation shuts down the whole of the plant, there are eight bulbs to start up again, and the first bulb switched in will be severely overloaded. How does the automatic plant bring the whole of the bulbs into operation?

Mr. A. J. Newman: Has the author had any experience with rectifiers used for conversion to direct current for purposes requiring wide variations of speed and possibly inching, such as dock crane work, cigarette-making machinery, and printing processes? With the general acceptance of the three-phase system as a standard for distribution, such experience would be extremely useful and would provide a happy solution to many problems often met with by a supply engineer.

Mr. F. Ellis: Can the author give the approximate cost per kilowatt of installation as against the ordinary

* Paper by Mr. G. Rogers (see page 157).

static substation, and state how the transformer losses compare? Does the mercury-vapour bulb give what might be called a direct or unidirectional current? I should be glad if the author would detail the cycle of operations taking place in the bulb from the a.c. side to the d.c. side.

Mr. W. A. Chamen: Mr. Burr has attributed the troubles experienced at Birmingham to the use of 25-period current, but I think that they were due to the use of direct current. It all depends upon the way the matter is looked at. Reference has been made to the springing up of residential districts in the Birmingham area. We have had a few such districts to deal with in South Wales, but our method of tackling the problem has been different. Many thousands of houses are lighted by current at 25 periods and I have lived for six or seven years in such a house. It is impossible to discover any flicker at all from 60-watt lamps used out of doors for street lighting. The system described in the paper might be usefully applied to places in South Wales where a direct-current supply exists and where a bulk supply might be required from 25-period current.

Mr. J. B. Higham: In Fig. 6 the 276-kW boosting-plant power-factor curve remains well above 90 per cent from quarter load to full load, while in the other two curves, for 92-kW and 660-kW lighting and traction plants respectively, it rises sharply to 90 per cent at about half load, afterwards following approximately the 276-kW boosting-plant curve. Is there any particular explanation for this? What purpose does the choke coil serve in the low-tension anode circuit? The flickering of lights on 25 periods can be considerably reduced by adopting the right type of shade or reflector for the particular lamp, or lamps, employed. Where direct lighting is employed the effect is particularly noticeable unless correct and scientific shades are fitted.

Mr. T. H. Haigh: Has the author given a 25-period supply to any of the Birmingham consumers without first informing them of the periodicity? My house has been supplied for 11 years with 25-period current, and I have not noticed any flickering; only ordinary common-sense shades, such as would be used on any good lighting scheme, were employed. The company with which I am connected has many thousands of consumers on the 25-period supply and has never had a complaint from them. Possibly they did not know that the 25-period system was being used.

Mr. C. T. Allan: I have had an even longer experience than Mr. Haigh of lighting at 25 periods and I have suffered no inconvenience. A case came to my knowledge of a local authority's 50-period supply being changed over to 25 periods without the consumers being aware of the change.

Mr. W. Nairn: I have no fault to find with 25-period lighting, provided the voltage is normal and that a little special attention is paid to the shades. As regards domestic appliances such as vacuum cleaners, cookers and radiators, a frequency of 25 is quite satisfactory. With regard to traction supply, I am rather doubtful about the desirability of using the automatic reclosing circuit breaker described by the author. In the event of a trolley wire falling to the ground, it is not desirable to have the supply restored immediately the wires are picked up. Probably the linesmen have instructions to open the feeder switch at the line end before handling the wire, but this means two sets of regulations on a matter which affects the safety of the public.

[The author's reply will be found on page 478.]

North-Eastern Centre, at Newcastle, 12 January, 1925.

Mr. L. C. Benton: The author's decision as given in the opening paragraph is correct, and I would go even further and say that in almost all cases where direct current is required, automatic converting plant is the best solution. He adds that "it is possible to carry automatic control to any extent," and in my opinion the increasing need for economy and greater reliability, in addition to the labour problem, will eventually result in not only the conversion but distribution and even, to a large extent, the generation of electricity being automatically controlled. The pioneer work on rectifiers carried out in Birmingham is only fully appreciated after visiting the substations referred to in the paper. The glass-bulb rectifiers in particular have a most unmechanical appearance and their operation with the peculiar coloured arc is both fascinating and weird. I consider that the author has made a good case under certain conditions for small-capacity rectifiers up to, say, 200 kW. No doubt there is a future, greater than is now realized, for rectifiers even of large capacity, as existing troubles will be eliminated as time goes on. Knowing the difficulties that other users of rectifiers have experienced, one wonders to what extent the success at Birmingham is the result of the very thorough manner in which the problem has been tackled. The author refers to the first automatic rotary converter substation in this country, which was installed at Liverpool some $2\frac{1}{2}$ years ago and which has been an unqualified success. An indication of the strides in automatic converting plant already made in this country is the decision of one of the London underground railways to install, in connection with a new extension, a remotely controlled rotary converter substation of 4 500 kW capacity with automatic gear control. Referring to the estimates given in the appendixes to the paper, I am strongly of the opinion that the figures given for rotary converters are excessive and that for capacities of 500 kW and upwards actual costs are decidedly unfavourable to rectifiers. The annual maintenance allowance given for bulbs seems to indicate frequent renewals and is many times the maintenance costs of rotary converters. Many rectifiers have been installed on the Continent; this is perhaps partly due to the less reluctance of the Continental engineer to use complicated and fragile apparatus. As no reference is made in the paper to interference with telephone circuits by rectified current, I should like to ask the

author if he has had any trouble of this kind and, if so, what steps have been found necessary to eliminate what can be a very disturbing influence. In view of the characteristics of rectifiers, is it possible to arrange for satisfactory parallel operation with rotary converters, especially if the latter be compound-wound? It is not possible to obtain power factor improvement with rectifiers as with rotary converters. "Forming" of the anodes is said to be essential. This is really a "warming up" process and yet excessive temperature is fatal, as evidenced by the need for continuous cooling by water or a fan in the iron and glass types respectively. What is the temperature of the anodes during normal operation, and what are the gases that have to be driven off during the "forming" process, or the impurities in the anodes that give rise to the gases which cause flash-overs? The author mentions that as the result of experience it has been found necessary to use reverse-current protection when bulbs are running in parallel, to avoid the flashing-over of one bulb causing a similar failure in the other. Is he satisfied that the speed of operation of the circuit breaker is high enough to give the desired protection? From the appearance of certain bulbs when in service it would seem possible that they might eventually "mirror" sufficiently to cause a flash-over. Has the author known this to happen, and, if so, what is the remedy? I have heard that there is a risk of failure if a bulb is thrown on to full load when first installed. Does this mean that a certain amount of "forming" is desirable with the bulb type? Can the author say what the life of a bulb operating at, say, full load would be in the event of the cooling fan failing? As I understand that flash-overs are usually the result of loss of vacuum, what effect has a failing vacuum on the efficiency of a rectifier? While describing the method of operation of automatic rectifiers the author remarked on the simplicity of the necessary gear. Whilst admitting that the absence of synchronizing apparatus is a good feature of rectifiers, I suggest that the automatic starting gear for rotary converters is also simple. It is the devices subsequently found necessary to add to give protection against service emergencies that cause the comparative complications. From the author's remarks it is evident that experience of rectifiers under load conditions has resulted in a gradual addition to the devices considered essential, and when one remembers the cooling arrangements, vacuum pumps and gauge, motor-generator set for striking the arc, no-load resistance and so on, one will realize that rectifiers require many accessories.

Mr. R. D. Spurr: We must not forget that Birmingham is handicapped by having a three-phase 25-period supply and cannot develop 4-wire a.c. distribution in outlying districts in the same manner that other places with three-phase 50-period supplies are doing. I do not agree with the author that direct current has distinct advantages over alternating current for domestic supplies and cooking, and although there are undoubtedly special cases where d.c. power is more suitable there are also cases where a.c. power is wanted when only direct current is available. The d.c. networks described are very small and we are told that, as the load increases, the rectifier substations are to be enlarged in size and increased in number. It is generally agreed that we are at present only touching the fringe of the domestic load in this country; it is also agreed that it takes quite a large number of domestic consumers to make up a 40 or 50 kW demand, but the scheme outlined in the paper does not appear to allow for future additions of any great magnitude before it becomes saddled with an unwieldy number of small converting units. The proposed subdivision of converting plant almost approaches the old house-to-house system of a.c. distribution which has gradually been displaced by larger and more efficient substations. I think that in estimate No. (2) of Appendix 2 for a manually-operated substation the cost of e.h.t. feeders and four low-tension feeders is excessive; if it is correct then an omission has been made in estimate No. (3). I cannot visualize the two estimates as affording equal facilities for handling equal loads, unless there are some local conditions very much in favour of estimate No. (3), and if so some allowance should be made or further explanation given.

Mr. T. Carter: What would otherwise have been a serious disadvantage to consumers of current for lighting in the author's area has been turned into a real advantage by the rectification of the current. To me the fluctuations in the light, even at the 40 periods of this district, are sometimes very noticeable, and at 25 periods I am told, although I have not had personal experience, that the effect is often really very trying. By means of rectifiers, the current supplied to consumers in and around Birmingham is a slightly pulsating one with a frequency of 150 per second, and the lighting must be very pleasing. Something has been said by previous speakers to throw doubt on the wisdom of putting down comparatively small substations; but, after all, it is what the consumer has to pay that makes the supply attractive or the reverse, and I should like very much to know what charge is made for lighting current and current for domestic use generally in the districts served by the rectifier substations. It would be interesting to compare it, for example, with the charges here, where the flat rate is 6d. per unit plus a meter rent. We have a special tariff also, under which, it is said, the charge is 1d. per unit for electricity; but I understand that this tariff includes some extras, and it is necessary to ascertain what the amount of the extras is before the real cost to the consumer is known. It is easier, therefore, to compare flat rates, and I hope that the author will give us some information on the subject.

Mr. H. W. Clothier: Where two or more rectifiers are employed in parallel, as shown in Fig. 9, four separate high-tension panels are used for each rectifier set. The size of these circuit breakers will be determined by the kVA to be dealt with during a short-circuit at the point in question, and, in a case like Birmingham, the switchgear for dealing effectively with this may be somewhat expensive. Would it not be possible to parallel the transformers and effect an economy by reducing the number of panels required? The paper is very useful in demonstrating the extent to which switchgear problems enter into modern systems of

supply. Whether a.c. or d.c. distribution is the more economical or advantageous system to adopt, time must determine whether the mercury-vapour rectifier is really more economical in the long run than the alternative rotating plant. The author emphasizes the simplicity of his static equipment. Whilst agreeing with him, I suggest that the automatic control apparatus for a motor converter can be made no more complicated, even when including all the relays necessary for fully automatic working, together with a discriminating system of locking out and reporting back to a central control station. The complication depends upon the function required; for instance, some motor-converter equipments provide for complete manual and semi-automatic operation of the plant, when so desired. The main item inherent in the two types of plant seems to be that the automatic synchronizing and starting equipment of the motor converter has its counterpart in the rocking and arc-striking equipment of the valves. The relays and general automatic gear on the control board are much the same. The author states that valves may flash over on an overload. How do they behave in the event of a short-circuit ?

[The author's reply will be found on page 478.]

SCOTTISH CENTRE, AT EDINBURGH, 13 JANUARY, 1925.

Mr. C. W. Marshall: In the summary of the paper, the author stresses the value of the rectifier as a d.c. feeder booster, which I believe to be its most successful application to power supply systems. He shows that as an economic proposition, the scheme followed by Birmingham is better than that of increasing the d.c.

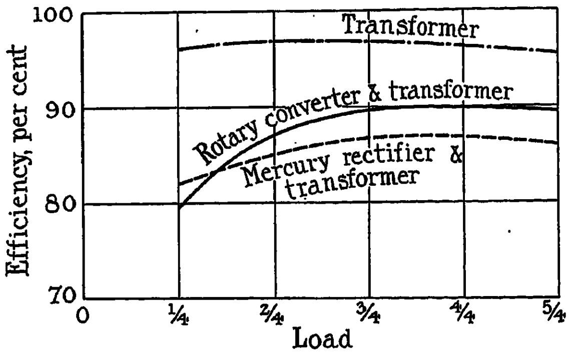

FIG. A.—Comparative efficiences of small rotary converters and mercury rectifiers with step-down transformers (5 000 volts a.c. to 440 volts d.c.).

low-tension copper, or of laying down large rotary-converter stations. He is, however, discreetly silent on the relative costs of low-tension a.c. systems and d.c. systems. There is always the possibility that some epoch-making invention will restore direct current to favour, and we must take the risk of that eventuality occurring. It is, however, a much simpler and cheaper matter to change from alternating to direct current than the converse. The steel-cylinder rectifier has not given very great satisfaction in this country, but on the Continent it has done very well, and both the A.E.G. and Siemens-Schuckert have developed steel-cylinder rectifiers for large outputs. It is significant, however, that both of these firms have adopted the glass-bulb rectifier for the capacities which Birmingham has standardized. The author has not made an exact comparison between the 92-kW rectifier and the rotary converter of corresponding size. As a matter of interest I took out some costs and figures for the corresponding small rotary converter, and I am satisfied that these would approach very near to those for the rectifier under the conditions existing at Birmingham. The efficiency is at least 4 per cent better at full load, and is as good at quarter load (see Fig. A). The price is about 5 per cent less, and the advantages of the rotary converter in overload capacity and in power factor are very marked. The main claim of Birmingham on behalf of direct current is that battery stand-by can be provided. I feel sure, however, that a purely a.c. system is more reliable than a d.c. one, even when there are batteries to fall back on in emergency. The standard economic argument (or apology) for direct current is that the percentage increase in capital required is so small that it is not worth serious consideration. This item should, however, be considered in conjunction with the following consequential increases in expenditure: Increased staff, maintenance and building charges on converting plant; decreased conversion efficiency; and increased initial and maintenance cost of meters.

Mr. E. Seddon: The application of the type of rectifier described in the paper is, of course, specially suited to stations operating at low frequency. The tramway supply referred to is of special interest, as this rectifier is an attractive proposition on the higher frequencies for such purposes; but the cost would, I think, operate against the rectifier for heavy traffic conditions requiring a large amount of power. It is of interest to me to know that the bulb lasts so long as 8 000 hours; I was of the opinion that the average life was very much less than this. In large power stations the installation of turbo-driven a.c. generators is now standard practice, and in consequence of this the extension to d.c. distribution has been curtailed. The universal application of electricity for all purposes makes it incumbent on the engineer to reduce the cost of production as far as possible, and in this respect the losses incurred in transmission and conversion are serious factors. In Edinburgh the transmission, conversion and distribution losses amount to 16 per cent of the total output to feeders, and about 75 per cent of the total output is converted to direct current. If we are to extend the d.c. system, we must find something which will be as efficient and reliable as the static transformer. Where the energy is generated at 50 periods per second, a.c. distribution, in my opinion, has no equal for cheapness and flexibility.

Mr. A. P. Robertson: I think that for traction the system advocated by the author has possibly some advantages, but I do not agree with him when he says

on page 157 that direct current has distinct advantages over alternating current for domestic supplies. I should like to ask what the advantages are. I have heard that alternating current is very dangerous to have in the house, but I never heard of any fatality that could be traced to the use of alternating current as against direct current, and if the author could give any concrete reasons for this statement I should like to hear them. I do not think that lighting at 25 periods is unsatisfactory. There is a very slight flicker, but this is overcome by ordinary shades, unless in a very small room where the ceilings and walls are white, but the flicker is not objectionable. The steel-cylinder rectifier is quite successful in certain ways, but I think that the glass-bulb rectifier is superior to it. The steel-cylinder rectifier has too much other gear connected with it, and that is a disadvantage. In addition the formation of the anodes is a great drawback. The glass-bulb rectifier, on the other hand, has no pumps and does not lose its vacuum. If left out of service it does not require to be re-formed, and the wiring is very much simpler. In regard to the automatic features of the steel rectifier given on page 159, after the oil switch is closed I do not see any provision for stopping the sequence of operation if the vacuum is not high enough. Then, again, the temperature of the cylinder is a very vital point and I see nothing to control it. Also, no provision is made for switching out should the vacuum fall, and loss of vacuum is the cause of most of the short-circuits and failures in steel cylinders. I believe that one of the causes of the success of the steel rectifier in Birmingham is, first, that it is a single cylinder on its own transformer; secondly, that it runs in parallel with a battery; and finally, that it is very seldom on full load. The glass rectifier, of course, has very great advantages over the other type, and these are obvious in reading the paper. Fig. 14 shows a substation of 276 kW feeding into an existing network. The author says that he feeds across the outers, and depends on the balancing from the nearest rotary substation. If the substation is more than 2 miles away this is not satisfactory unless there is a middle wire and a balancer of some kind. I am speaking of a rotary substation where the middle wire is left out periodically, and when the middle-wire switch is closed the balance is quite satisfactory. We in Glasgow have several substations with semi-automatic control, and the cost of that equipment is £150 per machine. The substation has all the good points of a fully automatic substation with the exception that it does not start up, and as the load on the substation is more than one machine can take satisfactorily at the peak we have a man in attendance, who puts in an extra machine over the peak and goes home when the load drops to the capacity of one machine. This machine runs day and night and is only shut down during the period that the man is there for cleaning. Another of our substations has no attendant at all; it is started up on Saturday after cleaning, which is done weekly, and left with no attendance unless outlying plant men happen to be passing. These men have instructions to enter every time they are near. We find that system perfectly satisfactory. For outlying districts, or where a district is being developed, I am of the opinion that a.c. distribution is best. Table A shows some figures which I took out for substations of about the same capacity as the installations detailed on page 172.

TABLE A.

Comparative Costs of Substations.

Static Substation, 300 kVA.

	£
Building, including site	400
300-kVA transformer	400
E.H.T. switchgear	250
L.T. switchgear, including 2 feeders	80
Cabling, etc.	200
	£1 230

No attendance required.

Rotary Substation, 250 kW.

	£
Building, including site	1 000
Rotary converter, 250 kW	1 800
E.H.T. switchgear	250
L.T. d.c. switchgear, including 2 feeders	360
Cabling, etc.	300
Semi-automatic gear	100
Capital cost of half time of man as he is only required to start and clean machine	1 000
	£4 810

Mercury Rectifier Substation, 276 kW.

	£
Building, including site	400
276-kW rectifier	2 246
E.H.T. switchgear	225
L.T. gear, including automatic gear	350
Cabling, etc.	50
	£3 271

I have omitted external cabling in all cases, because each case is different in this respect. Three 300-kW transformers will cost but little more than one rectifier substation, and I do not think that the attendance would cost very much. The feeders would be shorter, and there would be less loss in the copper.

Mr. W. S. Sawtell: I should be glad if the author would give some further information regarding the suitability of the rectifiers, described in the paper, for supplying a d.c. network which requires a 24 hours' service. This is somewhat different from the service anticipated by the author, inasmuch as on the system described in the paper is a ring of substations all interconnected; for that reason each and every equipment has a stand-by. On page 158 the life of the bulbs is given as 8 000 hours, and Mr. Seddon, during the discussion, gave 4 000 hours as the average life. If these sets are to maintain a 24-hour service daily, the system will be shut down once every 6 months as the result of bulb failures alone. This is rather serious, especially if one of these rectifiers be installed in a station without attendance and situated some miles from the nearest

depot. How long is allowed for changing a bulb, and what happens when a bulb fails? What are the chief reasons for failure, and what happens to the bulb if the protective switches fail to act when an external short-circuit occurs? Considering this matter from the aspect I have mentioned, I think station engineers will agree that the voltage regulator should have a compound chracteristic. I should be glad to know if the regulator described can be so designed. Mr. Robertson criticized the author's figures for the cost of his substations. I have not gone fully into the matter, but I notice that the cost of high-tension switchgear seems unusual. For instance, in Appendix 3 the figure of £323 includes the cost of 2 high-tension feeder switch panels, 1 busbar coupler switch, and 4 transformer switch panels, the average cost being £46. I think that the author would do considerable service by mentioning the name of the maker of this switchgear, as we must assume that he has found it satisfactory.

Mr. A. E. McColl: I cannot accept the author's statement that alternating current is unsatisfactory for domestic supplies. This seems to me to be a rather sweeping condemnation of the many efficient and satisfactory supplies given from 50-period systems. On the lower periodicity of 25, objection is occasionally taken to the use of alternating current because of what is termed the "objectionable flicker." The company with which I am associated have carried out experiments in order to determine if this "objectionable feature" can be reduced to negligible proportions. Our view is, therefore, that if scientific principles plus a little ordinary intelligence are applied to domestic lighting the bogy of flicker need not deter the consumer from adopting, or prevent the supply authority from developing, 25-period power for illuminating purposes. For the scattered urban areas which are indicated as being the main field for the employment of the glass-bulb rectifier, I do not see that there is any economic justification if 50-period alternating current is available. With alternating current we give supply from an essentially sound, efficient and satisfactory piece of apparatus, and why should we reduce the safety factor of the continuity of supply by introducing what seems to me to be an essentially weaker feature, viz. the glass-bulb rectifier? Perhaps there may be some justification for the use of the rectifier in certain cases such as acting as boosters on extensions of existing d.c. networks. Where an undertaking is committed to the laying down of a new low-pressure distribution system for domestic supplies, and alternating current is available, I see no justification for altering the system of supply. The rectifier appears to be a satisfactory piece of apparatus on isolated tramway routes with an infrequent car service, as it can be made automatic at a lower expenditure than is the case with a purely automatic rotary converter.

Prof. F. G. Baily: I think that Mr. Seddon is probably quite correct in his statements as to the life of the bulbs. Manufacturers are, however, working very hard extending the life of the larger bulbs. We had the same experience when the tungsten lamp was first introduced, and again when the gas-filled lamp was brought out, but once the initial difficulties were overcome very few complaints were received in regard to short life.

Mr. H. F. Hunt (*communicated*): As regards the retention of direct current in certain districts, and the general tendency in others for its replacement by alternating current, I think we ought to keep in mind the possibility, though admittedly remote so far as can be foreseen at present, that future generations may witness developments in electric lamps—not necessarily of the present filament or even vacuum-tube type—for which direct current alone will be suitable. Should such circumstances arise, many districts might have to revert to direct current with rectifiers or rotary converters, whereas Birmingham would be ready and would be saved the large capital cost of a double change-over.

Mr. G. Rogers (*in reply*): Mr. Burr is not convinced of the desirability of using automatic rectifiers for traction purposes. I can only say that I should like him to see the substations actually in operation and again carefully to examine the costs of this plant as compared with those of rotary converters.

In reply to Mr. Bache, bulbs do not give any indication when they are approaching the end of their life. Where a severe short-circuit occurs on the traction system, normally the feeder circuit breaker opens and clears the fault, and will reclose again only when the fault conditions are removed. It sometimes happens that the short-circuit is so severe that it also opens the overload circuit breakers protecting each bulb. These breakers reclose before the time lag of the feeder circuit breaker has expired. Should the main high-tension oil switch supplying a transformer be opened, then the one set remains out of service until re-started by manual operation.

In reply to Mr. Newman, I have had no experience of rectifiers on the particular work referred to, but the demands such as traction load, particularly on the peak, would be very similar to those made by crane work, etc. I should imagine that the bulbs would be entirely suitable for this class of work. The transformer losses are a little more for the rectifiers than for static transformers.

Mr. Chamen, with others, refers to the "troubles" experienced in Birmingham. I would say that these speakers are under a misapprehension. We are perfectly satisfied with the 25-period a.c. supply, and consider the d.c. supply to be the best that can be given for all domestic purposes. I note that Mr. Chamen agrees that where a d.c. supply exists, and where a bulk supply may be required from a 25-period supply, rectifiers may be used with advantage.

Mr. Higham raises the question of the power factor of the plant for traction and for lighting purposes. The difference in the figures is due to the different values of the reactance in circuit. The choke coil in each of the low-tension anode circuits is to allow of parallel running.

Mr. Nairn qualifies his approval of a 25-period supply by stating that the voltage must not vary and that special attention must be paid to the shades.

Mr. Benton questions the accuracy of the figures quoted in Appendix 2 for rotary converters. The figures given in the estimate were the ruling prices for the plant at the time the estimates were made. In regard to the use of reverse-current protection when the bulbs are running in parallel, this method has been adopted on later sets and at the moment I am not satisfied that the speed of operation of the reverse breaker is great enough to give the desired protection. Experiments are still being carried out in this respect. Occasionally bulbs mirror over, the mercury forming a deposit on the inside of the bulb. By applying light loads to the bulb it is possible to remove the film of mercury. With regard to the risk of failure, it is obviously a strain on a new bulb to switch full load on immediately and it is better to warm the bulb up gradually, starting with a low load and working up to full load. This process, however, is not absolutely necessary. The life of a bulb operating at full load in the event of a cooling fan failing, would depend on circumstances. A 230-volt bulb was subjected to full load for 1 hour without the fan running. The bulb became very hot, but no flash-over occurred and the bulb suffered no ill-effect whatever and is still in service. On the other hand we have had one case where the failure of the fan caused a flash-over in the bulb. It had been running on light load for some hours without the fan, but failed on the peak load in the evening.

Mr. Spurr draws attention to the small size of the three-wire lighting substations described in the paper. These substations, as now standardized, are capable of containing up to 750 kW of converting plant. In the areas now being developed by this means, this is likely to be sufficient for some years. Additional substations can be put down as in the case of static transformer substations.

I agree with Mr. Carter that the supply at 25 periods can be very trying, and I note his remarks that even at a periodicity of 40 the flicker is sometimes very noticeable. The charge to the consumer for a supply in the areas opened up by the rectifier substations is 4½d. per unit for lighting and 1½d. per unit for heating and power. I note that this compares very favourably with the flat rate of 6d. per unit at Newcastle.

In reply to Mr. Clothier, where rectifiers are employed in parallel the advantage of supplying each pair of bulbs with a separate high-tension switch is that it allows of the splitting-up of the unit, and in the event of a fault on one half the other half is available for service. With the type of switchgear used, the arrangement is not very expensive.

In reply to Mr. Marshall, I am convinced that for plants of small capacity the automatic rectifier substation is preferable to rotary converter equipment. I cannot agree that a purely a.c. system is more reliable than a d.c. one when provided with batteries to call upon in an emergency.

Mr. Seddon agrees that the rectifier for traction supplies in the case described in the paper is very attractive.

I would refer Mr. Robertson to the Annual Report of the Senior Electrical Inspector. The following is an extract taken from his report of 1922: " . . . of the medium-pressure and low-pressure accidents, 10 fatal cases were due to shock from alternating current at 250 volts or less, as against none from direct current. This is entirely in accordance with the experience of previous years." Referring to the automatic features of a steel-cylinder rectifier given on page 159, I agree that no provision has been made to stop the sequence of operations if the vacuum is not high enough. During the long period this set has been in service, however, no trouble has been experienced due to this. If the vacuum failed completely I would point out that the arc would not strike and the set would not go into commission. Provision can now be made for this feature, however, and has been described elsewhere in the discussion. Table A is interesting but it clearly shows the advantages of the completely automatic rectifier substation over the semi-automatic rotary substation which, according to Mr. Robertson, works out to £19 2s. per kW, against £11 8s. per kW for the completely automatic rectifier equipment.

In reply to Mr. Sawtell I would say that all the outlying substations mentioned in the paper for three-way supply give a continuous service. In some cases the network is run entirely separate from any other supply and under these conditions is quite satisfactory. With regard to the life of the bulbs, the 8 000 hours mentioned was the number of hours the test-bulbs had been in service at the time the paper was written. These bulbs are still in service and have now burned for over 12 000 hours. The average life of a bulb cannot be taken as 4 000 hours—it is considerably more than this. The voltage regulator described in the paper cannot be given a compound characteristic.

In reply to Mr. McColl, I must point out that the statement in the paper that alternating current is unsatisfactory for domestic supplies, distinctly referred to an a.c. supply at 25 periods.

I agree with Mr. Hunt's remarks. In the future there are bound to be great developments in the mercury rectifier. This may also apply to the use of thermionic valves for heavy-current work.

DISCUSSION ON

"THREE-WIRE DIRECT-CURRENT DISTRIBUTION NETWORKS." *

NORTH MIDLAND CENTRE, AT BRADFORD, 10 MARCH, 1925.

Mr. C. A. Gillin: On page 337 the author refers to a neutral conductor. This should not be too small, as in the event of faults it will have to carry the same current as the others. I think that the author lays rather too much stress on the current-carrying capacity of the cables. Even in the case of feeders, the size of the cable is chiefly determined by the voltage-drop. One has to arrange the feeders, no matter what the lengths are, so that the voltages at the feeding points are more or less equal, otherwise spare machines have to be run on separate bars, which necessitates running at a more or less inefficient rate, particularly on the larger machines. Referring to the "Method of Laying," on page 339, I do not agree that any saving in capital charges results by the use of conduits. Conduits have their uses, but their abuses appear to me to be more prevalent. There is a tendency to put down more conduits than may at present be necessary, and the extra cost of these added to the extra cost of their installation—for example the extra depth of excavation to get a decent run, in which case one often has to go three times as far down as one would with direct-laid cables—adds from 30 to 70 per cent to the cost of the job. The capital charges for the loan period of 25 years, the period granted by the Electricity Commissioners for mixed systems, at 4½ per cent interest and 3½ per cent accumulative sinking fund amount to 7·07 per cent per annum, and it is only a matter of a few years for a payment at this rate to become greater than the cost of opening up the ground again. We then have a further advantage in that it is possible to lay additional feeders in the same trench for a considerable portion of the route, and of thus reducing future annual capital charges. There is another point about the conduit system. I notice that the author mentions that in his opinion it is not necessary to put concrete round a duct, but generally speaking I think it is very necessary, although this increases the cost of the job. In addition it seems to lead outside contractors to think that there is debris to remove, and it incites them to break into the concrete surrounding of the duct, the result being that the number of faults is greater than in the case of a cable laid direct. Item 4 mentions "less depreciation," but I think that there is *more* depreciation in cables laid in ducts unless they are run at a lower current density. For example, there is trouble due to the lead cracking at the joints, and also trouble due to chemical action on account of water, it being almost impossible to exclude water from the ducts, and the chemical combinations that the water has gathered up in its progress through the ground to the ducts attack the lead sheaths. On page 340 the author refers to the life of cables. In Bradford we have unarmoured cables laid direct in the ground and covered with jute, well compounded, that are as good to-day as when they were laid 35 years ago, and we never have any trouble with them. In fact I should say that they are better than new cables—the present-day cables—made for the same pressure. On page 344 the author refers to the necessity, or advisability, of making a three-core cable dead when connecting up services, but I think that this is quite unnecessary. I have never had a cable made dead for this purpose, and I have had thousands of services made on multicore live cables. An exception is the case of a cable the insulation of which has greatly deteriorated, due to the cable carrying a heavy fault current, which results in the insulation crumbling away whenever the lead sheathing is taken off. Even in that case services are often made on that particular cable, although I will admit that rather extraordinary precautions have to be taken for the safety of the man and of the supply. The author seems to be a great advocate of single-core cables. I quite admit that they possess many advantages. In fact I have on many occasions advocated their use, but there is nothing better than multicore cables, from the point of view of economics, space occupied, and design of good systems. I agree that, for feeders of 1 sq. in. and over, single-core cables should be used. On page 344 also the author refers to fuse boxes and the fact, or the possibility, that they reduce the reliability of the system. Fuse boxes may do so, but fuse pillars certainly do not. They greatly restrict the risk of breakdown, and I should always advise that as many as can be afforded should be used.

Mr. R. W. Grubb: I am in favour of the use of three single-core cables instead of a three-core cable. Our system consists of practically all single cables for distribution, and they are found especially useful in locating faults. It is possible to put in a four-way distribution box without making the distributors dead, whereas with a three-core cable the risk is too great. Although the cost of three joint boxes instead of one for a three-core service, and the greater cost of two single cables over a two-core cable increases the cost, yet one has a greater feeling of security and ease of mind, and further it is safer to open out a tee joint box on a live single cable than on a live three-core cable. At the same time three joint boxes necessitate opening out more ground, which is a disadvantage in a congested pavement. We invariably find gas and water mains and services in our way in the pavement, and only large gas and water mains are laid in the roadway. At the moment, while laying cables, we are doing the gas department a great service by finding service pipes that fall to pieces when the ground is removed. The author mentions fuses in feeder pillars. We have found that copper wire fuses

* Paper by Mr. H. W. Taylor (see page 337).

have a tendency to waste away, and although they are put in of a sufficient size to carry a large overload they need frequent examination. I am not in favour of concrete being laid on the top of the ducts, and we have had several cases of other departments driving wedges through concrete, making holes in ducts, and in some cases piercing the cable. Some time ago a dead earth came on the positive side of our system, as shown by the earth switch dropping and the indicator lamps burning brightly, but the central-zero ammeter showed no reading, and the resistance (automatically inserted when the earth switch drops) became heated, showing that current was passing. A d.c. ammeter was inserted in the circuit as a check, but registered nothing. An a.c. ammeter was substituted and was found to read the amount that usually flows through the resistance when an earth is on the system. The earth was traced to a certain feeder by making and breaking the earth switch, and certain suspected consumers were asked to switch off their motors temporarily. Eventually the earth went off when a certain motor was shut down, and the cause of the earth was traced to one of the windings on the armature rubbing against the pole-tips.

Mr. W. W. Firth: The author advocates three single cables for feeders and three-core cables for distributors. Personally, from the point of view of current-carrying capacity, I think that the reverse is better, as generally one feeder is supplying several groups of distributors, any set of which may be overloaded and yet the feeder only lightly loaded. The number of faults on distributors is much greater than on feeders, and these are more easily repaired with single-core cables, whilst, due to the fact that only one core is damaged by the fault, the number of consumers likely to be affected is reduced. I should like to know the author's reason for advocating (on page 347) three-core distributors where three-core feeders are used. Provided the whole of the cables are at least lead-covered, and thereby the whole system is bonded, I see no great advantage from the point of view of fault localization. If it comes within the scope of the paper, I should be glad to hear the author's experience in using the enclosed type as against the open type of fuse.

Mr. W. H. N. James: It seems to me that the calculations dealt with in the Appendix cannot be carried out with much accuracy because of the difficulty in obtaining the requisite data; in particular, it is extremely difficult to get adequate information in regard to the load, the probable value of which it may be necessary to estimate for a time several years ahead. This being the case it occurs to me that possibly a certain amount of simplification might be made in the formula which is reached towards the end of the Appendix without sacrificing accuracy to any important extent. This view is strengthened by the fact that if the total annual cost incurred on account of the cable is plotted against the area of cross-section, the curve is, as a rule, flat near the most economical area of cross-section, since the increased fixed cost resulting from the larger cross-section is largely balanced by the decreased running cost on account of the energy wasted. Now the formula given in the paper for the total annual charges includes three terms, those numbered (1) and (2) giving costs that increase proportionally with the resistance of the cable (i.e. they are inversely proportional to the area of cross-section of the cable) and it would seem that term (2), which represents the annual cost incurred on account of the extra plant needed to supply the energy waste in the cable, is not likely to be more than 5 per cent or, at the most, 10 per cent, of the first of the two terms under consideration, and would not involve great inaccuracy if neglected. Coming now to the last term dealing with the annual charge on account of the cost of the cable and laying, this afternoon I plotted list prices for a number of sizes of cable against the corresponding area of cross-section and found that for low- and medium-pressure cables the resulting graph was a straight line passing very nearly through the origin, showing the annual fixed cost, for sizes likely to be used, to be practically proportional to the area of cross-section. Further, it would seem that the cost of laying would increase very slowly with the area of cross-section, thus giving a very flat curve which would have little influence on the most economical area of cross-section. These points being accepted, the formula given by the author can be simplified into one of the type

$$\text{Total annual cost} = \frac{X}{A} + YA$$

where A is the area of cross-section of the cable and X and Y are omnibus constants compounded of the constants mentioned in the paper and can readily be evaluated. Differentiating this expression with respect to area and equating the result to zero, the condition for the most economical area of cross-section is found to be $A = \sqrt{(X/Y)}$ and it appears that this will give all the accuracy needed.

Capt. J. E. Fletcher (*communicated*): The economic value of any system is in a large measure determined by the flexibility of that system, and it is therefore essential, where large capital costs for cabling are involved in places where the electric loads are likely to migrate, that very careful and intelligent studies be made "on the spot" with a view to determining the likely growth of development during a period of years. Inquiries of land agents, surveyors, municipal engineers and the like frequently enable information to be obtained as to the opening up of new districts, factories, etc., which all goes towards settling the problems of what size of cable should be provided at present and/or in a definite number of years. When all the possible information has been obtained the question of costs of provision can be intelligently studied and the most economical cable provided. In all such studies, however, a margin should be allowed for unforeseen development. In the case of feeder cables to the so-called "nodal" points there seems —without much examination—little doubt that the system adopted should be as flexible as possible for the following reasons: (*a*) That it is not economical to lay down cables much in excess of a 10-year requirement; (*b*) that it is desirable to build up a system gradually and so extend the capital charges over a number of years; (*c*) that the various improvements in the manufacture of cables from time to time may be made use of; and (*d*) that it is a costly matter to open out in situ

pavings. A duct system, then, appears to be the solution and the only question arising is how many ways should be provided at the outset. To solve this question, as I said before, is to make a comprehensive survey of the entire area to be served and compute in quinquennial periods the probable customers and their estimated consumption. The same remarks apply equally to the distributor cables. Greater flexibility and greater immunity from serious troubles go hand in hand with a larger number of cables which are the outcome of a system gradually built up. I agree with the author that three single-core cables should be used mainly from the point of view of reducing to a minimum the number of faults and consequently the inconvenience to the consumer (a most vital point). The current-carrying capacity of the individual cables as shown in Table 1 is less in a duct than when laid direct in the ground. It is assumed that the figures are based on "dry" ducts, but in practice it is found that it is almost impossible to maintain a dry duct system; if there is water in the vicinity of the track, it seems to find its way into the system. The ideal system is to lay the ducts in such a way that, if any water does get in, it drains into the surface boxes or manholes. This, however, is seldom possible in large towns and in many cases the ducts have necessarily to be laid in a concave fashion. The result is that, should water get in, it remains unless it escapes by way of the joints. I do not think that much trouble from freezing may be feared in this country, as the frost does not penetrate so far into the earth. Avoidance of concave and convex layings in any one section of ductwork is necessary, as should a second cable be required in the same duct there is little chance of getting it in. The value of the spare duct space is therefore lost. To overcome the difficulty an inspection chamber or a split coupling should be provided at the junction between the concave and the convex turning. Ducts laid with a cover of 2 ft. with the present-day roadway construction should be immune from danger of crushing without the use of concrete. When drawing lead-covered cables into conduits, a good plan is to cover them slightly with petroleum jelly; this not only affords a protection against electrolysis but serves as a lubricant. At this point I should add that it is sound engineering practice to bond all lead cable sheaths together and earth them at frequent points. The author says that in the case of cables laid direct in the ground: "A fact that becomes quickly apparent is the ease with which such work can be carried out." I should like to add a word of warning here. Although it may be easy to bury the cable it is just as important that every care should be taken to safeguard other undertakers' property by giving a proper and safe clearance as it is to safeguard the cable itself. With regard to Tables 3 and 4, and with special reference to the figures quoted in connection with the conduit system, I do not think that the figures are properly proportioned, as Table 3 actually includes what may be termed "spare plant," inasmuch as the figures cover the cost of providing spare capacity for a future cable, and Table 4 takes the credit of this. Conversely we might provide spare cable in the case of cables laid solid in bitumen or direct in the earth in the first place. In conclusion the author advocates the use of ducts for feeder cables and also earthenware conduits for service cables in order, amongst other reasons, to reduce the costs of repairing faults. It is therefore not at all clear why he does not advocate the use of similar plant for distributor cables, assuming that all in situ pavings in these days may be regarded as expensive to reinstate.

Mr. H. W. Taylor (*in reply*): Few points have been raised in this discussion which have not been dealt with in my reply to previous discussions at other Centres.

The instance which Mr. Gillin gives of the life of an unarmoured lead-covered, served and compounded cable laid direct in the ground is very interesting and I think that more use could be made of this type of cable in many instances, with a considerable reduction in the cost of extensions.

I am pleased that Mr. Grubb has also experienced the feeling of increased security which one obtains with a single-core system. Opinion seems to differ as to the advisability of covering conduits with concrete. I have personally experienced more cases of damage to cables in conduits so protected than in those unprotected.

The chief advantage of the single-core lead-covered system is that when an earth fault occurs the supply can usually be maintained owing to the trouble being confined to one cable. This advantage is to a large extent nullified by the introduction of multicore cables in any part of the network, as faults on this type of cable are rarely confined to one core. It is for this reason that I consider the single-core distributor cannot show sufficient advantages over the three-core to warrant its higher cost, if multicore cables are used for feeders. Replying to Mr. Firth's other question, in my experience I have found the open-type strip fuse to be preferable for continuous loads higher than 150 amperes.

The formula given by Mr. James will in many cases give sufficiently accurate results. As I stated in the paper, practical considerations generally prevent a hard-and-fast application of any such formula. In dealing with any specific case, when the only variable quantities are r and C_2, the formula which I give then assumes the simplified form: Total annual cost $= K_1 r + K_2 C_2$, where K_1 and K_2 are constants made up of the other constants mentioned.

I would point out to Mr. Fletcher that the costs shown in Table 3 for the conduit system include only the cost of the conduits necessary for the feeder concerned and do not include spare ducts. Table 4 shows the cost, exclusive of cable, of replacing the cable with one of larger size. Where circumstances warrant, it is often advisable to lay additional ducts, but this of course should not be included in the cost of the original cable. I only advocate the use of conduits for a service over that part of its route in which it would be expensive to repair a fault in a cable laid direct or solid, such as in crossing a main road or under a terrazzo floor in a consumer's premises, etc. The number of times that conduits used for distributors would have to be broken in order to make service connections would greatly limit their usefulness.

THE SIXTEENTH KELVIN LECTURE.

ELECTRIC FORCES AND QUANTA.

By J. H. JEANS, M.A., D.Sc., LL.D., Sec. R.S.

(*Lecture delivered before* THE INSTITUTION, *5th February*, 1925.)

It is just about twenty-five years since Lord Kelvin spoke of "two clouds" obscuring "the beauty and clearness of the dynamical theory which asserts light and heat to be two modes of motion." The clouds which Lord Kelvin saw as clouds no bigger then a man's hand have grown until they have almost filled the firmament: little can now be seen of the beauty and clearness of the dynamical theory of which Lord Kelvin spoke. The old dynamical theory has given place to the new theories of relativity and of quanta; what Lord Kelvin thought were transient clouds shortly to melt away have proved to be new theories in process of growth; the "beauty and clearness" he saw under these clouds was mostly a mirage.

I have chosen as my title "Electric Forces and Quanta," the two halves of this title corresponding roughly to the two new theories, and I propose to try to sketch out the changes these theories have introduced into our conception of fundamental electrical processes. Let us consider electric forces first. Lord Kelvin, following Maxwell and Faraday, regarded an electric force as evidence of a stress in the ether. An ether can transmit two kinds of stress, one arising from a state of static strain and the other from a transfer of momentum; these were supposed to be electric and magnetic forces respectively. Or, to put the matter in another way, an ether can possess two kinds of energy, potential and kinetic; these were identified with electrostatic and electromagnetic energy respectively. This mechanism of stresses in the ether was devised in order to escape the necessity of "action at a distance." The ether itself had no doubt originally been brought into existence for quite other reasons—to provide a nominative to the verb "to undulate," according to the late Lord Salisbury—but these other reasons were no longer of much cogency. Light, whether an undulation of a medium or not, was admittedly an electromagnetic phenomenon, and the electromagnetic theory of light had already made it clear that any mechanism which could account satisfactorily for electric and magnetic forces could carry the whole of the undulatory theory as well. It was because Maxwell and Faraday had disliked "action at a distance" that the ether continued in existence at the end of the nineteenth century.

A MEDIUM, OR ACTION AT A DISTANCE.

Nevertheless, the conception involved a difficulty which seems to have troubled the nineteenth century physicists not a little. The energy of the ether could represent all kinds of electromagnetic energy, but could represent nothing else. Gravitational energy, for example, could not be interpreted as ethereal energy, for the only two types of energy which the ether could hold were already allotted to electric and magnetic energy respectively. It is true that attempts were made to interpret gravitation as normal waves of compression or as pulsations of very high frequency in the luminiferous ether, but such explanations never survived comparison with facts, and those who tried to explain gravitation had to fall back either on a new and entirely separate ether or else on action at a distance. If action at a distance had to be called in to explain gravitation, it might just as well be allowed to explain electromagnetism as well; there seemed to be no logical resting-place between two ethers and none. But the need for multiple ethers simultaneously filling space aroused suspicions in those who were conversant with the history of science. In an earlier century, according to Sir Joseph Larmor, "aethers were invented for the planets to swim in, to constitute electric atmospheres and magnetic effluvia, to convey sensations from one part of our bodies to another, and so on, till all space had been filled three or four times over with aethers. It is only when we remember the extensive and mischievous influence on science which hypotheses about aethers used formerly to exercise, that we can appreciate the horror of aethers which sober-minded men had during the eighteenth century."

In time it became clear that the only thoroughly satisfactory possibility was no ether at all. First the development of the theory of relativity gave its deathblow to the old luminiferous ether of Lord Kelvin, Maxwell, and Faraday. The main result of this theory can be stated in the form that all the phenomena of Nature go on precisely as though there were no ether. This does not of course abolish the ether; it shows the conception of an ether to be superfluous and perhaps even a little bit ridiculous—for it is ridiculous to fill the whole of space with a medium and then agree that everything goes on just as if the medium were not there—but it does not show it to be illogical.

THE EXISTENCE OF AN ETHER.

To the question, "Does an ether exist?" science is still unable to give a definite answer. The question, "Does the ether exist?" if the ether is taken to mean the luminiferous ether of Maxwell and Faraday, ought almost certainly to be answered in the negative. Speaking for a moment in the language of technical mathematics, the reason is that all the phenomena of Nature are invariant to the Lorentzian transformation

(the transformation to axes moving with a uniform velocity), whereas the physical properties allotted to the ether by Maxwell and Faraday are not invariant. Let E and H denote the electric and magnetic force at a point in the supposed ether, then $E^2 - H^2$ (the integrand in the action integral) is invariant, so that all properties which follow from the principle of least action are independent of the motion of the observer. These are of course the dynamical properties of the system. But $E^2 + H^2$ is not invariant, so that the phenomena which follow from attributing energy to the ether at a rate $(1/8\pi)(E^2 + H^2)$ per unit volume are not the same for a moving observer as for a stationary one.

Of the six components of stress attributed by Maxwell to the ether only three are invariant, so that electromagnetic phenomena, if explained in terms of ether stresses, call for stresses which are not the same for a moving observer as for one at rest, even though the observed phenomena are absolutely identical. For example, if magnetic forces are of ethereal origin, then the forces observed by a moving observer must be of quite different nature and origin physically from those observed by an observer at rest. If the latter observer's forces are produced by Maxwell's mechanism, the former's cannot be. To take the simplest example: an observer moving through a stationary electrostatic field will in actual fact observe magnetic forces just as much as if the field moved past him, yet the ether at every point of his path possesses no kinetic energy and so, according to the Maxwell-Faraday conception, could show no magnetic forces. The old Maxwell-Faraday ether had in some way to provide a duplicate mechanism for a single phenomenon, the magnetic force arising from an electric charge—and similarly for most other phenomena. No one has ever shown that it is capable of doing this; but even if they had, the duplication of mechanism to produce a single phenomenon is so contrary to the usual workings of Nature that there is not much risk in dismissing the old ether to the lumber-room.

Thus we may be confident that if an ether exists, it must be something very different from the Maxwell-Faraday ether. It must probably be thought of as a four-dimensional structure and must be more subjective than the Maxwell-Faraday ether. Each of us must carry his own ether about with him, extending through all space and all time, much as in a shower of rain each observer carries his own rainbow about with him. Whether such a structure, if it exists, ought to be called an ether, others must decide.

We may remark, in passing, that the conception of an ether has always made a special appeal to the practical, one might almost say engineering, type of mind which we associate with the leaders of British science. While our own physicists have asked for Nature to be reduced to a machine transmitting tensions and stresses, the more metaphysical minds of the Continent have usually been content to accept action at a distance as an ultimate explanation of natural phenomena, or at least to regard such an explanation as being in every way as final and as satisfying as an explanation in terms of a medium. It was something more than a coincidence that Newton, Kelvin, Clerk Maxwell and Faraday were all British, while Boscovitch, Einstein and Weyl are not.

Four-Dimensional Geometry.

The paper which practically abolished the ether as a serious scientific hypothesis was published by Einstein in 1905. Ten years later he published a second paper which may be said to have shown us how to get on without either an ether or action at a distance. His first paper, as afterwards interpreted by Minkowski, had shown that all the phenomena of electromagnetism might be thought of as occurring in a continuum of four dimensions—three dimensions of space and one of time—*in which it is impossible to separate the space from the time in any absolute manner*. You may separate them in one way, but you will find that I separate them differently, and in the end we shall both agree that no objective separation is possible.

Einstein's second paper showed that the phenomena of gravitation could be explained on the supposition that the geometry of this four-dimensional continuum was not of the ordinary Euclidean type. The con-

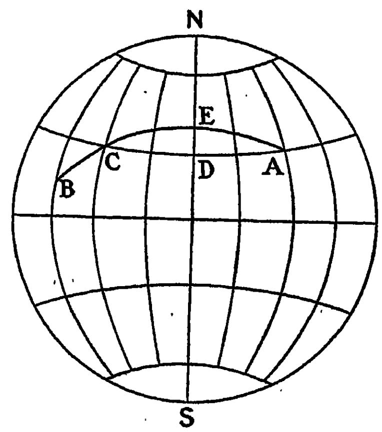

Fig. 1.

tinuum was supposed to be affected by kinks and twists in the neighbourhood of gravitating masses, and it was these, and not a "gravitational force," that threw a particle out of a straight course. It became just as inaccurate to say that the sun attracts the earth as to say that a bowl on an uneven bowling green is attracted or repelled by the other bowls. In this curved space the path of a particle is always a geodesic—the most direct distance between two points—and this may have very different properties from a Euclidean straight line.

We must, of course, remember that the paths we are discussing are in a four-dimensional space—if we were speaking of ordinary paths in three-dimensional space, it would clearly be ridiculous to say that the curved orbit of a planet provided the most direct path from perihelion to aphelion; it is only when we allow for the motion in time as well as in space that the statement becomes reasonable. We can get rid of most of the

motion in time by supposing our planet, or other body, to move with enormously high velocity, and then the path described actually approximates to a straight line, which is now the most direct path even in three-dimensional space.

We can gain some conception of the main features of Einstein's geometry from the analogy of spherical geometry; the curved surface of our earth provides a fair two-dimensional analogy to Einstein's curved four-dimensional space. To one who thinks in terms of "parallels" of latitude and longitude, or who studies geography on a Mercator chart, the most direct course on our earth's surface looks oddly curved: it is always a surprise to the unsophisticated traveller that the ship taking him from Southampton to New York (say from A to B in Fig. 1) turns a bit to the north on rounding the Lizard, while the great circle course on the ship's chart (A E C B in Fig. 1) looks very much as if the ship were describing an orbit about a centre of attraction in the middle of the Sahara.

If Einstein was able to avoid the evils both of action at a distance and of an ether in the gravitational problem, there would seem to be no reason why they should not be similarly avoided in the electromagnetic problem which specially interests us to-night. Not only is there no reason why this should not be done; it actually has been done. In 1918 Weyl pointed out that the geometry of Einstein was not the most general geometry which conformed to the relativity condition. Space could be distorted still further in ways unimagined by Einstein, these further distortions of the four-dimensional space being specified by the six components of a vector. Now the significant thing is this. On calculating the relations which must hold between the six components of the vector in order that the relativity condition may be satisfied, Weyl finds equations which are precisely identical with the electromagnetic equations of Maxwell, the six components in question now appearing as the three components of electric force and the three components of magnetic force.

Weyl's Electromagnetic Theory.

It is not easy to explain in non-mathematical language what is the essential difference between Weyl's space and the old Euclidean space. We can best attempt it by treating Einstein's space as a half-way house. Returning for a moment to the two-dimensional analogy provided by the earth's curved surface, we know that the lengh of a degree of longitude decreases as we recede from the equator; the ship turns north on its voyage from the Lizard to New York in order to take advantage of the shorter degrees of longitude up north. The planet going round the sun describes a curved path for a similar reason. According to Einstein's theory a measuring rod changes in length as it moves about in a gravitational field—a two-foot rule is no longer two feet in length if taken from the earth to the sun; it is because of this that the wave-length of the light represented by a definite spectral line when emitted at the sun's surface is different from that of the same light emitted on earth. The length of the rod depends only on its distance from the sun, being, in fact, proportional to

$$\left(1-\frac{2\gamma m}{rc^2}\right)^{-\frac{1}{2}}$$

where γ is the gravitation constant, m the mass of the sun, c the velocity of light, and r the distance from the sun. But in Weyl's space the length of such a rod does not depend solely on its position: it depends also on the path by which this position has been attained. A rod of length l displaced parallel to itself through a distance dx, dy, dz, dt in the four-dimensional continuum may be supposed to experience a change of length dl defined by

$$dl = l(Fdx + Gdy + Hdz - \Psi dt)$$

where F, G, H, Ψ are quantities which need not at present be specified. If the rod is taken a journey from P to Q its whole change of length will be given by

$$\log\frac{l_q}{l_p} = \int_P^Q (Fdx + Gdy + Hdz - \Psi dt).$$

In Einstein's geometry the integrand is necessarily a perfect differential, so that the value of l_q/l_p depends only on the position of Q and P and not on the particular path selected from P to Q; the condition that this integrand shall be a perfect differential is expressed by the six equations

$$\frac{\partial H}{\partial y}-\frac{\partial G}{\partial z}=0 \qquad -\frac{\partial \Psi}{\partial x}-\frac{\partial F}{\partial t}=0$$
$$\frac{\partial F}{\partial z}-\frac{\partial H}{\partial x}=0 \qquad -\frac{\partial \Psi}{\partial y}-\frac{\partial G}{\partial t}=0$$
$$\frac{\partial G}{\partial x}-\frac{\partial F}{\partial y}=0 \qquad -\frac{\partial \Psi}{\partial z}-\frac{\partial H}{\partial t}=0$$

In Weyl's geometry, on the other hand, the integrand $Fdx + Gdy + Hdz - \Psi dt$ is not a perfect differential, so that the quantities on the left-hand of the equations just written down do not vanish; they have values a, b, c, X, Y, Z different from zero, so that

$$\frac{\partial H}{\partial y}-\frac{\partial G}{\partial z}=a \qquad -\frac{\partial \Psi}{\partial x}-\frac{\partial F}{\partial t}=X$$
$$\frac{\partial F}{\partial z}-\frac{\partial H}{\partial x}=b \qquad -\frac{\partial \Psi}{\partial y}-\frac{\partial G}{\partial t}=Y$$
$$\frac{\partial G}{\partial x}-\frac{\partial F}{\partial y}=c \qquad -\frac{\partial \Psi}{\partial z}-\frac{\partial H}{\partial t}=Z$$

These are precisely Maxwell's electromagnetic equations, F, G, H being the components of the magnetic vector potential, and Ψ the electrostatic potential. Turning back, we see that F, G, H and Ψ are determined at any point by the rate at which a measuring rod of unit length changes its length as it passes through that point.

When Einstein explained gravitation in terms of curvatures and special metric properties of space, the equations of his theory were found to be different from

those of the old Newtonian theory. It was accordingly possible to make an observational test between the two theories, and this decided immediately and conclusively in favour of the theory of Einstein. There is no hope of establishing the truth of Weyl's theory in a similar way, for, as we have just seen, the equations to which it leads are precisely identical with the already universally accepted equations of Maxwell. Weyl's theory can only be judged by its inherent plausibility or the reverse.

Judged by this standard, everything seems to be in its favour. The luminiferous ether failed partly because it left no room for gravitation, partly because its mechanism had to be supposed to be too elaborate for the facts to be explained. The hypothesis of an ether led us to anticipate a whole series of different phenomena corresponding to different velocities through the ether, so that when these were not forthcoming, its advocates were compelled to elaborate a complicated theory by which all the forces of Nature were in collusion to make these different occurrences appear the same to us. The Einstein-Weyl geometrical theory escapes both these reproaches. Both gravitation and electromagnetism fit perfectly naturally into their places. These two systems of forces correspond exactly and completely to the ways in which a four-dimensional geometry can differ from the simple geometry of Euclid. The observed forces of gravitation and electromagnetism correspond exactly to the most general forces which are possible, if "force" is interpreted simply as an illusion arising from a crumpling up of space. Consequently the observed phenomena of Nature are precisely those which ought to be observed —not one is missing and neither is there room for a single one more. There is now no collusion among the forces of Nature to conceal a whole series of unobserved phenomena: indeed, there could be no concealment because there is nothing to conceal. By its simplicity, its completeness, and its perfect agreement with the observed phenomena of Nature, the theory seems likely to take its place as our final interpretation of the "forces" of Nature.

We now see that the universe of Euclid, in which parallel lines never meet and in which two sides of a triangle are always greater than the third, was a simplified ideal universe. In the same way the universe of Aristotle and Plato, in which space and time are permanently distinct and essentially different in their natures, was a simplified ideal universe. Both universes were too simple to fit the facts; remove the unwarranted simplifications and we are left with a universe the geometrical properties of which are expressed by such equations as Einstein's gravitational equations (to which Newton's inverse square law gives a good approximation) and Maxwell's electrodynamical equations. Thus geometry, cleared of *all* unjustifiable assumptions, transforms itself into mechanics, both gravitational and electrodynamical. A being who was born without any one of his five senses, but with unlimited geometrical reasoning powers, could deduce the general nature of the actual world without any experience of reality: he would anticipate that landslides, earthquakes, thunderstorms, and auroræ would occur; but he would know nothing about "forces," and would regard these phenomena merely as geometrical necessities.

Atomicity.

Although generalized geometry can predict and explain all the systems of forces of the universe it has its limitations; there are features of the actual universe before which it stands powerless. Nothing in geometry can explain the essential differences between positive and negative electricity, or the atomicity of electric charges, so that the whole inner structure of matter, including the whole of chemistry, would be outside the scope of the intuitions of our supposed geometer.

Electric charges are a consequence of, or at least are associated with, a curving or crumpling of space, but so far as pure geometry goes there is no restriction on the extent of this crumpling, so that our geometer, reasoning from geometry alone, might expect to find charges of all possible amounts, whereas in actual fact electric charges occur only in multiples of a definite unit, the charge of an electron. It is clear, then, that there is something more than geometry underlying the phenomena of Nature; the whole phenomenal universe may be geometry with restrictions if we like, but not merely the geometry which is obtained by generalizing the geometry of Euclid until we can generalize no further. Space can be crumpled up qualitatively in all the ways known to geometry but not quantitatively; the uniformity of electronic charge must in some way represent an absolute restriction on the measure of the crumpling.

Each particle of matter—each electron, let us say—occupies one point of space at any one instant of time, and the succession of these points will form a line in the four-dimensional space-time continuum—the "world-line" of the electron. In the neighbourhood of this world-line there is a deformation of the continuum due to the existence of the electron.

The near approach of two electrons or of any two charged particles is represented by a near approach of their world-lines in the four-dimensional continuum. Each world-line is surrounded by its associated deformation, and in regions in which the world-lines are near to one another the adjacent regions of the continuum will be doubly deformed.

A priori there are two possibilities open. The first is that the two deformations are merely additive, just as, when two ships approach, each making its own wash (or deformation of the surface of the sea), the height of wash at any point is the sum of the heights of the washes made by the two ships independently. The second possibility is that, as there have been found to be restrictions on the amount of deformation associated with the two separate world-lines, there may be a further restriction on the deformation arising from their combination.

In actual fact the former alternative appears to prevail when one or both of the charged particles are "free" electrons, but the latter alternative when they are "bound" together; that is, when they are permanently describing orbits about one another. It is these latter restrictions that have given rise to the

theory of quanta. Just as the restrictions associated with single world-lines give rise to an atomic constant e, the charge on an electron, so the restrictions associated with pairs of world-lines give rise to a second atomic constant. This is generally taken to be h, Planck's constant, but in many respects it is more appropriate to regard the product hc as the second constant, where c is the velocity of light. It is significant that hc is of the same physical dimensions as e^2 and so may be regarded as being the same thing as e^2 except for a numerical multiplier. Thus while the restrictions connected with one world-line introduce e, those connected with two world-lines, depending only on e^2, introduce no essentially new constant, whence it may reasonably be suspected that the two sets of restrictions are merely different aspects of one and the same set. It looks as though the atomicity of the quantum theory is only another aspect of the atomicity of electric charges.

Quantum-Restrictions.

We can perhaps best visualize the inner nature of the quantum-restrictions by going back to the analogy of the two ships making a combined wash which is in some way restricted to being of a certain height. We have supposed each wash individually to be restricted; if the velocity of the ships is fixed, this requires that each ship shall be of a definite size (corresponding to each electron having a definite charge). How can we now put a further restriction on the total wash of the two ships at points where their washes overlap? Only, I think, by keeping the ships at a specified distance apart. At any rate this is the way in which the quantum-restrictions work. The normal hydrogen atom consists of a negative electron describing a circular orbit about a positively charged nucleus; the quantum-restrictions compel this orbit to keep an unvarying radius of $0 \cdot 53 \times 10^{-8}$ cm. When the atom is in an abnormal state, as, for example, when excited in a vacuum tube, the orbit, if circular, may have radii equal to 4, 9, 16, 25 . . . times the radius of the normal atom. Elliptic orbits also are possible, but only of quite definitely restricted major and minor axes. In actual fact the semi-major axis must be equal to one of the radii permissible for a circular orbit, while the ratio of the two axes must be one of a range of commensurable ratios. The orbits which are possible for the electron of the hydrogen atom are shown in Fig. 2. If it were not for the quantum-restrictions, it would be impossible to exhibit these orbits in a diagram at all; orbits of every radius and of every eccentricity would be possible, just as they are for a planet or comet describing an orbit about the sun.

It will be understood that I have not approached the quantum theory by the road of its historical development. Planck originally discovered the existence of the quantum-constant h from a study of black-body radiation. The famous theorem of equipartition of energy showed that if the classical laws of dynamics were of universal validity, the whole energy of the material universe would at once degrade itself into radiant energy of infinitesimal wave-length. Planck showed that this conclusion could be avoided by supposing that the energy of radiating mechanisms changed only by complete quanta, the change of energy $W_2 - W_1$ being connected with the frequency ν of the radiator by the relation

$$W_2 - W_1 = h\nu$$

He further showed that this supposition led to a law of spectral distribution of black-body radiation, the now famous Planck's law, which was found to agree excellently with the observed distribution. In this way the quantum theory came into being at the very beginning of the quarter-century we have under review.

Some years elapsed before Einstein showed that the same constant was of fundamental importance in the photo-electric effect, and it then began to be suspected that it might conceivably be fundamental to the whole of physics. But it was not until 1913 that Bohr published the epoch-making paper which first suggested, and at the same time finally established, that this constant held the clue to the structure of the atom and determined the scale on which the universe

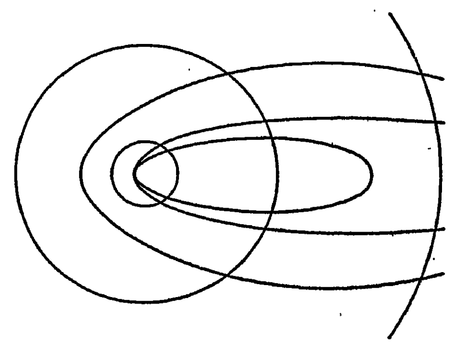

Fig 2.

is built. To-night I have disregarded historical development altogether, and have tried to approach the theory in the simplest manner; I am trying to make it look natural. There can be no reasonable doubt that the quantum theory is essentially true and so would appear perfectly natural to us if we could approach it with entirely fresh minds not already obsessed by erroneous ideas. But with our minds such as they are, the quantum theory as frequently presented does, it must be admitted, raise recollections of plausible conjuring performances. If I were to state the argument by which Planck first arrived at the existence of the quantum, the inclination might well be to dismiss it as mere mathematical sleight-of-hand. I agree it is still a bit surprising that the rabbit came out of the hat, but I have tried to show at least that there was so much room in the hat that almost anything might have emerged.

According to the Maxwellian electrodynamics an electron describing an orbit of any kind must necessarily radiate energy. We can calculate the rate at which energy ought to be radiated by the electron in the normal hydrogen atom; it is $0 \cdot 46$ erg a second. The resulting loss of energy would be compensated by a decrease in the radius of the orbit; we find that the

rate of this decrease would be about 112 cm a second, so that the atom ought to disappear altogether within a small fraction of a millionth of a second. Thus it is the quantum-restrictions which give a permanent existence to matter.

In conformity with the quantum-restrictions, the electron in the hydrogen atom describes an orbit of unvarying radius and so of constant energy. Maxwell's equations, as we have seen, would demand that radiation should be emitted and that the energy of the orbit should decrease accordingly. Here, then, we have a case where the requirements of Maxwell's theory and those of the quantum theory are in irreconcilable conflict. It is the quantum theory which carries the day. Somewhere before we reach the most minute of all structures Maxwell's theory fails and the quantum theory takes its place. For large-scale phenomena the two theories coincide—a thunderstorm is the same thing for Maxwell's theory as for the quantum theory, just as it was the same thing for the old "one-fluid" theory as for the modern electron theory—atomicity is of no consequence when the number of atoms involved approximates to infinity.

In terms of space curvatures we may say that Maxwell's theory is represented by a continuous curvature or crumpling such as might be applied to a rubber membrane, while possibly the quantum theory may be represented by a so-to-speak "jerky" deformation which is the best that can be done with a scaly surface such as a crocodile skin. If we wish to cover the earth's surface with a membrane, it makes little difference, from the point of view of closeness of fit, whether we select rubber membrane or crocodile skin, but it makes all the difference if we are manufacturing a pair of gloves. The quantum theory represents, perhaps, a quality of space, or rather of the four-dimensional continuum, which is somehow analogous to scaliness in a skin.

As the normal hydrogen atom is already in its configuration of minimum energy it can emit no radiation. But under electric bombardment or in the presence of intense radiation the electron may move to other orbits of energy higher than the minimum. Even now there can be no gradual change of energy, but there can be spasmodic jumps from one orbit to another orbit of lower energy. According to Bohr's theory of atomic mechanism, the energy lost to the orbit at each end of these jumps is emitted in the form of monochromatic radiation. A jump from energy W_2 to energy W_1 results in the emission of radiation of uniform frequency ν where

$$W_2 - W_1 = h\nu$$

h being the absolute constant of Nature already referred to. If λ is the wave-length of the radiation, $\lambda = c/\nu$, so that

$$W_2 - W_1 = \frac{hc}{\lambda}$$

We have already seen that hc is equal to Ke^2, where K is a numerical constant. The energy in an orbit of radius r (or, if elliptical, of semi-major axis r) is $\frac{1}{2}e^2/r$, so that if the jump is from an orbit of radius r_1 to one of radius r_2,

$$\tfrac{1}{2}e^2\left(\frac{1}{r_2} - \frac{1}{r_1}\right) = \frac{Ke^2}{\lambda}$$

and the wave-length of the radiation is given by

$$\frac{2K}{\lambda} = \frac{1}{r_2} - \frac{1}{r_1}$$

Now if a is the radius of the normal hydrogen atom, the possible values for r_2 and r_1 are $1^2, 2^2, 3^2, 4^2 \ldots$ times a, so that our formula becomes

$$\frac{2Ka}{\lambda} = \frac{1}{n_2^2} - \frac{1}{n_1^2}$$

In actual fact a formula of this type, in which n_1 and n_2 are given all possible integral values, is found to give with the utmost exactness the wave-lengths of the light emitted in the complicated spectrum of the hydrogen atom. On putting $n_2 = 2$ we obtain the Balmer series of lines, of which the principal lines H_α, H_β, $H_\gamma \ldots$ form the most conspicuous feature in the ordinary hydrogen spectrum. The lines obtained by putting $n_2 = 1, 3, 4, 5 \ldots$ are mostly in the infra-red or the ultra-violet. Many of these have been observed, and there is no reason to doubt that the remainder are there, although at present beyond the range of observation.

So far we have considered only the circular orbits; there must, of course, be other spectral lines arising out of the possibility of the electron describing elliptic orbits. Exact analysis shows, however, that these latter lines coincide almost exactly with those already discussed. They would coincide perfectly if it were not that the mass of a moving electron depends on the velocity of its motion. As a consequence of this dependence of mass on velocity, the two sets of lines do not exactly coincide. Each line of the simple series previously discussed is replaced by a "fine-structure"—a bunch of lines quite distinct in fact, although so close together as to look like a single line in all save the most powerful spectroscopes. Sommerfeld has worked out the structure to be expected theoretically for these bundles of lines and obtains a most gratifying agreement with observation. This and other experimental tests give the most convincing proof of the accuracy of Bohr's theories of atomic mechanism.

We can gain a knowledge of the arrangements of the electron orbits in even the most complicated atoms by using the equation

$$W_2 - W_1 = h\nu$$

which appears to be of universal validity. The frequencies ν of radiation can be measured, so that the energy-levels W_1, $W_2 \ldots$ of the various possible orbits can be calculated. The method has been applied not only to discovering the arrangements of electrons in the atom, but also to discovering the energy-levels of the protons in the nucleus. At present the hydrogen atom and the positively-charged helium atom are the only structures which are completely understood, but there can be little doubt that in time the method will unravel for us the secrets of even the most complicated of atomic and molecular structures.

Already Bohr has constructed a table, of which the first part is shown in Table 1, in which he attempts to

TABLE 1.

Electron Orbits.

		1_1	2_1	2_2	3_1	3_2	3_3
1	H	1					
2	He	2					
3	Li	2	1				
4	Be	2	2				
5	B	2	2	(1)			
10	Ne	2	4	4			
11	Na	2	4	4	1		
12	Mg	2	4	4	2		
13	Al	2	4	4	2	1	
18	A	2	4	4	4	4	

assign the different electrons in the atoms to the various orbits permitted to them by the quantum theory. The numbers in the top line specify the orbits in terms of their principal and subsidiary quantum numbers. The numbers below are the numbers of electrons which follow one another round in these different orbits. It will be noticed that in the simpler elements there are never more than four electrons in the same orbit, although in the heavier elements six and afterwards eight electrons may inhabit the same orbit. The table is largely conjectural, but recent spectroscopic research has gone far towards establishing its essential accuracy. When we remember that it is less than twelve years since Bohr first suggested that the quantum theory might provide the clue to the structure of matter, we must agree that the progress of the theory in these years has been remarkable.

THE NATURE OF RADIATION.

The quantum theory has been less successful in discovering the nature of radiation, although even here it has been beyond comparison more successful than any previous theory. To illustrate the difficulties of the problem, let us consider one single phenomenon—the X-ray photo-electric effect. A thin stream of electrons each moving with the same high velocity is allowed to impinge on a material target, and X-rays are emitted which carry off the energy destroyed by the collision. These X-rays pass through a gas, and it is found that as soon as the process starts, atoms are ionized and shoot off electrons with a velocity equal to that of the original stream of electrons. Even if the density of X-radiation is so slight that, according to the old view of radiation, an atom would take years to absorb the energy necessary for ionization, nevertheless ionization is found to begin at once, energy being absorbed which is not only sufficient for mere ionization, but also suffices in addition to endow the ejected electron with high velocity.

Such a phenomenon is of course totally inexplicable in terms of the luminiferous ether, or even in terms of Maxwell's equations. The quantum theory gives only a partial explanation. Since the frequency ν of the X-rays does not change with their passage through space, the equation $W_2 - W_1 = h\nu$ shows that the change of energy at the one end of the chain must be equal to that at the other. Thus as much energy is necessarily yielded up to one electron as is destroyed in another, but this does not touch the problem of the mechanism by which this energy is transferred.

Einstein at one time suggested that radiant energy was hurled through space tied up in indivisible packets like bullets from a rifle, but it has proved quite impossible to reconcile this suggestion with the optical phenomena of interference. A more recent hypothesis, also due to Einstein, calls for a revision of our conception of the action of an electric field on an electron.

According to the usual electrical theory an electric force X acting on an electron of charge e and mass m for a time t produces a change of velocity equal to Xet/m. According to Einstein's recent theory of radiation, this is only true if X arises from a steady field or from a field which changes infinitely slowly. A force X which results from the incidence of radiation will in general produce no change of velocity at all in an electron. Indeed a bound electron is compelled to describe a fixed orbit with a prescribed velocity which cannot change, while a quite simple argument shows that it would be contrary to the fundamental equation of the quantum theory for a free electron to have its velocity changed by radiation. Einstein, following Bohr, supposes that under certain conditions a bound electron can have its velocity changed by a definite amount Q. This amount is not equal to Xet/m, but is determined by the position and motion of the electron in the atom to which it belongs; Q must be such as to move the electron into a new orbit which is also one of the permitted few. The chance of such a jump of velocity occurring is supposed to be

$$\frac{(Xet/m)}{Q}.$$

This conception immediately explains the otherwise incomprehensible photo-electric effect as well as other puzzles in the behaviour of radiation. The difference between a strong and a weak electric field acting on an electron is no longer that the strong field produces a big change of velocity and the weak field a small one; it is that the strong field has a big chance of producing a change, and the weak field only a small chance of producing the same change. When radiation acts on a body containing a great number of electrons the final result is the same on the new theory as on the old. But there is a difference of method which is similar to the difference in propulsion between a motor-car and a steam engine; on the new theory the charged body is propelled by a succession of little kicks, whereas on the old theory it was propelled by a steady pressure.

I have tried to sketch, in the short time at my disposal, the outlines of the changes which the past quarter-century has introduced into our conception of the nature of electric forces and of the electromagnetic field. You will agree with me that there have been giants at work in the field of pure electrical theory. When the history of present-day science comes to be finally written, the quarter-century we have just lived through will, so far as we can now judge, stand out as the period in which man first began to understand the true nature of electricity.

ANNUAL DINNER, 1925.

The Annual Dinner of the Institution was held on Thursday, 12th February, 1925, at the Hotel Cecil, when the President, Mr. W. B. Woodhouse, presided over a gathering numbering 522 persons.

Among those present were: The Rt. Hon. Sir A. Steel-Maitland, Bart., M.P. (*Minister of Labour*), Lt.-Col. the Rt. Hon. Wilfrid Ashley, M.P. (*Minister of Transport*), The Rt. Hon. the Viscount Falmouth (*Member of Council*), The Rt. Hon. Sir Henry Norman, Bart., P.C., The Hon. Sir Charles A. Parsons, K.C.B., F.R.S. (*Hon. Member and Faraday Medallist, I.E.E.; President, Institute of Physics*), The Rt. Hon. Sir J. Cook, G.C.M.G. (*High Commissioner for the Commonwealth of Australia*), The Hon. Sir T. Mackenzie, G.C.M.G., M.L.C. (*New Zealand*), The Hon. Sir T. A. Coghlan, K.C.M.G., I.S.O. (*Agent-General for New South Wales*), Sir M. Sheldon, K.B.E. (*New South Wales*), The Hon. H. P. Colebatch, C.M.G. (*Agent-General for Western Australia*), The Hon. J. Huxham (*Agent-General for Queensland*), Sir Sydney Chapman, K.C.B., C.B.E. (*Permanent Secretary, Board of Trade*), Sir Frank Heath, K.C.B. (*Secretary, Department of Scientific and Industrial Research*), Sir James Devonshire, K.B.E. (*Vice-President*), Sir Joseph E. Petavel, K.B.E., D.Sc., F.R.S. (*Director, National Physical Laboratory*), Sir Charles Bright, F.R.S.E., Sir Tom Callender, Sir Arthur Durrant, C.B.E., M.V.O. (*H.M. Office of Works*), Sir Henry Mance, C.I.E. (*Past President*), Sir William Noble, Sir John Snell (*Past President, I.E.E.; Chairman, Electricity Commission*), Rear-Admiral C. T. M. Fuller, C.B., C.M.G., D.S.O. (*Third Sea Lord and Controller of the Admiralty*), Colonel G. H. Addison, C.M.G., D.S.O., R.E., Mr. T. H. U. Aldridge (*Chairman, China Centre*), Mr. P. F. Allan (*Hon. Secretary, North-Eastern Centre*), Mr. Ll. B. Atkinson (*Past President, I.E.E.; Chairman, British Electrical and Allied Industries Research Association*), Major R. L. Barclay, C.B.E. (*Chairman of Council, London Chamber of Commerce*), Mr. J. W. Beauchamp (*Member of Council*), Mr. H. Booth, O.B.E. (*Electricity Commissioner*), Mr. J. R. Brooke, C.B. (*Permanent Secretary, Ministry of Transport*), Mr. A. Carpmael, B.A., Mr. R. A. Chattock (*Member of Council*), Mr. F. W. Crawter (*Member of Council*), Colonel R. E. Crompton, C.B. (*Past President and Hon. Member*), Mr. J. Dalton (*Master, Drapers' Company*), Mr. R. A. Dalzell, C.B., C.B.E. (*Director of Telegraphs and Telephones, G.P.O.*), Mr. W. R. Davies, C.B. (*Principal Assistant Secretary, Technical Branch, Board of Education*), Mr. J. Duncan-Hughes (*Member of House of Representatives, South Australia*), Mr. D. N. Dunlop (*Member of Council*), Dr. W. H. Eccles, F.R.S., Lt.-Col. K. Edgcumbe (*Member of Council*), Dr. S. Z. de Ferranti (*Past President and Faraday Medallist*), Mr. F. Gill (*Past President*), Monsieur J. Grosselin (*Past President, Société Française des Electriciens; I.E.E. Local Hon. Secretary for France*), Mr. A. F. Harmer (*Member of Council*), Mr. H. H. Harrison [*Chairman, Mersey and North Wales (Liverpool) Centre*], Mr. H. Hastings (*Local Hon. Secretary for Spain*), Mr. W. C. Henderson, K.C., D.Sc., Mr. J. S. Highfield (*Past President*), Mr. W. E. Highfield (*Member of Council*), Mr. H. Hooper (*Hon. Secretary, South Midland Centre*), Mr. G. W. Humphreys, C.B.E. (*Chief Engineer, London County Council*), Dr. H. H. Jeffcott (*Secretary, Institution of Civil Engineers*), Mr. T. B. Johnson (*Chairman, North Midland Centre*), Mr. W. E. Tyldesley Jones, K.C., Mr. G. A. Juhlin (*Past Chairman, North-Western Centre*), Mr. J. E. Kingsbury, Mr. W. W. Lackie, C.B.E. (*Electricity Commissioner*), Mr. W. Lawson (*Chairman, South Midland Centre*), Mr. S. R. Lowcock (*Chairman, Association of Consulting Engineers*), Mr. W. McClelland, C.B., O.B.E., Captain L. McNamee, U.S.N. (*Naval Attaché, United States Embassy*), Mr. Stanley Machin, J.P. (*President, Association of British Chambers of Commerce*), Brig.-Gen. H. O. Mance, C.B., C.M.G., D.S.O., Mr. S. W. Melsom (*Member of Council*), Mr. H. M. Morgans, B.Sc. (*President, Institution of Mining and Metallurgy*), Brig.-General M. Mowat, C.B.E. (*Secretary, Institution of Mechanical Engineers*), Mr. W. Nairn (*Chairman, Western Centre*), Mr. W. H. Norton (*President, Incorporated Law Society*), Mr. A. Page (*Vice-President, I.E.E.; Electricity Commissioner*), Mr. F. Palmer, C.I.E. (*Past President, Institution of Civil Engineers*), Mr. C. C. Paterson, O.B.E., Mr. L. St. L. Pendred (*Member of Council, Institution of Mechanical Engineers*), Col. T. F. Purves, O.B.E. (*Member of Council, I.E.E.; Engineer-in-Chief, G.P.O.*), Mr. P. J. Pybus, C.B.E., Mr. W. R. Rawlings (*Member of Council*), Dr. Alexander Russell, M.A., LL.D., F.R.S. (*Past President*), Mr. E. H. Shaughnessy, O.B.E. (*Member of Council*), Mr. Roger T. Smith (*Past President*), Mr. C. P. Sparks, C.B.E. (*Past President*), Colonel H. C. Sparks, C.M.G., D.S.O., M.C., Mr. A. A. Campbell Swinton, F.R.S. (*Vice-President*), Mr. W. C. P. Tapper (*President, Incorporated Municipal Electrical Association*), Captain T. Toyoda, D.S.O., I.J.N., Mr. P. D. Tuckett (*Hon. Treasurer*), Mr. O. C. Waygood [*Hon. Secretary, Mersey and North Wales (Liverpool) Centre*], Mr. W. J. U. Woolcock (*President, Society of Chemical Industry*), and Mr. P. F. Rowell (*Secretary*).

After the Loyal Toasts had been duly honoured, the President read the following messages from other Societies :—

From the Société Française des Electriciens :—

"Heartily congratulate the Institution of Electrical Engineers on the magnificent example of development and fruitful activity which it gives to all sister societies. The French Society looks forward with pleasure to the opportunity for close collaboration which will be provided by the conference on High Tension Lines to be held in Paris next June."

From the Associazione Elettrotechnica Italiana :—

"While thanking you and the Council for the kind invitation to the Annual Dinner of your great Institution,

I much regret my unavoidable absence. At the same time I take the opportunity of presenting my deepest respects to you and of expressing to the Institution the deepest gratitude of the Italian Electrotechnical Association for the kindness shown to us in London last July. GIUSEPPE SARTORI, President."

The Rt. Hon. Sir Arthur Steel-Maitland, Bart., M.P. (Minister of Labour), in proposing the toast of "The Institution of Electrical Engineers," said: "I am deeply sensible of the honour of being asked to propose this toast. From one point of view it is quite superfluous to propose the Institution's health, because the vitality of the Institution is amply shown by the figures of its membership. There is, however, a greater significance in its growth than is indicated merely by its numerical well-being. It is my business—and not always a pleasant one—to look over the state of industry and employment throughout the country, and I find that unemployment in the electrical industry is much less than one-half of what it is in the insured trades of the country as a whole. I should be far from saying that this means that it is all plain sailing in the industry. If there is a margin of profit in the business it is very often not a great one, and I know that sometimes it does not exist at all. All the same, I do see in the electrical industry the expansion of exports—not rapid, but, still, steady—and the industry at home growing in volume though I am bound to say that I wish we could supply all the home requirements without assistance from abroad. Therefore, I always think that although the fortunes of other engineering trades are alternating, the electrical industry has got a quite direct current towards success, and truly the importance of such an expansion goes beyond the Institution and beyond the industry itself. It is over a century since this country knew anything like the depression in trade from which we have suffered here during the last four years. After the Napoleonic wars there was something akin to it, but only then; and in that day the cure came through the general manufacturing expansion that took place over the country as a whole. To-day there is no such possibility of great general expansion, but the electrical is the one industry in which there is a great and immediate and quite inevitable growth, and to my mind it is to the expansion in electricity, both in itself and in the facilities which it can provide to other industries in town and country, that we have got to look for the large improvement which we hope will take place in the existing conditions in England and Scotland to-day. In the electrical industry it always seems to me that, while it is true of all other industries that technical skill and organizing capacity are needed, there is a special need in electricity as in chemistry to use every means available for keeping up with and, if possible, getting in front of the other great competing countries. When I was in charge of the Department of Overseas Trade it always seemed to me that neither America nor Germany took any account of the electrical industry of our country when they set to work to divide up the world's markets. Broadly speaking, that was the case before the war, but during the war, and since, there has been a development here in the electrical world that has made other great countries take account of us as one of themselves before they proceed to divide up the trade of the world. It is, however, absolutely vital to us to keep abreast of them in technical skill and organization, and in an open-minded view of the whole situation, so that the development of electricity may work out to the benefit of the country as a whole. If these vital considerations are to be fulfilled they have got to be fulfilled by the Institution of Electrical Engineers. It is for that reason that, speaking as a business man to men of business and of science, I venture to wish in absolute sincerity all prosperity to the Institution and I am proud to propose its health this evening."

The President, in responding, said: "I must thank the proposer of the toast for the good wishes which he has expressed in regard to the Institution. The Institution is indeed growing rapidly, and its growth is, I think, an indication of the growing importance of electrical engineering in civilization to-day. We are living in a period of the most extraordinary scientific activity, when not merely are many of the fundamental theories of physics being upset and replaced by new ones, but almost it seems that every worker in the field of science is bound to discover some new result which can be applied at once by the engineers, and in practically all such applications electricity takes a part. That is not to be wondered at, I suppose, if one accepts the modern theory that electricity is more fundamental than matter. It must, however, make electrical engineers think not only of the immediate future, but of the enormous possibilities of development which are taking place and the enormous changes in scientific applications which must ultimately be brought about. The period in some respects reminds one of the latter part of the eighteenth century when the steam engine was being created and when every day the application of this new power led to some new discovery and some new development. In making that comparison I do not think that the position of the electrical engineer to-day can be more aptly described than in the remark that Matthew Bolton made to Boswell some 150 years ago when Boswell visited his works at Soho, two miles from Birmingham: 'I sell here, Sir, what all the world desires to have—POWER.' I think that is the keynote of the electrical engineer's work to-day.

"The transmission of messages by electrical means has brought about a closer association of mankind of the utmost value. It is only a very short time since one of our Past Presidents, Mr. F. Gill, told us of his dream of international telephony. That dream to-day seems as if it is going to be realized, and the work of electrical engineers in all civilized countries will by that means have a tremendous effect on their development. Broadcasting has become world-wide. We hear of telephone messages being received in the most distant parts of the earth, and the future possibility of vocal communication with our kinsmen in all the Dominions of the Empire is a consideration that one must welcome; communication between the far-off Dominions and this country by means of direct speech will be a change from our present method of communication which must bring about the closer and closer association of the English-speaking races.

"In the field of manufacture electrical engineers, in a time of national trade depression, have, relatively speaking, been prosperous. No doubt our manufacturers have to complain of high taxation. No doubt they have to complain also of the diminished power of foreign countries to purchase our products. But, as Sir Arthur Steel-Maitland has pointed out, we have a great deal for which to be thankful, as compared with the general engineering trade. Whatever deficiency there may be in our export trade, I think it will be agreed that it is not due to any deficiency of ability or energy on the part of the electrical manufacturers of this country. The wonderful exhibition of British engineering at Wembley last summer was a demonstration to the world that we have in no way lost our ability to produce the finest machinery in the world; and I have no doubt that the effect of that Exhibition will be far-reaching and will, in course of time, as other countries acquire the means of purchasing, have its effect on our export trade. As to the home market for our manufactures, perhaps the electricity supply industry is the best index of what that market is and may be, and I think one may safely say that the prospect there is rosy. The public supply of electricity is a very great power for increasing the comfort of the people, for improving health, and for the reduction of arduous labour—all of which must have an effect not only on the prosperity of the country, but on the happiness of the people. The use of electricity in the home is developing so rapidly that it seems to me that in a very few years the tasks of domestic labour will be reduced out of all knowledge, so much so, that one may perhaps look forward to the day when a candidate for Parliament need only say that he is an electrical engineer to receive the solid support of the women voters! The electricity supply industry, although in the past it has suffered very much from legislation, is now booming, and it will continue to do so, I think, if it is given a fair field. There is a considerable amount of public misunderstanding as to the progress that has been made in electricity supply in this country both during and since the war. In fact, only to-day I saw a statement in a newspaper that the average price of electricity in this country was 5d. a unit. It is hardly necessary to mention that that is erroneous. The average price at which the power companies in this country have been selling electricity is less than 1d. per unit, whilst the big municipalities, despite the larger proportion of lighting with which they have to deal, have sold current at an average price not much higher than that of the power companies. It only needs a continuation of the present development and demand for electricity to ensure that in a few years even these prices will be substantially reduced. To attain this the industry needs freedom from disturbance, or at least, if any change is proposed, an assurance that the views of the industry will be taken before any final plans are made. I think I can say on behalf of the members that the Institution will be only too glad to give its assistance in any matter of that kind. Whatever difference of opinion there may be as to electrical legislation, I think there is no doubt that we are all of one opinion as to the able way in which the laws governing electricity supply have been administered, and I should like to take this opportunity of expressing the widespread regret at the forthcoming retirement of one of the Electricity Commissioners, Mr. Harry Booth. Finally, as to the Institution, I think that the position of the electrical engineer to-day, and the position of the Institution also, are due very largely to that happy spirit of co-operation, that willingness to exchange information and that ability to work together for the good of science and industry which all engineers seem to possess. I believe that the Institution will continue to work for the development of science, for research, for invention, and for knowledge, not only in the interests of the profession of electrical engineers, but in the interests of our country and of the great Empire of which it is a part."

Sir John Snell (Past President, I.E.E., and Chairman, Electricity Commission) then proposed the toast of "Our Guests," to which **Lt.-Col. the Rt. Hon. Wilfrid Ashley, M.P.** (Minister of Transport), and **The Rt. Hon. Sir Joseph Cook, G.C.M.G.** (High Commissioner for the Commonwealth of Australia), responded.

A reunion was subsequently held in the Victoria Hall of the hotel.

THE OPTIMUM DAMPING IN THE AUDITIVE RECEPTION OF WIRELESS TELEGRAPH SIGNALS.

By L. B. Turner, M.A., Member, and F. P. Best, M.Sc., Student.

(*Paper received 3rd October, 1924, and read before the* Wireless Section *4th February*, 1925.)

Summary.

This paper is an account of an experimental investigation of the extent to which it is advantageous to reduce the damping in a receiver for telegraphic signals from modern continuous-wave stations, when the usual rectifier and telephone are used as indicator. It was found possible to produce, hold stable, and measure decrements below those giving optimum reception. Numerous determinations of optimum damping were made, the observed signals coming from six commercial transmitting stations of wave-lengths ranging from about 4 000 to 23 000 m. The several observations on any one station show remarkable accord amongst themselves, and the measured optimum damping exponents for all stations and wave-lengths are found to lie within a narrow range. The significances of speed of signalling in relay and in auditive reception are contrasted.

Table of Contents.

(1) Introduction.

It was pointed out in a recent paper * by one of the present authors that in the modern wireless technique it is feasible to employ receiving circuits in which the damping is reduced, by triode retroaction, further than it is advantageous to go. As the decrement of the receiving circuit is reduced, its response to a sustained tuned incoming signal is augmented, but therewith the inertia effects, which are responsible for the transient epochs following the starting and stopping of the incoming signal, become more and more pronounced. Sensibly "square-topped" signal E.M.F.'s impressed on the receiver by the sending station produce in the receiver "saw-tooth" current curves, resembling the "arrival curves" of a submarine telegraph cable, the shape of the curves being determined by the product $n\delta T$, where n is the frequency of the signal E.M.F., δ is the decrement of the receiving circuit, and T is the duration of the signal element (the morse dot). In the paper referred to, arrival curves were calculated for various values of $n\delta T$, with the specific object of estimating theoretically how small $n\delta T$ can advantageously be made when a relay is used to record the signals. A limiting value of $n\delta T$ in the neighbourhood of 2 is there suggested; this would make $n\delta = 200$ for a speed of 125 words per minute (w.p.m.), and $n\delta = 40$ for 25 w.p.m.

It might at first be thought that the results of this theoretical examination of relay reception could be applied to the ordinary auditive reception by rectifier and telephone, and that accordingly $n\delta = 40$ would be about the most propitious value of the damping index in such a receiver, since aural speeds are around 25 w.p.m. Any experimental test of such an hypothesis would of course be very valuable. But in truth the question is complicated by psychological considerations; and experience seems to indicate that the ear, when reading weak morse signals, is unable to tolerate too gradual a rise and fall of sound at the beginning and end of the morse dot or dash, however much protracted may be the sensibly uniform sound intervening. Expressed otherwise, the ear, unlike a relay, seems to demand adequate definition of the beginning and end of a mark, however low the rate of signalling. Consequently, although the operator of a suitable receiver may have complete control of the damping (and can indeed cause it to pass through zero, so that his receiving circuits generate oscillations), there must be some most propitious setting. This setting is probably more or less independent of the speed of signalling, provided the latter is low. He is able to reach it by trial, his ear being the guide; but what the damping of the receiver may then be appears to have been hitherto merely conjectural. We know of no data, before the present experiments, for making the definite calculation in any particular case, or even for framing a rough theoretical estimate.

The experimental investigation * described here had for its aim the determination of optimum receiver dampings for continuous-wave morse signals under practical working conditions. The signals observed were the ordinary signals issuing from various intercontinental stations at work on wave-lengths between 4 350 and 23 450 m; the receiver, with independent heterodyne, contained an oscillatory circuit of very low damping, the tuning and damping being under perfect control; and the adjustments were effected under guidance of the ear of the observer to make the resulting signals most easily *legible* when they were so reduced as to be only very faintly *audible* in the telephones. The decrement of the circuit thus adjusted is termed the optimum decrement for that incoming signal, and

* L. B. Turner: "The Relations between Damping and Speed in Wireless Reception," *Journal I.E.E.*, 1924, vol. 62, p. 192.

* The work was carried out in the wireless laboratory of the Engineering Laboratory, Cambridge University, with the permission of Prof. C. E. Inglis during 1922–23.

was thereupon measured. The chief experimental difficulty to be met was to ensure that the decrement during the measuring operations remained at the value given to it during the adjusting (receiving) operation; for the low decrements involved—down to 0·002—could be obtained only by resort to triode retroaction, and the value of negative resistance introduced by retroaction is of course subject to alteration with alterations of oscillation amplitude occurring in the process of measurement.

Our ignorance of the actual values of such receiver decrements seemed so profound that if results could only have been obtained subject to wide errors—say between twice and one-half the true value—the work would have been regarded as fruitful; and since the adjustment depended upon a psychological judgment of the optimum, it was expected that some such divergences would have been recorded, at least as between two observers, even if not so markedly with a single observer. Experience has shown, however, that the concordance between several independent adjustments and measurements on the same station is very much better than had been anticipated, the optimum degree of "ringing" of the signals as adjusted by two observers, or by one observer on different days, showing decrements of remarkable uniformity.*

(2) Experimental Method.

The circuits adopted are shown in skeleton in Fig. 1. The low-decrement circuit under test is C_1L_1. It forms part of the anode circuit of triode 2, and is excited by the signal applied to the grid of triode 2 from an aperiodic aerial circuit via an aperiodic amplifier triode 1. A powerful local heterodyne oscillator is very loosely coupled to L_1 by L_4. This oscillator serves as heterodyne when adjusting the receiver for the signals, and as the exciting circuit when the decrement of the receiver is subsequently measured. The amplitude of oscillation in C_1L_1 is observed by a Moullin voltmeter M.V.† placed across the anode circuit ‡ of an amplifier triode 3, which also excites the amplifier-rectifier 4. The anode circuit of triode 4 contains the retroaction coil L_3 very loosely coupled to L_1, serving to reduce the decrement of the C_1L_1 circuit to any desired value; also the telephone T for observing the signals when adjusting the retroaction. These circuits were arrived at after much preliminary work, and a brief explanation of their features is given.

The introduction of the amplifier triode 3 permits a very loose coupling between coils L_1 and L_3, so that wide mechanical movement of L_3 with respect to L_1 is required for small variations of retroaction, and the decrement of the circuit C_1L_1 is controlled with great precision.

In order to avoid all question of alteration of damping under the action of the signal itself, it is essential that the amplitude of signal used in adjusting for the optimum decrement should be extremely small. Further, the additional deflection of M.V. produced by the incoming signal must be negligible in comparison with the deflection already produced by the heterodyne alone, since otherwise the kick of the instrument would prevent an accurate reading. On this account, and in order that the coupling between L_1 and L_4 should be very small, an unusually powerful heterodyne oscillator was used.

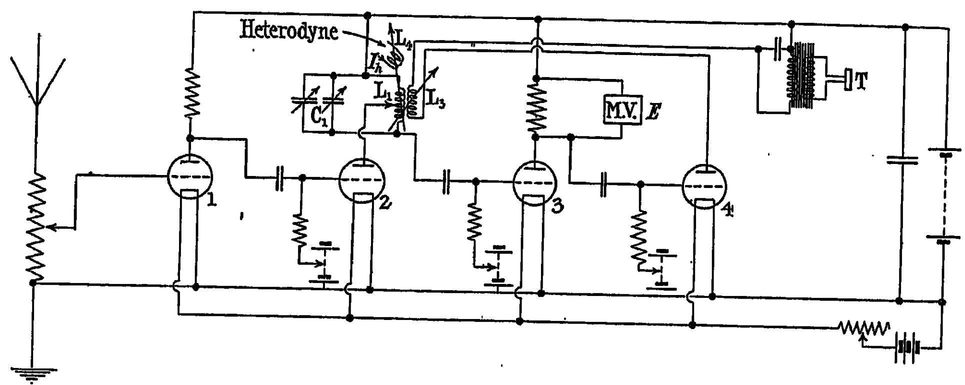

Fig. 1.—Circuit used in the tests.

The use of the heterodyne oscillator itself, with no displacement of the coupling coil L_4, for the subsequent measurement of the decrement is regarded as an important feature. With the very low decrements involved, a separate oscillator for measuring the decrement could hardly be introduced without endangering the constancy of the decrement.

It had seemed likely that, for reception of the American stations, it would be necessary to use an amplifier triode 1 between the aerial and the low-decrement circuit C_1L_1. This amplifier was later found to be unnecessary, but was retained as being quite innocuous.*

To avoid grid current damping in triode 3, which if present would necessarily vary with oscillation amplitude, a high anode potential was used, with considerable negative bias on the grid. The value of grid potential

* An observer whose assistance was requested was always asked to adjust until the signal became most legible in his own judgment.

† See *Journal I.E.E.*, 1923, vol. 61, p. 295.

‡ Shown here as a resistance, but actually a relatively highly damped oscillatory circuit, of which more will be said hereafter.

* The aerial used was some 90 ft. high at one end. Usually only a very small fraction of the available P.D. was tapped off from the aerial circuit potentiometer.

in each of the triodes 1, 2 and 3 was capable of separate adjustment, and before any measurements were made the grid potential was adjusted so that the triode was operating at about the middle of the nearly straight portion of its characteristic. Alterations of triode parameters consequent on minute unavoidable changes of amplitude while setting the receiver and measuring the decrement were thereby reduced to a minimum.

After the receiver has been adjusted, the decrement must be measured without making any change liable to alter that decrement. Consequently the amplitude in C_1L_1 must not be appreciably altered, a proviso which rules out the usual methods of determining the decrement of a circuit by observing change of amplitude therein consequent on a known alteration of its resistance or reactance (distuning). Further, even though L_3 and L_4 are but very lightly coupled to L_1, no movement of those coils should be made. These conditions led to the following rather elaborate ritual—viz. operations (*a*), (*b*), (*c*) and (*d*) described below—which was practised at each observation.

Operation (*a*). *Setting the receiver.*—Tune C_1L_1 to the signal, and tune the heterodyne to give a high-pitched note therewith. Increase the retroactive coupling L_1L_3, so strengthening the signal and increasing the sharpness of tuning of C_1L_1; and maintain the weakness of signal by lowering the tapping point on the aerial potentiometer. Adjust coupling L_1L_4 and (if necessary) the heterodyne current I_h in L_4, so that M.V. reads a value E between 1 and 2 volts.* Proceed with these adjustments and readjustments, taking special care to leave C_1L_1 exactly tuned to the signal, until the retroaction is judged to be that enabling limitingly weak signals to be most easily read. There is then a certain amount of "ringing" (merging of marks and spaces), any increase of which would more than offset the accompanying gain of strength. The damping of C_1L_1 is now of the "optimum" value; we have still to measure it.

Measuring the decrement.—The method is to impress in C_1L_1 two E.M.F.'s of slightly different frequencies and suitably different amplitudes such that the current amplitude in C_1L_1 remains at precisely the value given by operation (*a*). These E.M.F.'s are impressed from the heterodyne oscillator itself, without change of coupling L_1L_4. The strength of each of these E.M.F.'s is measured by the corresponding current I_h in coil L_4, and the frequency by the capacity K of the oscillatory circuit of the heterodyne.†

Operation (*b*).—Tune heterodyne exactly to C_1L_1,‡ reducing its current to I_b so as to maintain M.V. reading at the former value E.

Operation (*c*).—Increase the heterodyne current from I_b to I_a, retuning the heterodyne (if necessary) exactly to C_1L_1, the capacity being then (say) K_0. The reading of M.V. is now somewhat greater than E, and is of no significance for the decrement determination.

* Such a value is convenient for reading on M.V., and vastly exceeds the signal E.M.F. applied to the grid of 4, while giving a response in T varying sensitively with the signal E.M.F., so enabling C_1L_1 to be tuned precisely by ear. With the low dampings employed, exact tuning of C_1L_1 is of course vital to the success of the measurements.

† The oscillatory circuit of the heterodyne oscillator was provided with condensers permitting accurate measurement of minute changes of capacity, and with vacuo-thermo-junction in series with L_4 for measuring I_h.

‡ It was distuned by (say) 500–1 000 periods per second in (*a*).

Operation (*d*).—Distune the heterodyne from capacity K_0 to K_d and K_d' (one above, the other below, K_0), causing the voltmeter reading to fall back in each case to E. Let k be the amount of distuning, where $k = \frac{1}{2}(K_d - K_d')$.

If C_1L_1 is the only oscillatory circuit in the receiver, it is easily seen * that its decrement [during operations (*a*), (*b*) and (*d*), but not (*c*)] is given by the formula

$$\delta = \frac{\pi k/K_0}{\sqrt{[(I_a/I_b)^2 - 1]}}$$

It has already been stated, however, that the impedance in the anode circuit of triode 3 was not in fact a pure resistance but was a rejector circuit like C_1L_1, although much more highly damped. This seriously complicates the analysis,† since the amplification in triode 3 is a step between circuit C_1L_1 and M.V., and also (which is more important) between C_1L_1 and the retroaction E.M.F. impressed therein from L_3. After operation (*a*) this impressed E.M.F. is a maximum and sensibly in phase with the oscillatory current in C_1L_1; and after the distuning it is necessarily to some extent reduced in magnitude and changed in phase. To establish the validity of the above formula for δ, it is therefore necessary to show that the magnitude of that component of the retroaction E.M.F. which is in phase with the current is altered to a negligible extent by the change of heterodyne frequency as between operation (*a*) and operations (*b*), (*c*) and (*d*). That such is the case in these experiments is shown in Appendix 2.

(3) Results Obtained.

Complete particulars of the dimensions of the circuits employed are given in Appendix 3. The resistances there shown are those of the oscillatory circuit measured at the relevant wave-length.

One typical series of observations—those on Marion—is given completely in Table 2; and the values of δ_1 and $n\delta_1$ for every observation made on all stations are collected in Table 3.

(4) Discussion of Results.

A very satisfactory feature of the results given in Table 3 is the close uniformity of the several observations on each station. It had been expected that far wider divergences would have been found, as the setting of the circuit [operation (*a*) in Section 2] was necessarily a matter of personal judgment. The precautions particularly desirable in such cases, to eliminate all influence on the observer of prejudice and expectation, were taken; not only were all adjustments upset between one observation and the next, but heterodyne currents of very unequal values were employed in the several observations on one station.

It could not be observed that the optimum damping was affected by the pitch of the heterodyne note,

* Appendix I.

† It was realized, after the observations had been made, that for the sake of simplicity of theoretical analysis it might have been wiser to put up with various experimental inconveniences involved in making this impedance substantially a pure resistance, or in retuning it between operations (*a*) and (*d*).

* Information kindly supplied by Mr. R. N. Vyvyan, Engineer-in-Chief, Marconi's Wireless Telegraph Co.

provided that this was above about 500 periods per second.

Although the stations observed cover frequencies extending from 69×10^3 to 13×10^3 periods per second, the values of the product are seen to lie within the narrow range of 143 to 99. The view (referred to in Section 1) that it is the shape of the rising and falling portions of the amplitude time curves which determines the optimum decrement, is thus strongly supported. What, on this view, the critical "shaping" as demanded by the ear looks like to the eye is indicated in Fig. 2. Here the letter "C" as received is drawn for $n\delta = 100$, the curves of E.M.F. impressed from the transmitter being assumed sensibly square-topped in shape, and the speed of signalling being taken as 25 w.p.m.

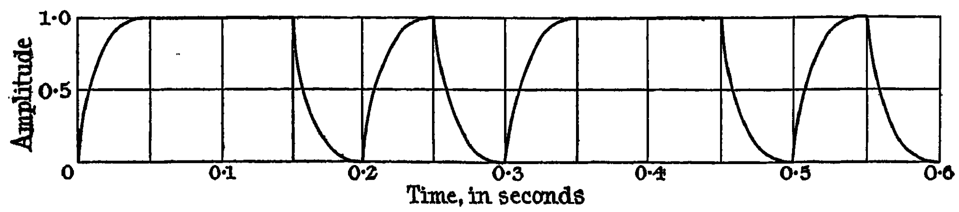

FIG. 2.—Letter "C" at 25 w.p.m. when $n\delta = 100$.

All the signals observed were of hand speed, and no attempts were made to measure any effect of changes of speed. The speeds did, of course, vary considerably from time to time; and no indication that the value of the optimum decrement depended on the speed was noticed. The authors' opinion is that, however much the speed of sending might be reduced, the optimum damping for auditive reception would not fall much below the values found in these experiments.

The optimum damping of the receiving circuit must, of course, depend on the sharpness of rise and fall at the sending antenna, the more the inertia there the less being the inertia tolerable in the receiver. It seems probable that the transmitter's share in the total inertia effects is small in comparison with that in a receiver in which $n\delta = 100$.* If it were not, the uniformity of the observations on stations covering so wide a range of wave-lengths, and including arc, alternator and triode generators, would be very surprising. It does not seem possible to infer from the observations any distinctions between the qualities of signalling, from the standpoint of the inertia effects we are studying, with these three different types of generator.

Summing up the positive results of the investigation, it may be concluded that the optimum damping for the auditive reception of signals from any modern continuous-wave station is such as to make the $n\delta$ of the receiving circuit of the order of 120, which corresponds to $\delta = 0\cdot0012$ at $\lambda = 3\,000$ m, and $\delta = 0\cdot008$ at $\lambda = 20\,000$ m; that such decrements are easily obtained by triode retroaction; and that with suitable care they may even be measured with considerable precision.

* The authors are not aware of any direct measurements of the rates of growth and decay of current in a sending aerial when the key is depressed and raised.

APPENDIX 1.

DERIVATION OF FORMULA FOR CALCULATING THE DECREMENT.

Let the circuit CLR in Fig. 3 represent the actual circuit $C_1R_1L_1$ with its triode retroaction and connections as in Fig. 1.* There is impressed in L from the heterodyne coil L_4 :—

In operation (b), an E.M.F. $\propto I_b$, of the resonance frequency $p/(2\pi)$, producing a current in CLR measured by the voltmeter reading E.

In operation (c), a larger E.M.F. $\propto I_c$, of slightly distuned frequency $q/(2\pi)$, producing sensibly the same current in CLR (since the reading E is unchanged, and the frequency is almost unchanged).

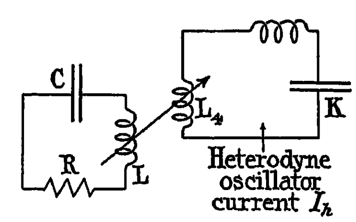

FIG. 3.

Now $q^2/p^2 = K_c/(K_c \pm k)$, and $p^2LC = 1$

$$\therefore \quad q^2LC = K_c/(K_c \pm k)$$
$$\doteqdot 1 \mp k/K_c$$

Hence
$$\frac{I_b^2}{R^2} = \frac{I_c^2}{R^2 + [qL - (1/qC)]^2}$$

i.e.
$$I_c^2R^2 = I_b^2\left[R^2 + \left(\frac{q^2LC - 1}{qC}\right)^2\right]$$
$$= I_b^2\left[R^2 + \frac{(k/K_c)^2}{q^2C^2}\right]$$

i.e.
$$\left(\frac{I_c^2}{I_b^2} - 1\right)R^2 = \left(\frac{k}{K_c}\right)^2 \frac{p^4L^2C^2}{q^2C^2}$$
$$\doteqdot \left(\frac{k}{K_c}\right)^2 p^2L^2$$

$$\therefore \quad \delta = \frac{\pi R}{pL} = \frac{\pi k/K_c}{\sqrt{[(I_c/I_b)^2 - 1]}}$$

* Taking a simple circuit with a constant resistance R to represent the actual retroactive arrangement may cause some apprehension; for the circuit is used with tuned and distuned impressed E.M.F.'s, and the "negative resistance" introduced by the retroaction depends to some extent upon the frequency. It can be shown, however, that in practical cases the effect of so small a distuning on the resistance of the equivalent simple circuit is quite negligible.

The utility of operation (*c*) lies in the fact that it gives the tuned value K_c of the heterodyne *after* the latter has been modified (by increase of filament current or otherwise) so as to increase its current from I_b to I_c. Such an alteration is apt to necessitate a small alteration of condenser value to hold the frequency constant, so that if the reading of K after operation (*b*) were taken in place of K_c it would be slightly inaccurate.

APPENDIX 2.

EFFECT OF ANODE CIRCUIT OF TRIODE 3 BEING AN OSCILLATORY CIRCUIT INSTEAD OF A PURE RESISTANCE.

The actual anode circuits of triodes 2 and 3, shown in skeleton in Fig. 1, were as shown in Fig. 4. We have to ascertain how the output anode voltage v_a of triode 3 is affected, with a given input grid voltage v_g, by distuning the v_g frequency from the resonance value $p/(2\pi) = 1/[2\pi\sqrt{(C_2L_2)}]$ to the slightly different value $q/(2\pi)$.

The impedance Z of the rejector circuit between anode and filament of triode 3 may be shown to be (dropping the suffixes 2)

$$Z = qL'\frac{\left[\frac{1}{qC} - qL''\left(1 - \frac{M^2}{L'L''}\right)\right] + jR}{R + j\left[qL - \frac{1}{qC}\right]}$$

where $j = \sqrt{-1}$.

At resonance the impedance is

$$Z_0 \doteqdot pL'\frac{\frac{1}{pC} - pL''\left(1 - \frac{M^2}{L'L''}\right)}{R}$$

Near resonance, when $q = p(1 + x)$, where $x << 1$,

$$Z_x \doteqdot Z_0 \frac{R}{R + j\left[qL - \frac{1}{qC}\right]}$$

$$= \frac{Z_0}{1 + j\frac{2\pi x}{d}} \qquad \text{where } d \equiv \frac{R}{2nL}$$

$$= Z_0\frac{1}{A}\underline{\left|\alpha\right.} \qquad \text{where } A \equiv \sqrt{[1 + (4\pi^2x^2/\delta^2)]}$$
$$\alpha \equiv \text{arc tan } 2\pi x/d$$

Calling ρ the anode-filament slope resistance of the triode (about 30 000 ohms) and ν the amplification factor, the performance of triode 3 is shown by the idealized circuit diagram and vector diagram of E.M.F.'s in Fig. 5. The output voltage v_a when tuned is OP, and when distuned is OQ. The distuning introduces negligible error in so far as OQ cos β (i.e. the resolved component of the retroaction E.M.F., distuned) is sensibly equal to OP (i.e. the retroaction E.M.F., tuned).

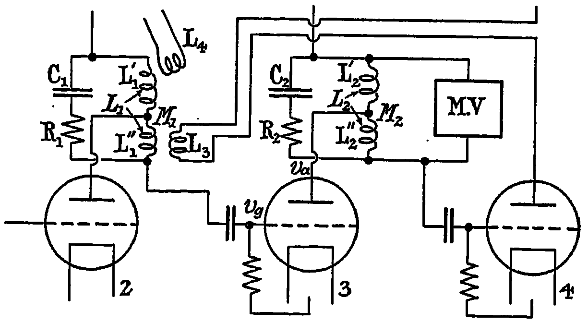

FIG. 4.—Anode circuits of triodes 2 and 3 in detail.

NOTE.—M_1, M_2 are the mutual inductances between the parts L_1', L_1'' and L_2', L_2'' of the coils whose whole inductances are L_1, L_2 respectively.

Now, since α and β are small angles,

$$\beta \doteqdot \alpha\frac{\rho}{Z_0 + \rho}$$

and

$$(\text{OQ cos } \beta)/\text{OP} \doteqdot \frac{(Z_0 + \rho)\frac{\alpha - \beta}{\alpha}\sqrt{(1 - \beta^2)}}{Z_0}$$

$$= \sqrt{(1 - \beta^2)}$$

$$\doteqdot 1 - \tfrac{1}{2}\beta^2$$

$$= 1 - \left(\frac{\rho}{Z_0 + \rho}\right)^2\frac{2\pi^2x^2}{d^2}$$

The circuit dimensions, tabulated in Appendix 3, enable us to evaluate this expression, bearing in mind that the distuning fraction x is half the ratio k/K_c of Section 2 and Table 2. The largest values of k/K_c, and the consequently worst values (i.e. departing most from unity) of (OQ cos β)/OP, in the observations on each of the several stations, are given in Table 4.

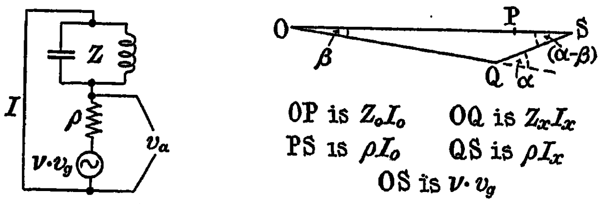

FIG. 5.—Action of amplifier 3.

In view of the closeness to unity of the last row of figures in Table 4, it is thought unnecessary to attempt to make allowance for the effect of distuning on the anode circuit of triode 3.

Ongar and unknown station :—$L_1 = 3\,450$, $L_2 = 3\,260$, $L_3 = 260$, $L_4 = 150$ μH.
Other stations :—$L_1 = 20\,500$, $L_2 = 22\,300$, $L_3 = 3\,040$, $L_4 = 150$ μH.

The triodes were of the well-known "R" pattern. Common filament and anode batteries were used, the latter being of 120 volts.

Discussion before the Wireless Section, 4 February, 1925.

Prof. E. W. Marchant: As the authors point out, the determination of the most suitable wave-shape for a dot would appear to depend on psychological effects, and I should like to ask whether the observers who determined what they considered to be the best damping of the system (which, of course, determines the shape of the dot) were of approximately the same age; sharpness of hearing varies considerably as between old and young people, and there may also be differences due to the kind of telephone used. Why is it that a high anode potential is best in order to reduce the damping of the grid circuit? I take it that the real test for damping is low energy absorption. The slope of the characteristic curve is appreciably the same for most anode voltages and, therefore, one would not anticipate that there would be very much difference in the variation in grid current that would be taken by a valve with different anode potentials. The method of measuring the decrement by altering the tuning of the receiving circuit is, of course, the one that is usually adopted. The method described in the paper of altering the frequency of the current in the heterodyne circuit and adjusting the strength of the heterodyne current is one that should be particularly useful for measuring decrements in circuits, where it is desirable that no tuning adjustments should be made. The comparison between the results depends on the shape of the received signal current and that, as the authors point out, must depend on the shape of the dot emitted from the transmitting station. Other things being equal, a square wave at the transmitting end gives a closer approximation to a square wave in the receiving circuit. I do not think that the authors have obtained as much from their results as they might have done. For the three Alexanderson alternator stations the value of $n\delta$ works out at about 107. For the arc station, which has a very much longer wave-length, very nearly the same value of $n\delta$ is obtained. It would appear, therefore, that the squareness of the transmitting signal for these two types of station would be about the same. The two triode transmitting stations have a very much shorter wave-length, but very closely corresponding results (142 and 143) are obtained for $n\delta$, and it seems possible that the difference between the results for the alternator and arc stations and those for the triode stations may be due to differences in the squareness of the dot sent from the transmitting station.

Captain N. Lea: It would, I think, be of interest if the results set forth in the paper were translated into terms involving decrement at musical frequency. The tests were apparently carried out under conditions where static interference was practically negligible—that is to say, "readability" was a function of signal strength and "ringing" only, and not of "noise level"—and thus there should be no fallacy in applying the alternative interpretation of results. If, however, a musical decrement term is used instead of a radio-frequency decrement term, the former would almost certainly appear in the expression for "readability." I do not know whether the authors made any assumptions or any investigation in regard to the signal form of the transmitters which were observed. I believe that in several of the transmitters on which readings were taken an effort is made to increase the power of the dot, for instance, and in other ways to have some control over the rate of growth and decay of the current in the transmitting aerial. It occurs to me that this may have some effect on the results, though the uniformity obtained with the various stations suggests that there is, perhaps, not so much in this point.

Mr. R. V. Hansford: The paper is very useful in describing a method of measuring the decrement of a receiving circuit, and the splendid series of consistent results obtained is a great testimonial to its sensitivity and accuracy. One wonders, when one sees the extraordinary uniformity obtained for $n\delta$, whether the figure obtained is not in some manner a measure of the best adjustment of a particular type of receiver rather

than a general independent value of $n\delta$, and it would be interesting to know if measurements have been made on more than one type of receiver. The authors comment on the fact that the shape of the curve depends on the decrement of the circuit, and that the psychology of the individual is such that it is necessary to have a distinct break between the dash and the dot, but it seems questionable whether in a complex receiver the rise and fall of the signal current follow the simple law corresponding to the shape of signal given in Fig. 2. It seems possible that the " ringing," which the authors suggest is the limiting condition, is a function of the *shape* of the received signal and could be improved by deliberately modifying the shape, e.g. cutting off the bottom tails. In practice, the operator actually adjusts the decrement of his receiver within wide limits by varying the retroaction until he obtains the best conditions, and I should be glad to hear if, independently of the great scientific interest, the authors are able to draw any conclusion from their results in regard to practical receiver design.

Mr. R. E. H. Carpenter: Have the authors made any observations on stations which emit a spacing wave, particularly those which emit during the spacing period a feeble wave of the same frequency as that used for marking? It would seem that such observations might alter a little the conclusions to which the authors have come.

Major A. G. Lee: The measurement of the decrement of a circuit which is not retroacted is a comparatively easy matter, but when retroaction is present a number of difficulties present themselves. Some of these difficulties have not been discussed in the paper, and, while they may not relatively be of great importance, I propose to outline them for the sake of completeness. With reference to Appendix 1, which gives the derivation of the formula for calculating the decrement, the method adopted is one in which a mistuned oscillator is adjusted to give an output equal to that given by a weaker oscillator when the latter is adjusted to resonance. Now in the mistuned case the current in the circuit will be dependent upon the value of the impedance, viz. $\sqrt{[R^2 + \{qL - (1/qC)\}^2]}$. The variation of R with mistuning is dealt with by the authors in a footnote on page 497, which states that the effect is negligible. The reactance will, however, also be affected by the retroaction, and for mistuning which is not too wide the reactance varies much more rapidly with frequency than the same function does in a circuit without retroaction. The expression $\{qL - (1/qC)\}^2$ should therefore be replaced by one which takes into account the effect of the retroaction on the reactance. This effect has been worked out by Bennett and Peters.* A further point is whether the frequency of the heterodyne oscillator q is accurately given by the expression on page 497, viz. $q^2/p^2 = K_o/(K_o \pm k)$. If a valve oscillator is brought near a tuned circuit the frequency generated will be affected by the presence of that circuit, the effect differing according to whether the tune of the circuit is above or below the heterodyne oscillator frequency, so that k is not necessarily a measure of the change of frequency. Very loose coupling, which was adopted by the authors, is one of the means of reducing the discrepancy, and another more certain method is to use a screened heterodyne and to pass the output of the heterodyne oscillator through a unidirectional coupling such as a triode. The method adopted in which the combined signal and heterodyne currents are passed through a rectifying valve and the circuit of retroaction L_3, leads to the difficulty that it is not clear whether the retroaction is the same as it would have been if the signal only had been subject to retroaction. When the measurement is made the heterodyne oscillator alone passes through the retroaction circuits. It is not clear, for example, that the proportions of signal and heterodyne are the same after the process of grid rectification in triode 4 as they are before they reach that grid, or that the retroaction on the weak signal is the same as that measured by the aid of the powerful oscillator, owing to the action of the rectifier 4 through which the retroaction has to pass. During the positive peaks of the heterodyne the signal will be damped by grid current and the retroaction reduced. The phenomenon of " ringing " described by the authors is present on most wireless receivers when there is a very narrow band obtained by fine tuning. This ringing trouble appears to be due to the fact that the ear is not very sensitive to changes of amplitude of sound and does not appear to be able to distinguish in correct proportion the peaks and hollows of a signal which does not die away completely during the spacing intervals. The method adopted in commercial wireless receivers to overcome this defect is to use negative grid bias on some of the later stages of the receiver, such as the low-frequency portion. This process cuts off the hollows, and the ear now has definite periods of sound followed by equally definite periods of silence. The limit to this proceeding is, of course, that eventually the dots would disappear in the negative grid bias.

Messrs. L. B. Turner and **F. P. Best** (*in reply*): In reply to Prof. Marchant, no investigation was made as to the possible influence of age of observer, or pattern of telephone receiver used. No doubt there is a conceivable connection between youthfulness and sharpness of rise and fall, in acoustics as in other affairs; but we do not think that the kind of telephone could be of appreciable significance unless it possessed quite unusually low damping. The virtue of adequately high anode potential in avoiding grid damping is that it permits the use of sufficient negative grid bias to keep grid currents out of the question. With reference to the suggested distinction between the optimum values of $n\delta$ with triode transmitters on the one hand, and with arc and alternator transmitters on the other, the results, as far as they go, certainly point in the direction Prof. Marchant indicates. The distinction is the more remarkable in that the presumably greater steadiness or " purity " of the triode oscillation would tend towards lower decrements with the triode. The fact that the values of $n\delta$ appear to be distinctly higher with triodes than with arc or alternator, points towards greater keying inertia effects with the former than with the latter. We think, however, that the stations observed were too few to justify any but the most

* BENNETT and PETERS: "Resistance Neutralization," *Journal of the American Institute of Electrical Engineers*, 1922, vol. 41, p. 234.

tentative conclusion as to the relative qualities of the several types of transmitter.

Captain Lea's remarks imply, very truly, that in consideration of the effect on the ear the acoustic amplitude-time curves are of more direct interest than those for the high-frequency currents. But with the superposed heterodyne oscillation, the rectified current is proportional to the high-frequency amplitude; so that curves such as Fig. 2 may be supposed to portray approximately acoustic amplitude also. With the high damping of the acoustic system, and upwards of 25 acoustic (heterodyne note) cycles per morse dot, it is likely that the high-frequency and the acoustic amplitudes rise and fall in close concordance. It is noted in the paper (bottom of page 495) that reduction of the note to some low pitch did appear to affect results, and high pitches were employed in consequence.

Mr. Hansford wonders whether the surprisingly consistent values of optimum $n\delta$ may not be a property of one particular type of receiver. But, apart from a long chain of tuned circuits, we do not see how one receiver can differ from another, in its response to signals to which it is tuned, in other respects than sensitivity (which is irrelevant) and decrement (which we had under complete control). The influence of the "shape" of the received E.M.F. has been referred to in the paper and by several speakers (see our reply to Prof. Marchant above). The suggested possible improvement by some form of curbing has been referred to in the paper already published in the *Journal* (loc. cit., page 493). With regard to Mr. Hansford's concluding remarks, we do not wish to suggest that the information as to working decrements here afforded will be of any help to an operator in setting his instruments, but we do hope that it will be of use to the calculator who provides him with better instruments. In inquiries as to the effect of atmospherics in receiving circuits, for example, the lack of this knowledge has been acutely felt.

Two of the stations whose signals were observed were of the kind mentioned by Mr. Carpenter. Bordeaux used the distuned spacing wave, and Ongar the feeble continued emission between the marks.

Major Lee casts some doubt on the validity of the formulæ of Appendix 1, on three counts. First, he fears the distuning effect of the retroaction employed to reduce resistance. But this, we think, is a second-order effect which vanishes when the retroaction just reduces the decrement to zero; and in any case, whether great or small, it is no more than an experimental inconvenience, since the reactance of the circuit was maintained at zero by retuning during the retroaction adjustments [see under "Operation (*a*)," page 495]. Secondly, he fears that the coupling between L_4 and L_1 (Fig. 1) might make the frequency of the heterodyne depart appreciably from proportionality to the square root of its capacity K. We point in reply to the extreme looseness of the coupling between the heterodyne L_4 and the test circuit L_1C_1. Thus the heterodyne generated E.M.F.'s in its oscillatory circuit of the order of 100 volts. From this a minute E.M.F. is impressed on L_1 from L_4, so small that on multiplication by π/δ (say 500 times) in the circuit L_1C_1, and again between grid and anode in triode 3 (say a further 4 times, or 2 000 times in all), it produces only 1 volt or so on the measuring instrument M.V.; that is to say, the anode fluctuation of the heterodyne oscillator was some 200 000 times the E.M.F. it impressed on L_1C_1. Thirdly, he suggests that the decrement as measured, when only the heterodyne oscillation was present in the circuits, may have been appreciably different from its value in the system as adjusted for optimum reception in the telephone, when signal and heterodyne were present together. To this we can only reply that the amplitude of the signal was so small in comparison with the heterodyne as to produce no observable effect on the deflection of M.V., and point to the precaution taken with the triodes to reduce to a minimum "alterations of triode parameters consequent on minute unavoidable changes of amplitude while setting the receiver and measuring the decrement" (see top of page 495).

SOME ACOUSTIC EXPERIMENTS WITH TELEPHONE RECEIVERS.*

By Professor E. MALLETT, M.Sc., Member, and G. F. DUTTON, Ph.D., Student.

(*Paper first received 17th September, 1924, and in final form 13th January, 1925.*)

SUMMARY.

A Rayleigh disc is used to find the resonant frequency and decay factor of a telephone receiver under different circumstances as regards diaphragm clamping and air cavity behind the diaphragm. The field of sound in front of a resonator tube and a telephone receiver is investigated by the Rayleigh disc and by a device for measuring sound pressures, and direct measurements are made of the overall acoustical-electrical efficiency of a telephone receiver.

TABLE OF CONTENTS.

INTRODUCTION.

Investigations of the properties of telephone receivers have received much attention in recent years and our knowledge of these instruments has been very largely increased, especially by the work of Prof. A. E. Kennelly and his various collaborators, now collected and published in book form.† In all of these investigations the method of attack has been by electrical measurements of the supply to the receiver, and by measurements of the actual movement of the telephone diaphragm. In the experiments described in the first part of the present paper an alternative method of attack is developed which depends upon measurements made on the sound wave produced by the receiver.

The particle velocity of the sound wave is measured by the well-known Rayleigh disc. The construction of a suitable form of disc, and its calibration, are described in Section (1). Measurement of the particle velocity in front of the telephone receiver, while constant current of variable frequency is passed through it, gives the resonance curve of the receiver, and from the resonance curve the resonance frequency and the decay factor can be obtained. That the values obtained in this way by measurements with the Rayleigh disc are the same as those obtained from electrical impedance measurements is shown by the experiments described in Section (2). With this established, the Rayleigh disc method, on account of its greater simplicity, is applied to investigate some of the outstanding problems of the telephone receiver. In Section (3) the unsymmetrical resonance curves very often obtained are shown to be due to imperfection of clamping of the receiver diaphragm, and a design of rigid clamping which gives symmetrical curves is described. Using this rigid clamping, the influence of the size of the air cavity behind the diaphragm on the resonant frequency and on the decay factor is examined in Section (4). It is found that as the cavity volume is decreased the resonant frequency is increased owing to the additional stiffness given to the diaphragm by the increasingly stiff air cushion. At the same time, the decay factor is increased, and the increase is measured with substances of different sound-absorbing properties forming part of the cavity walls. The results given in this section provide a ready means of tuning a diaphragm to a desired frequency, and indicate the importance of making all surfaces in the cavity smooth and rigid in order to avoid losses. In marked contrast with the fundamental, the influence of the air cavity on the overtone frequencies is shown to be negligible. Some interesting double-resonance effects are obtained in Section (5) by extending the cavity by means of a tube of variable length.

In the second part of the paper a direct measurement of the efficiency of a telephone receiver is made by measuring the electrical input power and the acoustical output power. The electrical input measurement is made by the use of a valve voltmeter in the well-known three-voltmeter method of power measurement. The measurement of the acoustical power output presents greater difficulties. The power from any acoustical source is the surface integration of the product of the particle velocity, the pressure, and the cosine of the phase angle between the two, carried out over any complete surface containing the source. But if the surface is a sphere with the source at the centre, and the radius of the sphere is sufficiently great, the sound wave has become at this surface a spherical wave with an equivalent point source at the centre of the sphere, and a single measurement of the particle velocity or the alternating

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† A. E. KENNELLY: "Electrical Vibration Instruments" [MacMillan].

air pressure is sufficient to determine the power output of the source.

This approximation to a spherical wave is shown to be true [see Section (6)] in the case of a source of sound consisting of a resonator tube excited by a telephone receiver, by the agreement with theory of the particle velocities measured at various distances along the axis of the tube. Except at frequencies close to resonance, however, the output of a receiver alone is insufficient to make this method applicable. So a more sensitive sound-measuring device is constructed [see Section (7)] consisting of a long thin tube opening out on to the diaphragm of a telephone receiver, the coils of which are connected through a three-stage amplifier to a valve voltmeter. This device is calibrated against the Rayleigh disc in the spherical field of sound produced by the resonator tube, and its indications are found to depend upon the pressure at its mouth. Finally [Section (8)] this device is used to explore the field of sound around a telephone receiver fitted with a large flange, to find the least radius at which the wave may be considered to be hemispherical, and so to make measurements of the acoustical output. Close to resonance of the receiver, where the pressure explorer fails owing to its own resonance nearly coinciding, the Rayleigh disc is used for the measurement. The overall efficiency of the receiver measured is found to be about 1 per cent at resonance, falling to 0·1 per cent at a frequency removed from resonance by about 200 cycles.

Part I. Use of Rayleigh Disc in Telephone Receiver Experiments.

(1) The Construction and Calibration of a Rayleigh Disc.

Experiments such as the determination of the efficiency of telephones and microphones, the resonant frequencies and damping of telephone discs and loud-speaker horns, require sound-measuring devices which have no reaction upon the source and which can be accurately calibrated. The Rayleigh disc, used without any resonator, suggests itself for the measurement of the vibrating air velocity. Its calibration may be performed accurately with unidirectional air flow.

König * has from theoretical considerations determined the following relation connecting the torque upon a thin circular disc and the gas velocity:—

$$\text{Torque} = \tfrac{4}{3}\rho r^3 v^2 \sin 2\theta$$

where ρ = density of the gas,
v = velocity of the gas,
r = radius of the disc,
θ = angle which the normal to the disc makes with the direction of gas flow.

If the stream of gas is alternating in direction, such as in a sound wave, the velocity v will be the R.M.S. velocity of the gas.

The torque produced on a disc is very small for low gas velocities; with a disc 0·5 cm diameter and velocity of air 0·5 cm/sec. (R.M.S.) the torque developed is 0·0438 dyne-cm when $\theta = 45°$; at a frequency of about 500 cycles per sec. this velocity represents a loud sound.

* *Annalen der Physik und Chemie*, 1891 vol. 43, p. 43.

A thin mirror 0·5 cm in diameter suspended by unspun silk was at first employed. It was sensitive but its zero was not sufficiently stable. Very thin phosphor-bronze strip (1 mil wire, rolled) was tried but found to be too stiff, but exceedingly thin glass fibre was found to be perfectly stable and sensitive. The fibre was made by C. V. Boys's method of making quartz fibres. It was found that unless the mirror was very thin and light, considerable difficulty was encountered due to lack of sufficient damping. Silvered microscope cover-slips answer admirably. Such a disc 5 mm in diameter

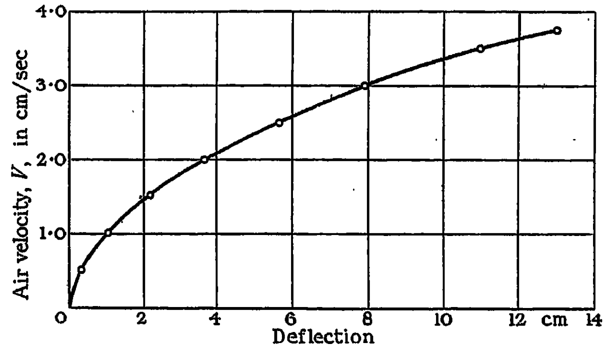

Fig. 1.—Rayleigh disc calibration.

with a glass-fibre suspension will come to rest, after being violently disturbed, in 2 or 3 seconds.

Since the elastic constants of the suspension fibre were not known, it was decided to calibrate the disc in a direct current of air. The disc was suspended in the centre of a tube 5 cm diameter, in a current of air caused by the displacement of water in a tank. The rate of flow of the water in the tank was observed, and from the knowledge of the respective areas of the tank and tube the air velocity was deduced. With air velocities above 2 cm per sec., however, the air flow was very erratic, due to the formation of eddies in the water

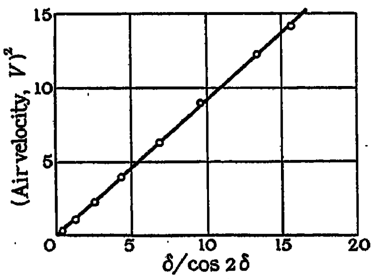

Fig. 1 (*a*).

pipes and valve. To surmount this difficulty a sensitive inclined Venturi meter was constructed and calibrated. Velocities above 2 cm/per sec. were then obtained with the use of this meter and a rotary air pump. A large air reservoir was placed in series with the air supply from the pump to eliminate slight pulsations.

The deflection of the disc mirror was observed by means of a lamp and scale. The initial position of the plane of the mirror was 45° to the direction of air flow, the length of the suspension fibre was 39 cm, and the distance of the disc to the scale 48 cm.

Fig. 1 shows the calibration curve obtained for this

disc, where the air velocity in cm per sec. is plotted against the deflection a. Fig. 1 (a) gives a verification of the formula Torque $= KV^2 \sin 2\theta$. For equilibrium the torque $= A\delta$, where δ is the angle of deflection of the disc, and is given by $\tan 2\delta = a/d$, where d = distance from scale to disc = 48 cm. When the disc is deflected by an angle δ, the angle θ of the formula becomes $(45 - \delta)$, and $\sin 2\theta = \sin (90 - 2\delta) = \cos 2\delta$.

Hence $A\delta = KV^2 \cos 2\delta$, or $V^2 = \text{const.} \times \delta/\cos 2\delta$. The relation between V^2 and $\delta/\cos 2\delta$ should be a straight line, and that this is very nearly true for the curve of Fig. 1 is shown in Fig. 1 (a).

The calibration of the disc carried out in a steady air current by theory holds for an alternating air current of any telephone frequency. This is confirmed by later experiments, which indicate that the disc calibration is independent of frequency.

(2) Receiver Resonance Curves.

A Rayleigh disc calibrated in this way was used to find the resonance curve of a receiver diaphragm, and hence its decay factor and resonant frequency, and

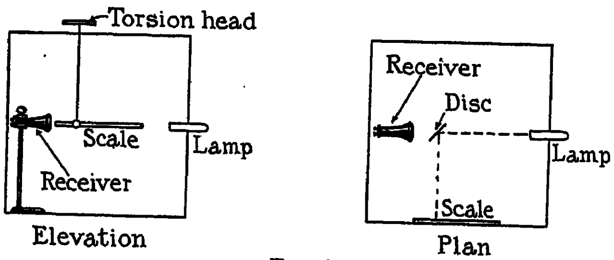

Fig. 2.

at the same time impedance measurements were made so that the values obtained could be compared with those obtained by the method described previously.* Power of known frequency was obtained by actuating a triode amplifier with a valve oscillator, care being taken that the anode voltage and grid voltage of the amplifier were so arranged that no load was placed on the oscillator. In this way the frequency calibration of the oscillator is not interfered with by current changes in the telephone. The oscillator was calibrated against the fundamental and harmonics of a valve-maintained tuning-fork by adjusting the capacity of the oscillator until beats from telephones in the anode circuits of the maintained fork and the amplifier disappeared. The value of K in the relation

$$\text{Frequency} = \frac{K}{\sqrt{\text{(capacity)}}}$$

decreased slightly with rise of frequency. A curve connecting K and the capacity was drawn so that the frequency could be determined on a slide-rule from the value of the capacity.

A sound chamber was made of a wooden box 1 metre cube, the inside walls of which were coated with a 4-in. layer of loose cotton waste. Such walls, as will be seen in later experiments, are sufficiently sound-absorbent to prevent any trouble from reflected waves.

* E. Mallett: *Journal I.E.E.*, 1924, vol. 62, p. 517.

The receiver under investigation was supported by a retort stand in this chamber. A torsion head on the top of the box carried the Rayleigh disc, which was illuminated by a lamp in the side of the box opposite the receiver, and the deflections of the disc were read on a translucent scale let into the side of the box next to the lamp (see Fig. 2). The zero position of the disc was adjusted by means of the torsion head so that its normal made an angle of 45° with the axis of the telephone and hence with the sound wave from the telephone.

The current to the receiver was supplied from a step-down transformer in the anode circuit of the amplifier valve, and included in the receiver circuit was a Duddell thermal milliammeter and a variable resistance. A valve voltmeter was connected across the receiver terminals, and the resistance always adjusted so that the voltage was the same, viz., 2·2 volts. The impedance at any frequency was therefore $2 \cdot 2/i$, where i is the current reading on the milliammeter.

Table 1.

Comparison of Damping and Resonant Frequency by Impedance Measurement and by Rayleigh Disc. Potential Difference across Receiver = 2·2 volts.

Frequency	Current	Air velocity V	Z	V/i
~/sec.	mA	cm/sec.	ohms	cm/sec./amp.
613	8·6	0·35	256	40·6
637	8·35	0·45	264	54·0
651	8·1	0·55	272	68·0
704	7·3	1·35	301	185
711	7·58	1·85	290	244
716	8·2	2·25	268	275
723	9·0	2·55	244	284
739	10·33	2·55	212	247
753	10·25	1·85	214	180
775	9·5	1·25	232	132
797	8·95	0·85	246	95
850	8·13	0·45	270	55

The force actuating the diaphragm is proportional to the current, and the diaphragm velocity at any frequency is given by

$$\dot{x} = \frac{F}{z} = \frac{Ai}{z}*$$

where F is the alternating force, A the force factor and z the mechanical impedance of the diaphragm. The air velocities V in front of the receiver will presumably be proportional to the diaphragm velocities, so that

$$V \propto \dot{x} \propto \frac{Ai}{z}$$

or $\frac{V}{i} = \frac{B}{z}$, where B is a constant.

To obtain a resonance curve $(1/z)$ of the diaphragm, V/i must therefore be plotted against the frequency.

The figures obtained in this experiment are given in Table 1. In the first column is the frequency, in the

* Kennelly, *loc. cit.*, p. 93.

second the current through the receiver, and in the third the R.M.S. air velocity as measured by the Rayleigh disc. The calculated value of the receiver impedance ($Z=2\cdot2/i$) is entered in the fourth column, and the air velocity per ampere (V/i) in the fifth. Z is plotted against the frequency at the top of Fig. 3, and V/i below. The circle construction previously described* is carried out on each curve to obtain the tan α/frequency lines at the bottom of the diagram. It is seen that these lines very nearly coincide. The decay factor Δ from each is 146, while the resonant frequencies are 721 from the impedance measurements and 724 from the Rayleigh disc measurements.

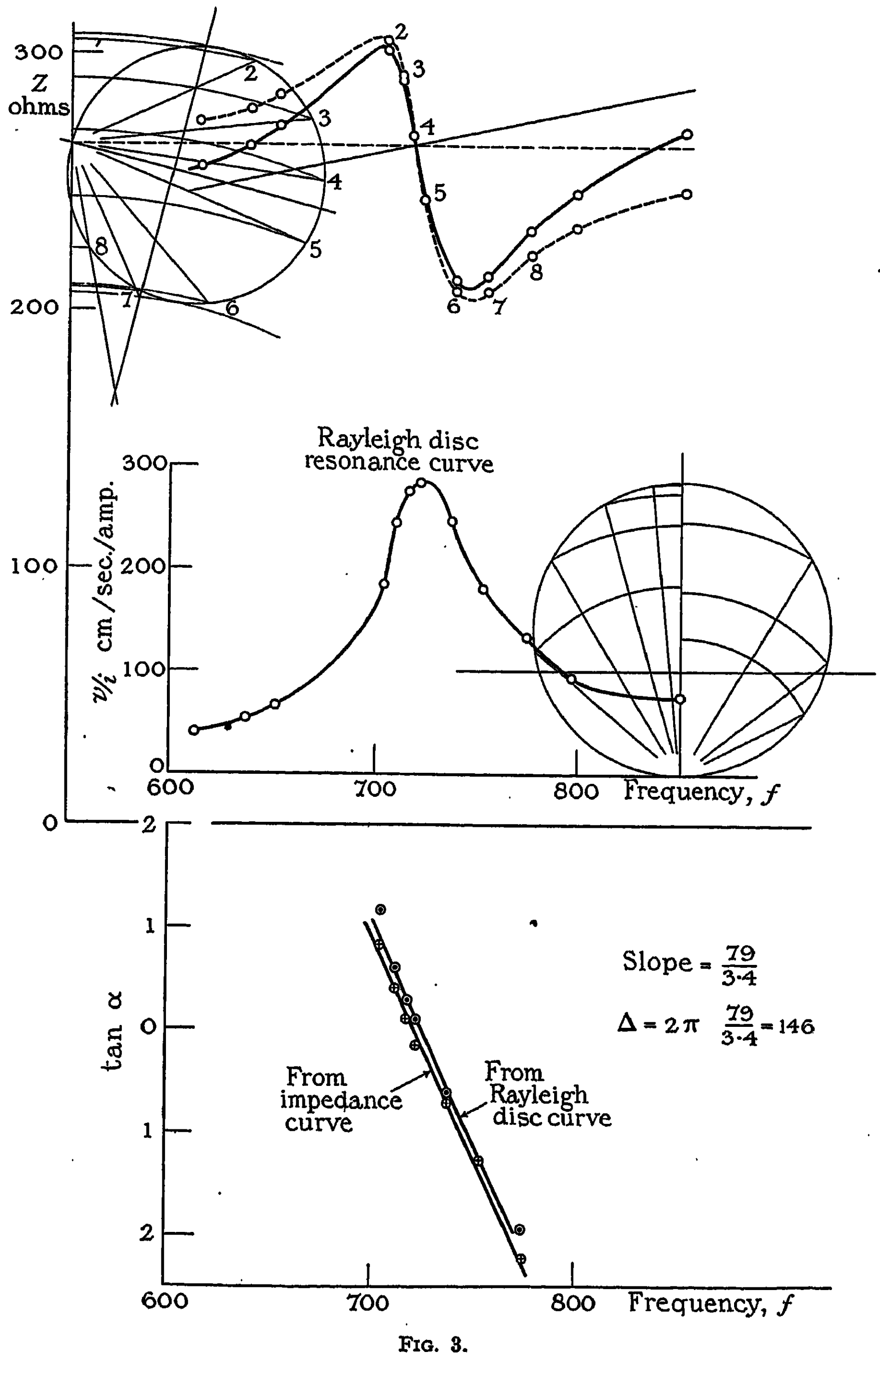

FIG. 3.

It is evident, therefore, that the Rayleigh disc method gives essentially the same values as the impedance method for the resonant frequency and decay factor of the diaphragm, and it was used as a general method in further investigations in preference to the impedance method, on account of its greater simplicity.

* E. MALLETT, *loc. cit.*

In order to reduce the time taken for the disc to come to rest after any adjustments of current or frequency, a key was included in the receiver circuit so that the current supply could be stopped or reduced so as to give, by reason of the altered sound-wave intensity, a judicious impulse to the disc.

(3) Lack of Symmetry in Resonance Curves.

A lack of symmetry was very often observed in the resonance curves obtained from receivers with the diaphragm clamped in the usual way with a screw cap of ebonite, for example in the curve of Fig. 4 for an

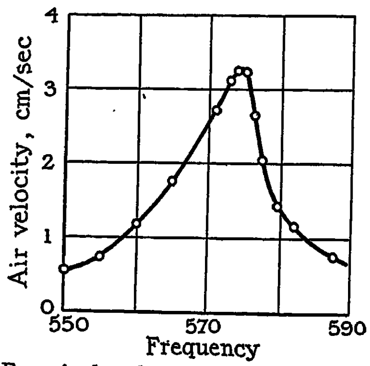

Fig. 4.—For single-pole receiver; diaphragm clamped with ebonite screw-cap.

old single-pole receiver. Here the rise of amplitude while approaching the maximum from low frequencies is much slower than the fall of amplitude after the maximum has been passed. In other cases the reverse has been found. Kennelly * has noticed a similar departure from the theoretical resonance of a single system, and suggests in the discussion on a paper by Prof. R. L. Jones on "Vibration Galvanometers with Asymmetric Moving Systems" (*Proceedings of the Physical Society*, 1923, vol. 35, p. 67) that it may be caused by asymmetry introduced by uneven clamping

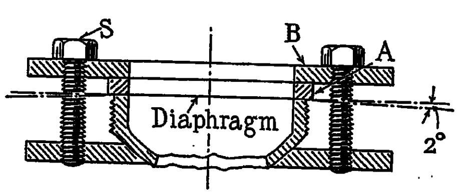

Fig. 5.

of the diaphragms round the edge. That asymmetry exists generally is also noted in a paper † in which the nodal lines of various overtones of a receiver diaphragm were mapped out by sand figures, and was indicated by the appearance of nodal diameters at two different frequencies. The asymmetry was also indicated by the departure of the nodal circle from a true circle into ellipses or pear-shaped figures. In fact the clamping of the diaphragm in those experiments was adjusted until the figure was most nearly a circle.

The receiver from which Fig. 4 was taken was accordingly modified as indicated in Fig. 5 by replacing the ebonite screw-cap by a brass ring A, both the ring and the receiver case being ground slightly conical so that, when the heavy clamping ring B was screwed up tight by the set-screws S, the diaphragm was slightly stretched. The resonance curve now obtained is given in Fig. 6. The asymmetry has disappeared, while the resonant frequency has been raised from 575 to 718 cycles per second, partly owing to the stretch given to the diaphragm but, probably, also owing to the more rigid clamping obtained. It was found, moreover, that only one resonance was obtained for the nodal diameters, and that the nodal circle was apparently a true circle.

It appears therefore that, for experiments on tele-

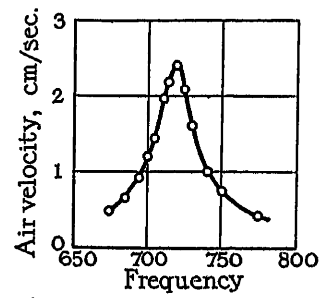

Fig. 6.—For single-pole receiver; diaphragm clamped with heavy brass ring.

phone receivers, clamping in the ordinary way with a screw cap is not satisfactory, but that an arrangement such as the one indicated in Fig. 5 gives perfectly satisfactory results.

(4) The Influence of the Air Chamber on the Resonant Frequencies and Damping of a Telephone Diaphragm.

It has been noticed * that the ratios of the overtones of a telephone diaphragm to the fundamental do not

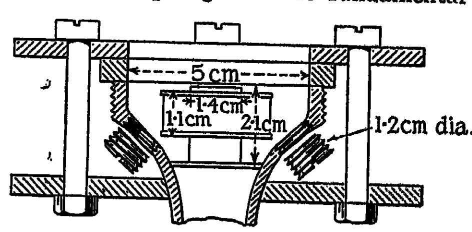

Fig. 7.

conform with either the membrane or the plate theory, but that the ratios of the overtones to the nodal circle agree quite well with the plate theory. Investigations were carried out to ascertain the effect of the air cavity behind the telephone diaphragm upon the resonant frequencies of the fundamental and overtones, with the hope of explaining the apparent departure of the fundamental from the plate theory.

A telephone of the dimensions shown in Fig. 7 was used. The diaphragm was of stalloy 5 mils thick with the enamel removed. It was clamped by a heavy brass ring and four set-screws, with the clamping surfaces

ground dead flat, so that the diaphragm was neither stretched nor buckled when clamped. Under these conditions a true smooth resonance curve was obtained for the fundamental and the first nodal circle. Four

screw plugs 1·2 cm in diameter were tapped into the air cavity casing. With these plugs removed the cavity volume was considered to be infinite.

The resonant frequencies were obtained, for all modes by the ear and the nodal figures were shown by light dry sand.

Table 2 shows the ratios of the higher modes to the fundamental for an infinite cavity and for a cavity volume of 24 cm^3. When the cavity volume is infinite these ratios conform very accurately with those calculated from the theory of a circular plate rigidly clamped at its edge. With a cavity volume of 24 cm^3 all the ratios are too small. The fundamental of the diaphragm has been raised by the increase of stiffness given by the air cavity, while the frequencies of the overtones are not affected.

In order to obtain a relation between the resonant frequency and air cavity a standard telephone was used. The diaphragm was enamelled to an equal thickness on either side, the total thickness of enamel being 5 mils and of the metal 7 mils. The variation of the cavity volume was obtained by pouring in paraffin wax; a period of at least four hours was allowed for the wax to cool and harden before observations were made. The volumes were measured by pouring fine silver sand into the cavity up to the diaphragm level and then pouring the sand from the cavity into a calibrated tube. In taking the resonance curves the Rayleigh disc was suspended at a distance of 2 cm from the diaphragm, and the receiver was actuated by a constant current of 2 mA for the fundamental and 4 mA for the nodal circle.

The curves obtained for the fundamental are shown in Fig. 8, while Fig. 8 (*a*) gives the curve obtained with each cavity for the nodal circle. It is seen that while the reduction of cavity results in a successive increase of resonant frequency in the case of the fundamental, it has no influence on the nodal circle curve. The two curves with different dampings at a cavity volume of 13·6 cm^3 are dealt with later.

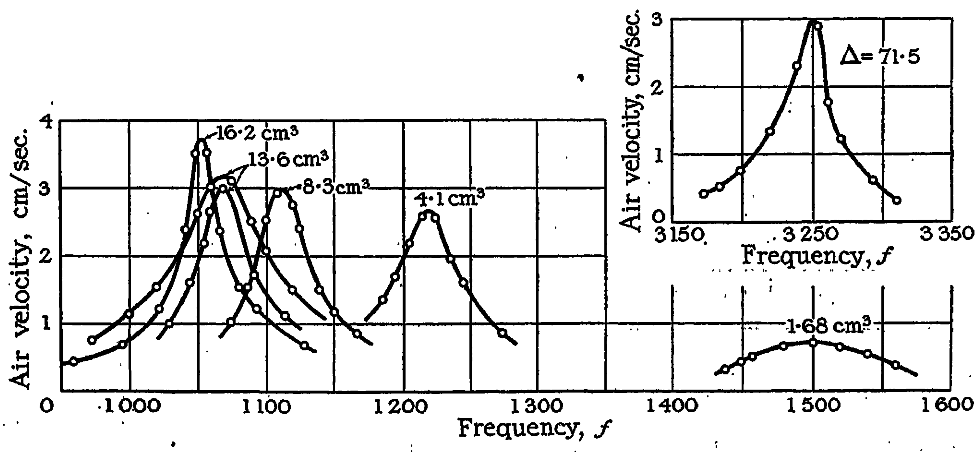

FIG. 8.—Resonance curves for fundamental with various cavity volumes.

FIG. 8 (*a*).—Resonance curve for nodal circle overtone.

up to and including the nodal circle, by means of the Rayleigh disc suspended at a distance of 2 cm from the diaphragm. Plotting air velocity against frequency with constant exciting current, the maximum or peak velocity gave the resonant frequency direct. For higher modes than the circle the resonant point was detected

These results may be explained by the consideration that the pressure alterations of the air in the cavity give rise to an additional restoring force on the diaphragm, and this restoring force for a given diaphragm movement will be inversely proportional to the volume of the air cavity.

Under ordinary circumstances the resonant frequency of a diaphragm is given by

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{S}{m}}\ *$$

where S is the restoring force for unit deflection and m the equivalent mass. If to S we add a quantity $S' = A/v$, where v is the cavity volume, we obtain

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{(S + S')}{m}}$$

from which

$$f_0^2 = \frac{1}{4\pi^2}\left(\frac{S + S'}{m}\right) = \frac{1}{4\pi^2}\left\{\frac{S}{m} + \frac{A}{vm}\right\}$$

$$= B + \frac{C}{v}$$

where A, B and C are constants.

Thus f_0^2 plotted against $1/v$ should give a straight line.

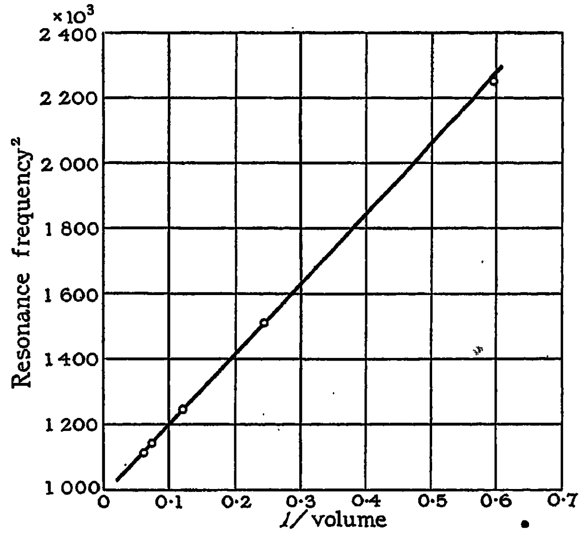

FIG. 9.

In Table 3 are entered the values of f_0 and v from Fig. 8, and the values of f_0^2 and $1/v$ are plotted in Fig. 9.

TABLE 3.

v	f_0	$1/v$	$f_0^2 \times 10^{-3}$	Δ
cm³				
16·2	1 055	0·0617	1 112	84·9
13·6	1 068	0·0736	1 140	167 and 105
8·34	1 115	0·120	1 244	99·3
4·10	1 230	0·244	1 511	124
1·68	1 500	0·595	2 251	314

The points obtained lie on a straight line, thus confirming the explanation given above of the influence of the air cavity.

Fig. 8 (a) shows the resonance curve for the nodal circle overtone. The resonant frequency and damping of this overtone were found to be independent of the air cavity volume down to 1·68 cm³. In the case of the overtones, therefore, there is no communication of alternating air pressure to the cavity as a whole; the outward displacements of parts of the diaphragm are at any instant equal to the inward displacements of the other parts. A reciprocating air flow must take place between the parts of the diaphragm of opposite phase, and not until the cavity is so small as to impede this flow will an alteration of reasonant frequency and damping be expected.

It is thought that these results may explain to some extent the lack of success of the static method of finding the stiffness coefficient of a telephone diaphragm.* The increase of deflection with time of application of load described by Kennelly may be due to the gradual leaking away of air from the cavity, while if the cavity is open to the air through the holes through which the leads are brought, the static determination of the coefficient will not include the stiffness due to the air cushion.

The values of the decay factor $r/(2m)$ derived from the curves of Fig. 8 are entered in the last column of Table 3, and it is at once evident that the volume of the cavity has a large effect upon the damping. The increase of damping with reduction of volume was, however, somewhat irregular in the first readings taken, and it was thought that this might possibly be explained by the surrounding of the coils of the receiver by wax. This supposition was to some extent confirmed by the second figure at $v = 13·6$, which was obtained by boring out some of the wax after it had been nearly full so that now when the receiver coils were nearly completely covered with wax the decay factor was 105, whereas previously when the coils were almost completely exposed, but the cavity volume was the same, the value was 167.

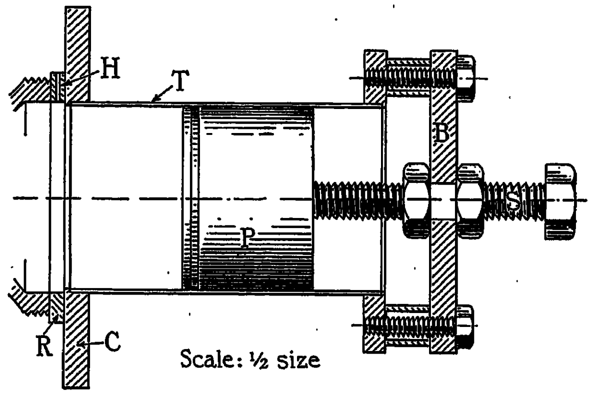

FIG. 10.—Variable air cavity.

Obviously, therefore, the method by adding wax is not a good way to investigate the influence of the air cavity on the damping, and a special device was constructed as shown in Fig. 10, in which an artificial adjustable cavity is fitted on to the front of the telephone, while the normal cavity behind the diaphragm was opened to the atmosphere by removing the plugs shown in Fig. 7. T is a brass tube, 4·9 cm long, sweated into

* KENNELLY, *loc. cit.*, p. 47.

* KENNELLY, *loc. cit.*, p. 41.

the telephone clamping ring C. Within the tube slides an airtight boxwood piston P. The space between the piston and the telephone diaphragm forms the air cavity, the volume of which may be adjusted to a nicety by the screw S and lock-nuts working between the bridge B. To relieve the pressure in the cavity after an adjustment of volume, a taper pin is withdrawn from the hole H in the clamping ring. A Rayleigh disc was suspended in front of one of the holes in the cavity casing, and the whole apparatus was placed in the sound chamber to screen the suspended disc from draughts.

The variation of damping factor with volume was determined with the piston face covered with :—

(i) Smooth brass 0·4 cm thick.
(ii) Hard felt 0·5 cm thick.
(iii) Vaseline 0·2 cm thick.

The results are given in Table 4 and the decay factor is shown plotted against 1/volume in Fig. 11. The

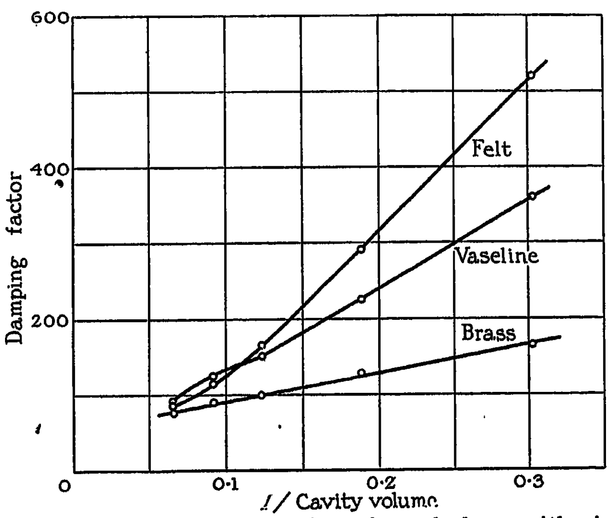

FIG. 11.—Variation of damping of a telephone with air cavity volume and material.

readings for brass give an approximately straight line. Probably the energy loss does not take place to much extent on the surface of the thick brass but is mainly due to air leakage.

TABLE 4.

Volume	1/volume	Damping factor		
		Brass	Felt	Vaseline
cm³				
15·0	0·0667	76·8	87	90
10·7	0·0935	89·0	115	112
8·1	0·1235	100·0	165	150
5·3	0·1890	128·0	290	224
3·3	0·3030	165·0	520	360

The damping factors for felt give a curve which has a tendency to become steeper as the air volume is reduced. The departure from the straight line may be due to the error in the measurement of the air volume, for the felt has a very rough surface. The damping factor for vaseline is at first greater than for felt, but the average slope of the curve is less, the result being that at 3·3 cm³ the damping is 360, while that for felt is 520. The values for vaseline give a very fair straight line. It should be mentioned that the vaseline contained numerous very small air bubbles, and it would therefore be imagined that losses took place owing to the viscosity of the air in these small bubbles and to that of the vaseline round about them.

These experiments show that the acoustical-electrical efficiency of a telephone will depend to some extent upon the air cavity volume and the material of its walls. For large cavities such as 15 to 20 cm³ and with the standard size of diaphragm the effect of different materials will be small, but if small cavity volumes are used the material of the cavity will be a matter of considerable importance. In such cases the insulating material of the windings should be consolidated with wax or, better still, the windings should be enamelled solid. Some commercial telephone receivers have this feature. The reminder of the cavity walls should be of smooth metal, free from air leakage to the external atmosphere or to the receiver handle.

(5) EXTENSION OF CAVITY.

An adjustable air column in the form of a long brass tube was coupled direct to the air cavity behind the telephone receiver by screwing the tube in the casing. The tube was 30 cm long by 1 cm bore, fitted with an airtight piston packed with greased leather. By adjusting this piston the length of the air column could be varied at will from 0 to 28 cm. It was found necessary to equalize the pressure on either side of the diaphragm between each variation of air-column length, by withdrawing a small plug (formed by a knitting-needle) from a hole in the cavity casing.

The telephone was placed in the padded sound chamber with the diaphragm 2·8 cm from the Rayleigh disc. Resonance curves for various lengths of air column were then taken with constant current over a frequency range of 200–3 000 cycles. There was a slight fall in the fundamental resonant frequency according to the theory of Section I (*d*), until the air column was about 10·5 cm long, but beyond this point a double-resonance effect appeared.

Resonant curves are shown in Fig. 12 for air-column lengths of 10·6, 11·6, 14·7 and 19·9 cm. Between tube lengths of 10 and 20 cm, since only two resonances could be detected, it may be concluded that the fundamentals of the diaphragm and of the tube only were acting as a coupled system. No double resonance could be obtained with the overtones of the diaphragm. This confirms the conclusion arrived at in Section 1 (*d*) that a diaphragm vibrating in an overtone produces no change of air pressure in the cavity.

The arrangement is analogous in many ways to the familiar coupled electrical circuits. In such a system, referring to Fig. 12, if OA = OB = natural wave-length of one circuit λ_1, OC = natural wave-length of the other circuit λ_2, and $\sin\theta = \sin \mathrm{COB} = \tau$, the coupling coefficient, then the two wave-lengths λ', λ''

at which resonance appears are given by $\frac{1}{2}$(AC + CB) and $\frac{1}{2}$(AC − CB).*

In Table 5 and Fig. 12 it is shown how far the mechanical coupled system in question agreed with the electrical laws.

When air columns greater than 23 cm were tried, double resonance again occurred, the column then vibrating on its third harmonic.

The application of this investigation is to the loud-speaker, where the horn with its various resonant frequencies must act in a similar manner to the tube in causing multiple resonance frequencies.

TABLE 5.

1 Tube length, l	2 Resonant frequencies		3 Resonant wave-length		4 $(\lambda' + \lambda'')$	5 $(\lambda' - \lambda'')$	6 Wave-length of tube, $4l$	7 Wave-length of tube, from construction
			λ'	λ''				
cm 0	715		47·0		—	—	—	—
10·6	670	910	50·0	36·8	86·8	13·2	42·4	41·0
11·6	650	855	51·5	39·2	90·7	12·3	46·4	45·0
14·7	590	770	56·8	43·5	100·3	13·3	58·8	54·2
19·7	476	735	70·4	45·6	116·0	24·8	79·6	69·5

In cols. 1 and 2 are collected the data of Fig. 12. In col. 3 are entered the resonant wave-lengths (λ' and λ'') calculated from col. 2 as 33 500/f.

In Fig. 13 we have

$$\lambda' = \tfrac{1}{2}(AC + CB)\,; \quad \lambda'' = \tfrac{1}{2}(AC - CB)$$
$$\therefore \lambda' + \lambda'' = AC \quad \text{and} \quad \lambda' - \lambda'' = CB$$

$\lambda' + \lambda''$ is entered in col. 4 and $\lambda' - \lambda''$ in col. 5, and these values are used to construct the wave-length triangles, taking AO = OB = 33 500/715 = 47·0, the natural wave-length of the diaphragm with air cavity.

In col. 6 is entered the wave-length of the tube (4 times its length) and in col. 7 the wave-length measured off as OC from the triangles. The agreement is not too good, and the analogy is probably not complete, but it is sufficiently good to show the points of similarity.

The "coupling coefficient" varies from sin 15·2° (= 0·28) in the case of the 10·6 cm tube, to sin 10·6° (= 0·18) in the case of the 19·7 cm tube.

* PIERCE: "Electric Oscillations and Electric Waves," p. 81.

Part II. ACOUSTICAL-ELECTRICAL EFFICIENCY OF TELEPHONE RECEIVER.

(6) A SOURCE OF SOUND OF PURE AND VARIABLE FREQUENCY.

The well-known equation for the actuating force on a telephone diaphragm is :—

$$\text{Force} = K\{B_0^2 - (B_0 + b \sin \omega t)^2\}$$
$$= -K\{2B_0 b \sin \omega t + \tfrac{1}{2}b^2 - \tfrac{1}{2}b^2 \cos 2\omega t\}$$

where B_0 is the permanent flux,
b is the R.M.S. alternating flux due to the current in the windings, and
ω is the angular velocity.

It will be seen that if the alternating flux b is so large that its square is comparable with $B_0 b$, then the second harmonic will be appreciable.

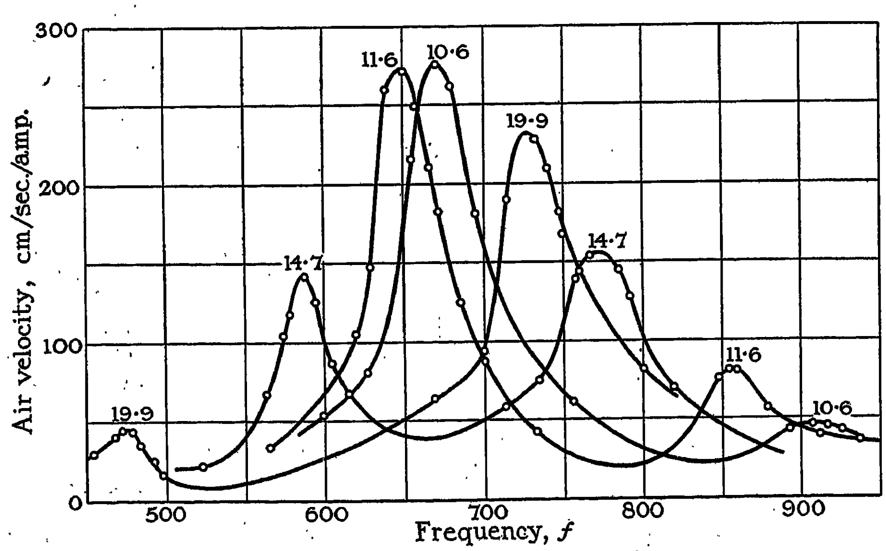

FIG. 12.—Resonance curves for telephone coupled with closed air column.

Again, the restoring force per unit displacement is not symmetrical about the zero, hence a full series of harmonics of rapidly decreasing amplitudes with increase

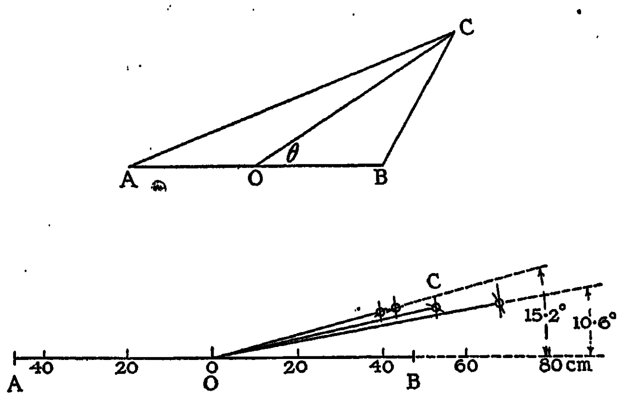

FIG. 13.

of frequency is likely to occur if the amplitude of vibration is large. The second, however, is the only harmonic that is likely to be appreciable.

Resonance curves were taken with a fixed frequency and current and variable tube length. Fig. 16 shows such a curve. It will be seen that the resonances are very sharp, hence if the tube is to give a steady sound output the frequency of the supply must be kept very constant. The distances apart of the peaks are half the wave-length, and the small decrease of amplitude with successive peaks shows how small is the damping introduced by the tube walls.

THE DISTRIBUTION OF SOUND INTENSITY ABOUT THE RESONATOR TUBE, AND THE CALIBRATION OF A TELEPHONE SOUND-PRESSURE EXPLORER.

The shape of a sound wave proceeding from an open tube changes rapidly from a more or less plane wave within the tube to a spherical one at a distance of a few cm from the mouth. The change takes place more rapidly the higher the frequency. According to the results of the experiments at a frequency of 400 and upwards, the wave-front at 5 cm from the mouth of the tube had become sufficiently spherical to obey the law of variation of air velocity with radius within the limits of experimental error. This was the case with or without a large flange on the end of the resonator tube.

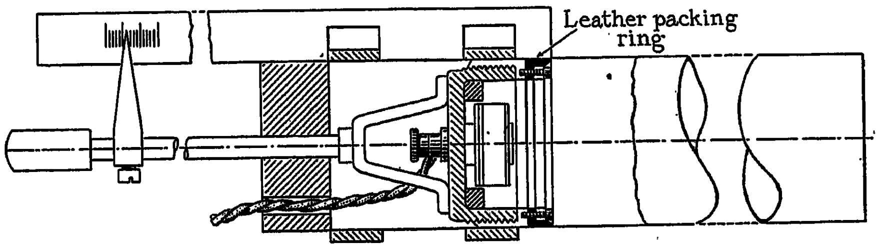

FIG. 14.—Resonator tube and telephone. Scale about half size.

A tube of uniform bore, open at one end and closed at the other, resonates to a fundamental frequency the wave-length of which is about 4 times the length of the tube. The natural overtones of such a tube form an odd series, and if the tube is wide these resonant frequencies will vary considerably from the harmonic series of the fundamental. Such a tube is almost ideal for purifying the sound emitted from a telephone receiver inserted into the closed end of the tube. The second harmonic, if present in the vibration of the telephone diaphragm, will not be reinforced by the tube, and its intensity will fall into insignificance compared with the fundamental. The odd harmonics will be but slightly reinforced by the tube, due to the departure of its natural overtones from the harmonic series.

Such a resonator tube was made of drawn brass 5 cm in diameter and 120 cm long. A telephone of 60 ohms resistance, mounted on a long brass rod, slides within the tube. The sliding fit is rendered perfectly airtight by a greased leather packing ring as shown in Fig. 14. A pointer fixed to the telephone rod indicates the length of the air column on a scale fixed to the tube.

The resonator tube was mounted in the wall of the sound-absorbing chamber; readings were then taken of the variation of air velocity with the telephone receiver current. The relation was found to be a linear one for any frequency (up to 3 000) and length of tube (see Fig. 15).

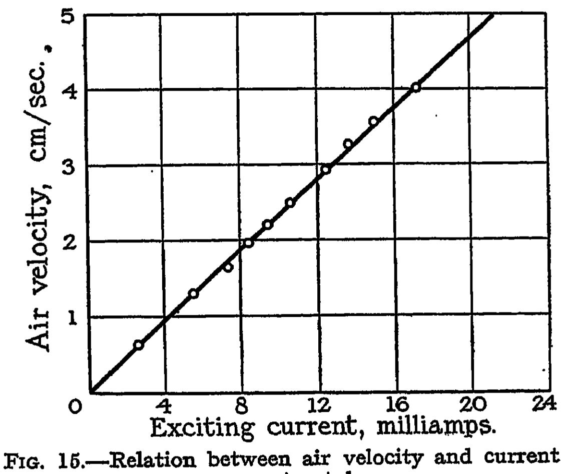

FIG. 15.—Relation between air velocity and current in resonator tube.

For a diverging spherical wave the velocity potential is given by

$$\Phi = \frac{A}{4\pi r}\cos\omega\left(t - \frac{r}{c}\right)^{*}.$$

* *Vide* LAMB: "Dynamical Theory of Sound," chap. 8.

where Φ = velocity potential,
r = radius from the imaginary point source,
c = velocity of propagation of sound in the medium, and
A = a constant.

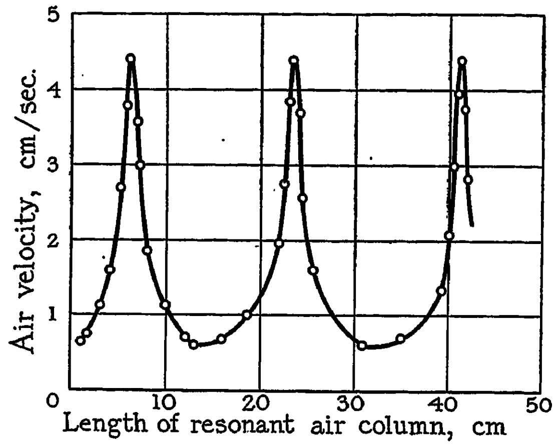

FIG. 16.—Relation between air velocity and length of air column in resonator tube. Frequency = 940 cycles per sec.

The air velocity v is therefore given by

$$v = -\frac{\partial\Phi}{\partial r} = -\frac{A}{4\pi r}\cdot\frac{\omega}{c}\sin\omega\left(t-\frac{r}{c}\right) + \frac{A}{4\pi r^2}\cos\omega\left(t-\frac{r}{c}\right)$$

$$= \frac{A}{4\pi}\left\{-\frac{1}{r}\cdot\frac{\omega}{c}\sin\omega\left(t-\frac{r}{c}\right) + \frac{1}{r^2}\cos\omega\left(t-\frac{r}{c}\right)\right\}$$

$$\therefore \text{R.M.S. velocity } V = \frac{A}{4\pi\sqrt{2}}\sqrt{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}+\frac{1}{r^4}\right)} \quad . \quad (1)$$

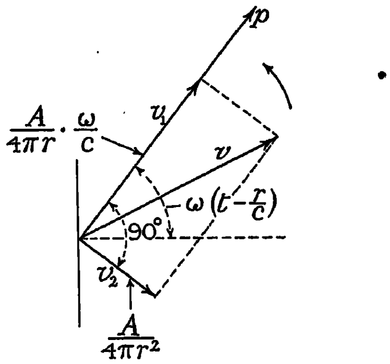

FIG. 17.

The alternating pressure

$$p = \frac{\partial\Phi}{\partial t} = -\frac{A\rho}{4\pi r}\,\omega\sin\omega\left(t-\frac{r}{c}\right) \quad . \quad . \quad (2)$$

and the R.M.S. pressure

$$p = \frac{A\rho\omega}{4\pi r\sqrt{2}}$$

These results are shown vectorially in Fig. 17.

The velocity component v_2 which varies as $1/r^2$ is 90° out of phase with the component varying as $1/r$, and the latter is in phase with the pressure. The sound intensity at the radius r is represented by the product of the pressure and the in-phase velocity component.

Table 6 and Figs. 18 and 18 (a) show the experimental verification of the equation

$$V = \frac{A}{4\pi\sqrt{2}}\sqrt{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}+\frac{1}{r^4}\right)}$$

In the table the distance r is measured from the mouth of the tube, and it will be seen that it is the radius of the spherical wave, or, in other words, the centre of the wave is exactly at the mouth of the tube.

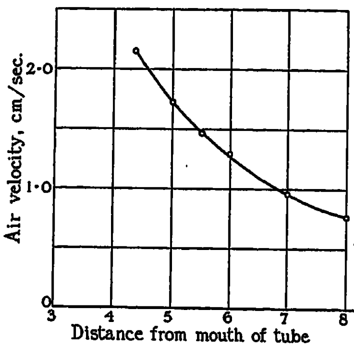

FIG. 18.

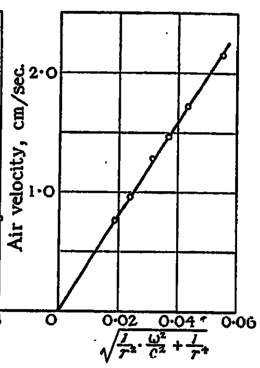

FIG. 18 (a).

The good agreement of the above results with theory, shows that reflection within the sound chamber is negligible, at least within 15 cm from the source.

Similar results were obtained at a number of different frequencies.

TABLE 6.

f = 439; c (at 15° C.) = $3\cdot40 \times 10^4$ cm/sec.
ω = 2750; ω/c = 0·084; current = 3·8 mA.

Distance r	Air velocity V	$\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}$	$\frac{1}{r^4}$	$\sqrt{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}+\frac{1}{r^4}\right)}$
cm	cm/sec.

7·00	0·96	0·000144	0·000415	0·0236
8·00	0·77	0·000110	0·000245	0·0188

Slope of line = 38·4

$$\therefore v = 38\cdot4\sqrt{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}+\frac{1}{r^4}\right)}$$

The values of the air velocity V are plotted against the distance r from the mouth in Fig. 18, and in Fig. 18 (a) against the value of $\sqrt{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}+\frac{1}{r^4}\right)}$.

(7) SOUND-PRESSURE EXPLORER.

The Rayleigh disc was not sufficiently sensitive to measure the sound velocities a few cm in front of a receiver diaphragm at frequencies removed from resonance, and it does not lend itself readily to mapping out the velocities in an acoustic field. Another instrument for this purpose was required. It is essential that the introduction of the instrument should in no way affect the pressure distribution, and that its reaction upon the source should be negligible.

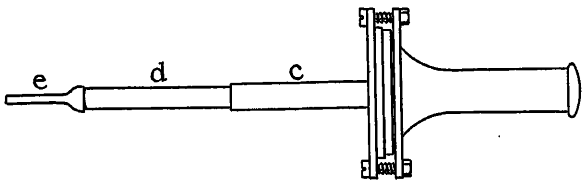

FIG. 19.—Sound-pressure explorer.

With the above requirements in view the device shown in Fig. 19 was constructed. The apparatus consists of an electromagnetic telephone, the diaphragm of which is coupled to the external atmosphere through the system of tubes "c," "d" and "e." The mouth of the tube "e" is introduced into the sound field. The long length of tube was in order to have the mouth "e", as far as possible from the disturbing presence of the telephone upon the sound waves. The telephone and the tube "c" were coated with a layer of cotton waste to reduce reflection, while tubes "e" and "d" were coated with petroleum jelly.

The cross-sectional area of the mouth of the tube "e" is $0 \cdot 12\ \mathrm{cm}^2$, hence the energy abstracted from the sound waves is very small, resulting in small induced E.M.F.'s in the telephone windings. These small E.M.F.'s were increased by a three-stage transformer-coupled valve amplifier in order that the response could be conveniently read upon a valve voltmeter.

DESCRIPTION OF AMPLIFIER AND VALVE VOLTMETER.

Stray alternating electrostatic and magnetic fields had to be guarded against with great care, due to the proximity of heavy electrical machinery and valve oscillators. The flexible leads from the exploring telephone consisted of twin workshop cable armoured with stranded copper. This armouring acted as an excellent screen against alternating electrostatic fields; without such protection the latter were very troublesome. All metal work on the search telephone was connected to the armouring and, hence, to earth. Fig. 20 gives a diagram of connections. The first transformer primary had a resistance of 50 ohms, the secondary a resistance of 5 000 ohms shunted by a 10 000-ohm resistance arranged as a potentiometer. The valves were of the ordinary R type with an anode voltage of 120, 4 volts on the filaments and $1 \cdot 5$ volts negative on the grids. The intervalve transformer had a step-up ratio of 1/2. The whole amplifier except the first transformer was placed in an earthed iron box. It was found necessary to place the first transformer in a separate iron box to prevent the amplifier oscillating.

The voltage on the secondary of the last transformer was read on a valve voltmeter. The valve used for the voltmeter was a Marconi R-type dull-emitter, anode voltage 20 and grid potential $4 \cdot 5$ volts negative. The galvanometer was a 500-ohm Paul unipivot moving-coil instrument giving a maximum scale deflection with 6 μA. This was provided with a variable shunt in order to increase the range. Up to $4 \cdot 8$ volts there is no appreciable grid current; beyond $5 \cdot 5$ volts, however, the grid current rises rapidly. It is essential that the voltmeter should take no grid current from the amplifier transformer, otherwise the voltage-drop would be considerable, resulting in a departure from the direct proportionality between the input and the output amplifier voltages.

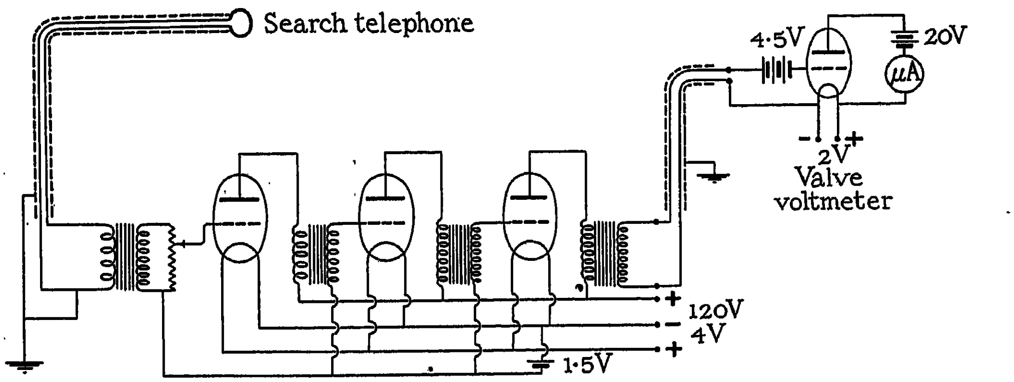

FIG. 20.—Diagram of amplifier.

The calibration of the explorer was carried out with the resonator tube and Rayleigh disc in the sound-absorbing chamber. The disc and the mouth of the explorer were mounted side by side and the distance of the mouth of the resonator tube—i.e. the distance r of the source of sound—was varied.

Table 7 gives the results obtained at a frequency of 694. Col. 1 gives the distance of the source in cm, col. 2 the air velocity as measured by the disc, and col. 3 the amplified explorer voltage e. Col. 5 gives the ratio air velocity$\Big/\sqrt{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}+\frac{1}{r^4}\right)}$, and shows that the resonator tube is acting as a point source, while in col. 4 is

7·00	0·67	1·020	7·15	24·2
10·10	0·39	0·700	7·06	24·0
			7·04	24·5

entered the product re of the distance and the amplified voltage. The fact that re is constant indicates that the explorer is measuring pressures, and that the reading of the voltmeter is directly proportional to the pressure of the sound wave at the mouth of the explorer.

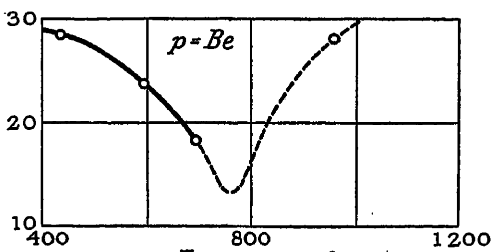

FIG. 21.

We have seen that in a spherical wave

$$V\ (\text{R.M.S.}) = \frac{A}{4\pi\sqrt{2}}\sqrt{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}+\frac{1}{r^4}\right)}$$

and $$p\ (\text{R.M.S.}) = \frac{A\omega\rho}{4\pi r\sqrt{2}}$$

The average of col. 5 is 24·5, and this is the value of $\dfrac{A}{4\pi\sqrt{2}} = \dfrac{pr}{\omega\rho}$.

And since $re = 7\cdot04$ from col. 4, we have

$$p = \frac{A}{4\pi\sqrt{2}}\cdot\frac{\omega\rho}{7\cdot04}e$$

$$= 24\cdot5 \times \frac{694 \times 2\pi \times 0\cdot0012}{7\cdot04}e$$

$$= 18\cdot2\,e$$

for the calibration of the pressure explorer at this frequency. Writing $p = Be$, the values of B found in this way at frequencies of 439, 590, 694 and 960 are entered in Table 8 and shown graphically in Fig. 21.

These values are used in the efficiency determination described later.

In the neighbourhood of 790 cycles, which was the resonant frequency of the explorer telephone, the latter fails to give a measure of the pressure, since the values of re no longer come constant. At 790 cycles it was found that $(r + 4)e$ was a constant, while the values of $V\Big/\sqrt{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}+\frac{1}{r^4}\right)}$ were constant as before. This phenomenon was not further investigated, but the use of the explorer at frequencies near 790 was avoided.

590	37·4	7·07	23·6
694	24·5	7·04	18·2
960	46·3	11·92	28·1

(8) THE DIRECT MEASUREMENT OF THE ACOUSTICAL-ELECTRICAL EFFICIENCY OF A STANDARD DOUBLE-POLE TELEPHONE.

Before the efficiency of the telephone could be determined by the sound-pressure explorer, the shape of the wave-front of the sound proceeding from the telephone had to be determined.

To simplify as far as possible the contour of the wave-front, a flange was fitted to the telephone and the diaphragm placed 1·1 cm from the plane of the flange, as shown in Fig. 22. The telephone was mounted with

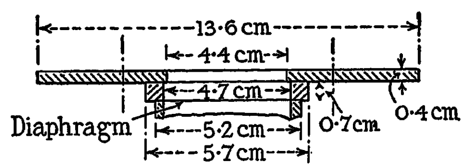

FIG. 22.—Telephone flange.

the plane of the flange vertical, on a piece of apparatus capable of rotating 180° about the centre of the mouth of the flange. The search tube "e" of the sound explorer was placed in front of the telephone, in the horizontal plane passing through the centre of the telephone diaphragm and at a convenient radius from the centre of the flange mouth. The semicircular horizontal arc about the flange mouth could thus be explored by rotating the telephone, the search tube remaining fixed, and its exact position read off on a scale graduated in degrees. It was found that the angle which the search tube made with the wave-front did not affect the reading. The current in the receiver was always kept below that value at which the second harmonic in the sound wave, as tested by means of a Helmholtz resonator, became appreciable.

Table 9 shows the results of pressure explorations with the above apparatus. With a radius greater than 4 cm for any frequency above 400 the pressure is uniform along the 180° arc, indicating that the wave-front has

at this radius become spherical. The higher the frequency the more quickly does the wave-front become spherical. In the determination of the sound-energy output, one measurement only need be made with the pressure explorer, for the flanged telephone may be considered to be a point source sending out hemispherical waves the centre of which lies at the mouth of the flange.

TABLE 9.

Sound-Pressure Explorations around Telephone. Frequency 439 *cycles/sec.*

Position of explorer along 180° arc	Explorer response at radius of :—			
	2·4 cm	3·2 cm	4·0 cm	6·0 cm
degrees	volt	volt	volt	volt

110	0·83	0·690	0·460	0·308
125	0·86	0·694	0·460	0·308
140	0·90	0·705	0·460	0·308
155	0·95	0·711	0·460	0·308
170	1·01	0·719	0·460	0·308

The power may therefore be obtained, since the value of the source A will be known from the pressure determination. The electrical power absorbed by the telephone was determined with the aid of the valve voltmeter previously described and a Duddell thermo-ammeter. The power factor was determined by the three-voltmeter method.* This method of measuring

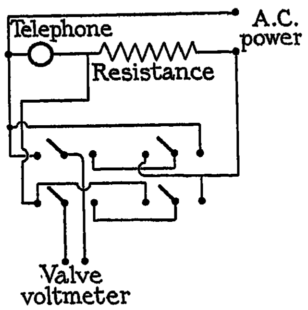

FIG. 23.

small powers is very liable to error unless the readings are very accurately taken with no absorption of power by the measuring instruments. The valve voltmeter was therefore given a sufficiently negative grid potential and a high anode voltage, so that no grid current was taken for voltages up to 5·5.

* A valve voltmeter was used with the switching arrangement shown in Fig. 23.

The results of the efficiency tests may be divided into two parts: (A) in which the Rayleigh disc was used to measure the sound energy, and (B) in which the pressure explorer was used. All the results are collected in Table 10. Method (A) was used for the frequencies near resonance, i.e. for 790, 840 and 885, while (B) was used where the sound intensities were much smaller, at frequencies of 439, 590, 694 and 960. Col. 1 gives the frequency and col. 2 the distance of the sound-measuring device from the flange of the receiver, i.e. from the apparent point source as indicated in Table 9. In col. 3 is entered the sound velocity V as measured by the Rayleigh disc in the (A) series, and the voltage e of the pressure explorer in the (B) series. In cols. 4, 5 and 6 are the voltages V_1, V_2, V_3 across the non-inductive resistance R, the telephone, and the two in series, and in col. 7 is the value of the non-inductive resistance R. In col. 8 is entered the electrical power input calculated from cols. 4, 5, 6 and 7, and as

$$P = \frac{1}{2R}\{V_3^2 - V_1^2 - V_2^2\}$$

In col. 9 for the (B) series is entered the pressure constant B from Table 8.

The velocity at any point of a spherical wave is given by

$$v = \frac{A}{4\pi}\left\{-\frac{1}{r}\cdot\frac{\omega}{c}\sin\omega\left(t-\frac{r}{c}\right)+\frac{1}{r^2}\cos\omega\left(t-\frac{r}{c}\right)\right\}$$

and the pressure by

$$p = -\frac{A\rho\omega}{4\pi r}\sin\omega\left(t-\frac{r}{c}\right) \quad \text{(see Section 6)}$$

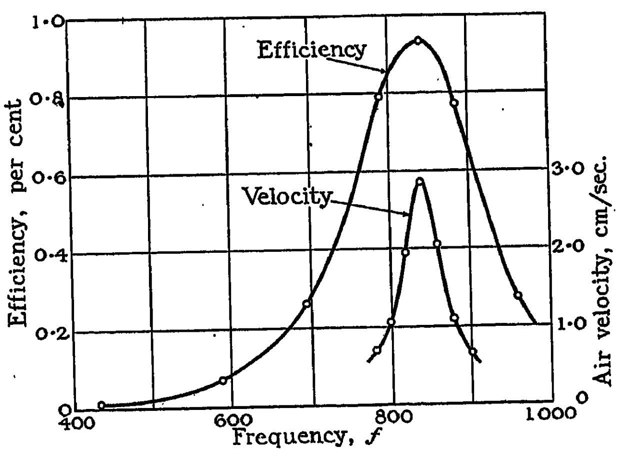

FIG. 24.

and the instantaneous flux of energy across each square centimetre of the sphere is given by the product of these two, and the average flux by the mean of the product or by

$$\frac{1}{2}\cdot\frac{A^2\rho}{16\pi^2}\cdot\frac{1}{r^2}\cdot\frac{\omega^2}{c}$$

The total flux of energy over the hemisphere is therefore

this quantity multiplied by the area of the hemisphere, $2\pi r^2$, and is

$$W = \frac{A^2 \rho \omega^2}{16\pi c}$$

and this is the sound energy output of the telephone receiver, given in ergs/sec. if C.G.S. units are employed throughout.

In the (A) series of results where we measure the R.M.S. sound velocity V, we have for the determination of A the expression

$$V = \frac{A}{4\pi\sqrt{2}}\sqrt{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}+\frac{1}{r^4}\right)}$$

and hence $$W = \frac{2\pi r^2 B^2 e^2}{\rho c} \text{ ergs/sec.}$$

B is determined from Table 8 and the calculated value of W is entered in col. 10.

In col. 11 is entered the overall acoustical-electrical efficiency, given as $W/(P \times 10^7) \times 100$ per cent (P in watts is multiplied by 10^7 to bring it to ergs/sec.) i.e.

$$\frac{W}{P} \times 10^{-5} \text{ per cent.}$$

These values of the efficiency are plotted in Fig. 24 against the frequency, and there is also plotted for comparison the resonance curve of the receiver diaphragm, which has a decay factor of 125.

TABLE 10.

	1	2	3	4	5	6	7	8	9	10	11
	f	r	V	V_1	V_2	V_3	R	P	B	W	Efficiency $\frac{W}{P} \times 10^{-5}$
		cm	cm/sec.	volts	volts	volts	ohms	watts		ergs/sec.	per cent
(A)	790	3·6	1·44	1·98	2·41	4·09	200	0·0172	—	1 360	0·79
	840	3·6	1·45	1·94	2·20	3·93	200	0·0175	—	1 640	0·936
	885	3·6	1·42	2·02	2·56	4·40	200	0·0237	—	1 830	0·772
			e volts								
(B)	439	4·28	0·210	6·42	2·85	9·25	200	0·0915	28·5	100	0·011
	590	4·28	0·215	1·94	1·67	3·28	200	0·0108	23·6	72·5	0·067
	694	4·28	0·652	2·06	1·96	3·76	200	0·0152	18·2	395	0·26
	960	4·28	0·352	1·80	1·443	3·045	237	0·00988	28·1	275	0·278

Hence

$$W = \frac{2\pi\omega^2\rho}{c}\cdot\frac{V^2}{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2}+\frac{1}{r^4}\right)} \text{ ergs/sec.}$$

and this value is entered in col. 10, taking $\rho = 0{\cdot}0012$ g/cm^3 and $c = 34\,000$ cm/sec.

In the (B) series we have

$$p = Be = \frac{A\omega\rho}{4\pi r\sqrt{2}}$$

The value of the efficiency at resonance—about 1 per cent—is just about what is generally accepted to be the figure for a standard receiver, but as far as the authors are aware no direct measurement has previously been made.

The whole of the experimental work was carried out in the Telegraphy and Telephony Laboratories, at the City and Guilds (Engineering) College, South Kensington, where the authors have had the privilege of discussing their results with Prof. C. L. Fortescue, O.B.E.

WORLD-WIDE RADIO TELEGRAPHY.

By Professor G. W. O. Howe, D.Sc., Member.

(Abstract *of* Faraday Lecture *delivered before the* North-Eastern Centre *17th December,* 1924; *also before the* North-Western Centre *6th January, before the* North Midland Centre *27th January, before the* South Midland Centre *28th January, and before the* Scottish Centre *17th February,* 1925.)

I wish in the first place to take you back in imagination a hundred years and trace the evolution of the conception of electromagnetic waves, their experimental realization, and their ultimate application to world-wide radio telegraphy and telephony.

At the beginning of last century three apparently independent phenomena were known to scientists, viz. the attraction and repulsion between magnet poles, the attraction and repulsion between electric charges, and the production of an electric current by means of a voltaic cell. It is only just over a hundred years ago that Oersted discovered the connection between the magnetic and the electric effects. It was Faraday who, seeking a physical explanation rather than a mathematical expression of the forces, investigated the phenomena in the medium and formulated his conceptions of the magnetic and electric fields with their lines or tubes of force. It was in the sixties that James Clerk Maxwell conceived and developed his electromagnetic theory, one of the greatest achievements of the human intellect. By analogy from the propagation of pulses or waves through a material medium, depending on its density and elasticity, he predicted that electromagnetic waves should travel through space at a speed depending on its magnetic and electric properties, and calculation gave this speed as 300 000 km per second, which was exactly the speed at which experiment had shown light to travel. The obvious inference that light is an electromagnetic phenomenon has been amply corroborated.

It was in 1888 that Hertz succeeded in producing electromagnetic waves in space by purely electrical methods, but it was not until 1895, 18 months after the untimely death of Hertz, that Marconi commenced his experiments with the definite object of using the Hertzian waves for the purpose of telegraphy, and it is largely due to his prophetic foresight, courage and perseverance that we owe the rapid development of radio telegraphy in those early days. By 1899 he had established communication across the English Channel, using single masts 150 ft. high. The transmitters consisted of Ruhmkorff coils and Leyden jars, the receivers of coherers and morse inkers. Thus encouraged, Marconi decided to attempt communication across the Atlantic and made preliminary tests in 1901 with a power of about 10 kW. The report that signals had been heard over such a distance was received with some incredulity, which was not surprising in view of the improbability of such an achievement. The waves were known to be of the same character as light, to travel in straight lines and to be unable to penetrate far into the earth. Why then should they bend round the curvature of the earth and arrive in America, which is separated from Cornwall by a mountain of sea water 200 miles high? Mathematical investigation has shown that these doubts were well founded—or rather, would have been well founded had it not been for some mysterious agency, up to that time unsuspected, which introduced a new factor into the problem. Signals were undoubtedly received and this led to the completion of the stations at Poldhu and Cape Cod, Clifden and Glace Bay, and thus to the inauguration of a trans-oceanic wireless service.

Although it is now over 20 years since the discovery that the electromagnetic waves employed in radio telegraphy bend around the earth, the exact nature of the beneficent agency is still a matter of discussion, but it is now generally agreed that the cause lies in the upper atmosphere being to some extent conducting due to the presence of free electrons or ions. This suggestion was put forward about the same time by Prof. Kennelly of Harvard and by Oliver Heaviside, and the postulated layer of conducting rarefied gas is known as the Heaviside layer. The idea of reflection at the lower surface of such a layer has been generally abandoned in favour of the alternative theory that the waves are refracted or bent downwards by passing through the conducting stratum. There are many peculiarities in the transmission of wireless signals which compel us to look to the upper atmosphere for an explanation, and it is interesting to note that meteorologists have made somewhat similar assumptions as to the conductivity of the upper atmosphere to explain the causes of the diurnal variation of the earth's magnetism.

To send out waves, it is necessary to produce in the vertical wire of the transmitting aerial an alternating current of very high frequency, and in order that a large current may flow it is necessary to provide at the top a large electrical reservoir or capacity into which the current can flow. This takes the form of a network of wires spread out horizontally. In large stations this may cover a square mile or more, and the masts or towers required to support it are one of the most costly items of the installations. The waves are produced by the rapid starting and stopping of the current in the vertical wire; a very close analogy is the kink transmitted along a stretched cord when the end is suddenly jerked up or down.

The various ways of producing the high-frequency current in the aerial may be divided into those such as the spark, arc, and thermionic valve in which the frequency of the oscillations is determined by the inductances and capacities of circuits, and those in which the frequency is fixed by the speed of an alternator.

All the early development was carried out by means of the spark system, but this method is now obsolete for long-distance transmission. The spark merely acted as an automatic switch which, when the voltage across the condenser had reached a given value, closed a circuit by which the condenser discharged through an inductive coil. The use of the spark in all the early wireless transmitters led to the idea that it was in some way the source of the radiated electromagnetic waves, whereas it was really a very unimportant detail. The fallacy was given the appearance of official sanction in Germany by the adoption of the name Telefunken (Funke = spark) by the leading company; it is being perpetuated by calling the broadcasting service "Rundfunkdienst," a peculiarly misleading designation.

The first competitor with the spark in long-distance communication was the arc converter originally discovered by Duddell but modified and made applicable to radio telegraphy by Poulsen. This method is still employed in a number of high-power stations.

The most modern method of producing the requisite high-frequency current is by means of the three-electrode thermionic valve. In principle this is very similar to the arc method, both devices converting a direct-current supply into an alternating current in an oscillatory circuit. Whereas arcs can be constructed to give an output of 1 000 kW, thermionic valves cannot conveniently be constructed to give more than about 20 kW, and large radiated power is obtained by employing a number of valves in parallel.

The other class of generator is in principle the same as those alternating-current generators in the local power station, in which a magnet wheel is rotated and induces in the stationary winding a current of a frequency determined entirely by the speed of rotation and the number of poles in the machine. Many of the largest wireless stations in the world now employ this method, which must always appeal to the electrical engineer as the ideal method of producing alternating currents. The difficulties of design, however, increase rapidly with the frequency, and alternators can only be constructed on a large scale for frequencies up to about 20 000 cycles per second ($\lambda = 15$ km). At frequencies of 500 000 to 1 000 000 such as are used for ordinary marine work and broadcasting, to say nothing of the frequencies of several millions now being used in the latest short-wave systems, the engineering problems in the design of an efficient a.c. generator become almost insuperable.

The German Telefunken Company favour a method in which the alternator delivers the current at a quarter of the requisite frequency to special transformers which are made dissymmetrical in their operation by means of a direct-current excitation and which consequently give a secondary current having double the primary frequency. By repeating the process the original frequency is quadrupled. This method has the very great advantage of lowering the alternator frequency from about 20 000 to about 5 000 cycles per second.

Reception can be carried out by means of a vertical non-directive aerial, a directive coil aerial, or a long horizontal wire which is also directive in its action.

In all cases the high-frequency oscillations must be rectified, i.e. made more or less unidirectional, in order that they may influence the telephone diaphragm or galvanometer. This is the function of the detector. In all except spark stations and a few special cases, the waves sent out by a telegraph transmitter are continuous so long as the key is held down. Such oscillations, even although rectified, would still be inaudible unless made intermittent in their action on the telephone. This intermittency is generally produced by the interference set up in the receiving circuits between the received oscillations and other oscillations of nearly the same frequency set up by a local oscillator. By altering the frequency of this local oscillator, the rapidity of the "beats" between it and the received oscillations can be adjusted, and the receiving operator can thus adjust the pitch of the note heard in the telephone. This is the so-called heterodyne method of reception.

In modern commercial long-distance radio communication, the transmitting and receiving stations are placed several miles apart, so that the latter can receive from the distant station while the transmitting station is working, without undue interference. They are both controlled and operated from a central office in the city by means of ordinary telegraph lines.

In conclusion, reference may be made to the so-called beam systems in which either by reflectors or by suitably arranged transmitting aerials the radiated energy is sent out in the desired direction, thus greatly increasing the efficiency of the transmission.

[The lecture was illustrated by a large number of lantern slides.]

INSTITUTION NOTES.

Specimens of Mica.

A collection of 90 specimens of mica will be on view in the Institution Library for the next few months. A table is also available showing the classification of the specimens and giving their composition, characteristics, descriptions and trade names.

National Certificates and Diplomas in Electrical Engineering.

The following Institute has been approved under the scheme drawn up by the Board of Education and the Institution:—

Approved for Higher Grade Certificates (Advanced Part-time Course).

Woolwich Polytechnic Institute.

Electrical Appointments Board.

The Board desires to remind members who have applied for registration that the period for the retention of names on the Register is three months from the date of application. If after this period members are still without positions, they should notify the Secretary of the Board who will extend the registration period for a further three months.

Failure to comply with this regulation will be regarded as an indication that members desire their names to be struck off the Register.

Informal Meetings.

The following Informal Meetings have been held :—

65TH INFORMAL MEETING (9TH FEBRUARY, 1925).

Chairman : Mr. A. G. Hilling.

Subject of Discussion : " Broadcasting " (introduced by Capt. P. P. Eckersley).

Speakers : Messrs. C. F. Phillips, J. Coxon, P. Voigt, H. H. Dyer, E. S. Ritter, A. T. Smee, — Mulholland, H. E. Morrish and E. G. Bedford.

66TH INFORMAL MEETING (23RD FEBRUARY, 1925).

Chairman : Mr. H. T. Young.

Subject of Discussion : " The Electric Journals; Past, Present and Future " (introduced by Mr. W. E. Warrilow).

Speakers : Messrs. J. W. Beauchamp, J. F. Shipley, W. Day, E. Kilburn Scott, A. H. Allen, E. S. Ritter, J. Coxon, M. Whitgift, J. R. Bedford, F. H. Masters, W. L. Randell, E. A. Gatehouse, W. A. Moore and H. T. Young.

67TH INFORMAL MEETING (9TH MARCH, 1925).

Chairman : Mr. W. E. Warrilow.

Subject of Discussion : " Illumination " (introduced by Mr. C. W. Sully).

Speakers : Messrs. J. R. Bedford, A. B. Mann, R. J. Hines, W. E. Rogers, J. Coxon, W. A. Erlebach, A. G. Hilling, P. Dunsheath, O.B.E., F. Peake Sexton, A. F. Harmer, A. Collins, M. Whitgift and W. E. Warrilow.

68TH INFORMAL MEETING (23RD MARCH, 1925).

Chairman : Mr. L. J. Gooch.

Subject of Discussion : " Panel Heating " (introduced by Mr. R. Grierson).

Speakers : Messrs. H. T. Young, H. H. Perry, P. Dunsheath, O.B.E., J. Coxon, R. J. Hines, J. R. Bedford, L. M. Jockel, W. A. Ritchie, A. E. Falkus, W. E. Spiers, N. Prentice, C. T. Walrond, W. L. Wreford, F. Pooley, V. Cornelius, F. Tremain, P. S. Davies, D. A. B. Partridge and L. J. Gooch.

69TH INFORMAL MEETING (6TH APRIL, 1925).

Chairman : Lt.-Col. K. Edgcumbe.

Subject of Discussion : " Insulation Problems in High-voltage Engineering " (introduced by Mr. A. Collins).

Speakers : Col. K. S. Maxwell, Messrs. Duncan, H. C. Silver, P. Dunsheath, O.B.E., J. F. Shipley, S. Messent, H. F. Quinton, A. Berkeley, W. A. Erlebach, R. T. Fleming, E. S. Ritter and Col. K. Edgcumbe.

70TH INFORMAL MEETING (20TH APRIL, 1925).

Chairman : Mr. W. E. Warrilow.

Subject of Discussion : " Latter-day Wireless " (introduced by Mr. M. Hart).

Speakers : Messrs. A. F. Harmer, H. E. Morrish, P. W. Willans, T. McGrath, H. Brown, J. Coxon, E. W. Moss, W. Day, A. E. Lee, E. W. Braendle, W. A. Erlebach, A. G. Hilling, H. H. Easter and W. E. Warrilow.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 March–25 April, 1925 :—

SUMMARY.

The mining industry is one of the largest producers and users of electric power in this country. It is generally assumed that the methods of production and utilization are not as economical as they might be. The following notes of some efforts to achieve efficiency and increase reliability, together with results of tests made with this end in view, may be of general interest.

For the purpose of reference the paper is divided into three parts:—

Part 1 deals with the general problem of power production at mines, giving briefly the essential differences between a colliery power plant and a normal power plant.

Part 2 deals with the modern methods of supplying the four main power-consuming units at mines, with particular reference in each case to the question of the utilization of synchronous motors, and also discusses the advantages and disadvantages of alternating-current and Ward-Leonard control for electric winders.

Part 3 gives the results of progressive conversion of several mines from steam to electric drive for the various main units and also the effect of supplying compressed-air power from a central station in a similar way to electric power.

Part 1.

Dealing first with the generation of power, it is of interest to note that the first high-pressure high-temperature station of moderate size in this country, and possibly in the world, to operate continuously was installed in connection with a group of collieries.

A colliery power station should be capable of dealing with all classes of fuel which from time to time are not marketable. These will mostly be the lower grades, and the boiler plant should therefore have ample grate area and draught capacity and proper furnace construction for the economical combustion of these fuels. The utilization of coke-oven gas is a difficult problem. Gas engines have higher thermodynamic efficiency but higher maintenance cost, poor flexibility and reliability. These have all to be weighed against their one advantage. Compared with modern high-efficiency turbine plants the margin of thermodynamic efficiency in their favour is small, and in most cases it is a better commercial proposition to burn the gas under boilers.

Table 1 gives a comparison of the cost per electrical unit for the two methods of utilization. The gas-engine units are of the 1 600-kW low-speed 4-cylinder type, and the steam plant is a 350 lb./sq. in., 700° F. installation, the gas being used to supplement coal-firing in 35 000-lb. boiler units. The test efficiency when coal-fired was 87 per cent, and the daily efficiency 80 to 82 per cent, so that an efficiency of 85 per cent for gas-firing is reasonable.

The gas-engine figures are based on an output of 16 million units per annum. The new gas engines are fitted with waste-heat recuperator boilers. The gas- and coal-fired steam stations are based on an output of 150 million units per annum.

The disposal of coke breeze and coke ashes has also to be provided for. A system of blanketing with medium volatile coal has proved a satisfactory method of burning them. Low-grade fuels should be washed if the ash content exceeds 10 per cent, but a minimum of 5 to 6 per cent ash is quite low enough.

The high capital cost of extra-high-pressure and extra-high-temperature steam, combined with the attendant fuel-saving devices such as evaporators, feed-water heaters fed with bled steam, air-heaters, etc., hardly seems justified with cheap fuel delivered direct to the boilers free of railway charges, but in some collieries where all fuel raised has a fairly high value, high capital expenditure may be justified.

Boiler efficiencies of 70 to 75 per cent can be maintained with fuel of high calorific value, even in small

TABLE 1.

Coke-Oven Gas Utilization from 150 *Ovens.**

	Old gas engines	New gas engines	Gas-fired boilers	Coal-fired boilers

* All values are expressed as percentages of the cost per unit in the coal-fired station.

colliery boiler plants, but efficiencies of this order require constant high-class technical supervision, which can better be concentrated in large central stations. Where fuels are available which cannot be burned on any ordinary stokers, pulverizing is a feasible proposition.

Water for both boiler feed and condensing purposes is one of the great difficulties at most collieries, and at high-pressure stations evaporators are a necessity.

The other problems such as size of generating units, reactance (self-contained or external) of transmission, and substation equipment, etc., are common to all power schemes and have been fully dealt with in recent papers. Switchgear has to be particularly robust and must also not be susceptible to the effect of dust and damp. Compound-filled gear seems to meet most requirements.

Power factor correction has become a pressing need in large power installations. Overhead transmission lines with their comparatively high reactance, high-reactance transformers and, in many cases, busbar and feeder reactances necessary for protection of generating plant and switchgear, have lowered the already bad colliery power factor, resulting in reduced outputs from generating plant and in high voltage-drop in transmission lines, transformers and reactances. Phase-advancers, synchronous and static condensers have all been tried, but the best results have been obtained from synchronous motors driving the larger units.

Salient-pole and cylindrical-rotor types of motors each have their advantages, which have been fully discussed in recent papers before the Institution.* The present author gave comparative figures of various drives in the discussions on these papers and, in the discussion on Kapp's paper, an example of the use of a static condenser, with the results obtained therefrom and suggestions as to where this apparatus is applicable.

Part 2.

The four most important loads to be dealt with at modern collieries are pumping, ventilation, air compressing and winding. The units consumed per ton of coal raised for a modern colliery raising 2 000 tons of coal per day from a depth of 600–700 yards and using compressed air for cutting, conveying, inbye haulages and pumps are given in Table 2.

TABLE 2.

	Units per ton
Winder	4
Fan	3
Compressed air	20
General pit use	$1\frac{1}{2}$
Pumping	$3\frac{1}{2}$
Total	32

These figures apply specifically to South Wales conditions with highly developed compressed-air utilization, and very different figures will be obtained from other districts.

Pumping.—The efficiency and reliability of modern multi-stage turbine pumps, combined with their compact size, make them particularly suitable for use in mines. Up to 150 h.p., squirrel-cage motors are quite satisfactory, particularly those with the Boucherot type of rotor winding which may be switched directly on to the line. Auto-transformers for starting are unsatisfactory and slip-ring motors are preferable above 150 h.p. High power factor and efficiency are obtainable with 4-pole or 2-pole machines of all sizes, and only in exceptional circumstances need synchronous-type induction motors be considered for pump drives.

Fans.—Ventilating fans provide an almost uniform load and are particularly suited for power factor correction. The starting torque required is moderate, but, as it is usual to start fans under load in this country, the synchronizing torque required is high. Salient-pole motors cannot give the required torque, and cylindrical-type rotors are used. Experiments have been carried out in the United States with salient-pole machines using a friction clutch drive and also reducing the starting effort by closing the fan discharge.*

Owing to the moderate speed of mine-ventilating fans it is usual to drive through some type of reduction gear. In the early stages of the development of a mine the quantity of ventilating air is low, the requirements gradually increasing in both volume and pressure as roads lengthen and workings extend. It is sometimes required to reduce the volume and pressure during non-working days. Variable-speed motors were largely used in the early days, but these hardly justified their extra cost and lower efficiency, particularly on low loads. Progressive increases in speed can be arranged in the reduction gear, where this is of the spur and pinion type, by changing the gear wheels. Recently the author introduced the old jockey-pulley drive with modern improvements and this has proved a most efficient and flexible method of speed reduction. To change the fan speed, all that is necessary is to change the motor pulley. Owing to the flat efficiency curve of the synchronous motor at unity power factor, the light-load efficiency is high. A comparison of the efficiencies of a cascade motor and of a synchronous motor is given in Fig. 1.

In addition to the very much higher efficiency at all loads—an important factor in a machine which runs for 8 760 hours per annum—power factor correction can be obtained up to 0·80 leading at full load, and to a still greater extent at lower loads. Further, the initial cost of the variable-speed motor and starting gear is 10–15 per cent higher than that of the synchronous motor. Reduction of ventilation during week-ends or stop-days is a questionable economy. Mining engineers usually prefer to maintain full volume of air to clean out the workings and dilute gas. At one colliery under the author's notice, where a variable-speed d.c. motor-driven fan is installed, the speed has not been varied for three years. Where reduced speed and water gauge are clearly required at week-ends or stop-days, two-speed cascade motors of either the ordinary or synchronous type are giving satisfactory results.

Starting up a 450-kVA synchronous induction-type fan motor on light load (about 90 kW), excited to a

* See, for instance, L. H. A. CARR: "Induction-type Synchronous Motors," *Journal I.E.E.*, 1922, vol. 60, p. 190; also G. KAPP: "Improvement of Power Factor," *ibid.*, 1923, vol. 61, p. 89.

* CRAMER and MACDONALD: *Proceedings of the Association of Iron and Steel Electrical Engineers* [Pittsburg], vol. 4, no. 5.

power factor of about 0·5 leading, improved the power factor of a colliery system from 0·7 to 0·87 or 0·9 and the voltage at the busbars increased from 3 050 to 3 150 volts, with both a.c. winders off.

The Lenix belt drive has some peculiar properties. There is no measurable slip; in fact the speed ratio appears to be proportional to the diameters of the pulleys plus the belt thickness, i.e. the diameters to the neutral axis of the belt. It is very difficult to give accurate figures for the efficiency, but the belt drive appears to be equal, if not superior, to a high-class helical gear reduction.

Another interesting type of synchronous motor for fan drives has a salient-pole rotor with extended pole-tips having a single-phase winding in semi-enclosed slots. The pole windings are split in halves for starting and are connected as a second phase, and a metallic resistance is placed in series with these two windings. The motor starts and has a torque characteristic similar

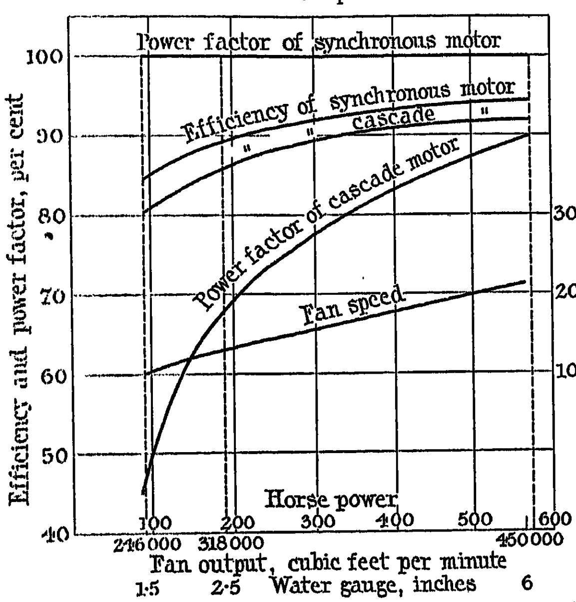

FIG. 1.—Curves of synchronous and cascade motors driving fans.

to that of an ordinary slip-ring machine. The pole-face winding is short-circuited when up to speed and forms an amortisseur. The salient-pole winding is excited in the usual way. Fig. 2 shows the connections. The advantages of this machine over an induction-type synchronous motor are (1) higher efficiency and (2) normal voltage excitation.

Compressed air.—In the gassy seams of the South Wales steam-coal measures there is strong opposition to the use of electricity, whilst every effort is being made to overcome this prejudice and to produce electrical machines which can claim to be absolutely safe under all conditions of operation. In the meantime the mining engineer's demand for compressed air as an operating medium at the working face has to be met, and the low efficiency of machines utilizing compressed air is neutralized as far as possible by higher efficiency in production and distribution.

Compressors.—The high-speed vertical two-stage compressor which is favoured in this country for electric drive was until 1918 thought to be unsuited for direct coupling to salient-pole synchronous motors, and the wound type of rotor with its higher starting torque was considered necessary. Owing to unsatisfactory experiences with this type, the author carried out a series of starting experiments with a large d.c. motor-driven compressor of the horizontal cross-compound type and also with an induction-motor-driven high-speed vertical type, both fitted with unloading devices on the high- and low-pressure cylinders. The cross-compound type took 25 to 30 per cent of full-load torque to start, and the vertical type about the same. In the meantime a salient-pole synchronous motor had been installed in a

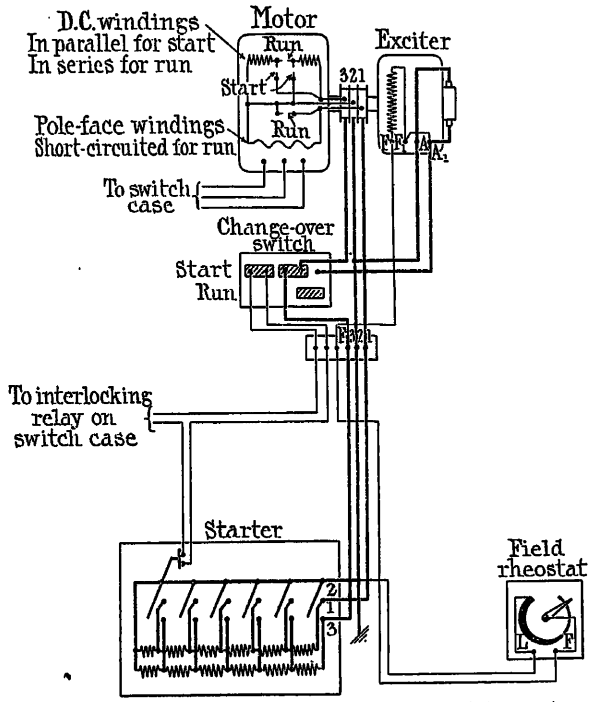

FIG. 2.—Connections of S.G.E. salient-pole, high-starting-torque synchronous motor.

Lancashire colliery to drive a Walker vertical compressor through a friction clutch. It was soon found that the clutch was unnecessary, and two salient-pole motors of 1 125 h.p. at 214 r.p.m. were installed driving vertical two-stage compressors having an output of 6 500 cubic ft. per min. compressed to 75 lb./sq. in. Starting curves of one of these are given in Fig. 3. Slightly more than full-load current is taken at the start and when changing over from tap to full voltage. This is momentary and is carried by the system with a hardly appreciable voltage-drop. Owing to the large air-gap used in this type of motor it was found possible to dispense with the bearing between the compressor flywheel and the rotor, thus reducing the length of the set by 4 ft. compared with a synchronous induction motor of similar horse-power. The efficiency of these motors at full load and unity power factor is 95·7 per cent, a remarkable figure for motors of this size and speed. The corresponding figure for a synchronous induction motor is 93·2 per

cent, a difference of 2·5 per cent in favour of the salient-pole machine.

A comparison between the efficiency of this type of compressor equipment and a large steam-turbine compressor is of interest. These figures are based upon tests made on a Bellis compressor of 6 500 cubic ft. per min. capacity at 75 lb./sq. in. installed at Penallta colliery and were published in *Engineering* (1921, vol. 112, p. 535), but are now corrected for the later type higher-efficiency motor.

Motor compressor—

back to the power station. To supply 1 110 h.p (830 kW), assuming an alternator efficiency of 95 per cent, requires 872 kW at the turbine coupling. The direct-coupled turbine driving the turbo-compressor has the same steam consumption and for 1 038 h.p. (775 kW) takes 11·2 per cent less steam than the electrically driven unit. The latter has one compensating advantage, i.e. the light-load losses are much lower than those of the turbo-compressor, in the above cases being only 65 kW with zero output. Of this, 6 kW represents work done in compressing the air, 29 kW the mechanical losses in the compressor (the inlet valve being closed and the high-pressure cylinder unloaded), and 30 kW the core losses, excitation, copper losses and friction and windage of the motor. Where the load varies considerably, as in a single colliery, this is an advantage, but when a group of collieries can be supplied from a central station the load is found to be very uniform owing to the diversity factor of the various compressed-air-consuming machines and the receiver effect of large mains. Typical load curves for a colliery compressed-air plant and an electrical plant are given in Fig. 4. Their resemblance is remarkable.

Experience with the synchronous-motor-driven compressors has been satisfactory, but the starting gear has given some trouble. A number of failures occurred in the auto-transformers. All these showed signs of abnormal mechanical stresses, clampings being strained and coils crushed. Excessive burning of the switch contacts also occurred. It was found that the arc drawn out on the starting-switch contacts was maintained for a length of time sufficient to cause a short-circuit

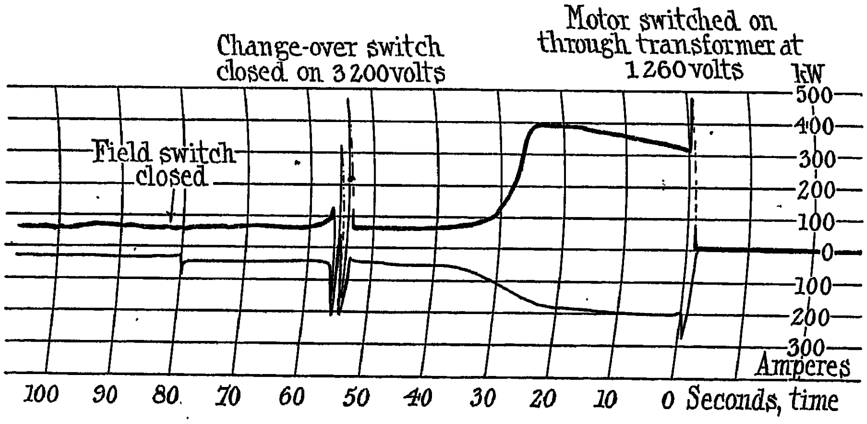

FIG. 3.—Starting curves of 1 125 h.p., 214 r.p.m. synchronous motor.

The losses in transmission for compressed air and electrical power for distances up to 5 miles are nearly equal.

Ignoring these losses, the comparison can be carried in the circuit formed by the transformer coils, the switch "starting" and "running" contacts, and the connection from the transformer taps to the motor (see Fig. 5). The trouble was overcome first by closing the transformer neutral later and opening it earlier, and secondly by closing the running switch slowly, giving ample time for the arc on the starting contacts to be quenched. Even smoother starting is obtained by the Korndorfer patented method which uses the transformer windings as choking coils. The operations in this method are:—

(1) Switch on transformer with neutral open.
(2) Close tapping switch (this charges the motor through the transformer winding). If the load is very light the motor will start.
(3) Close neutral of transformer. This impresses tapping volts on the motor, which starts or speeds up.
(4) Motor up to speed. Open neutral of transformer. Motor now draws light-load current through the transformer windings so that the choking effect is slight and the motor has nearly full voltage on its terminals.
(5) Close running switch. This short-circuits the transformer windings and impresses full voltage on the motor terminals.
(6) Open tapping switch and starting switch. The transformer is now out of circuit, and the motor is connected to the supply through the running switch only and may be synchronized by closing the field switch.

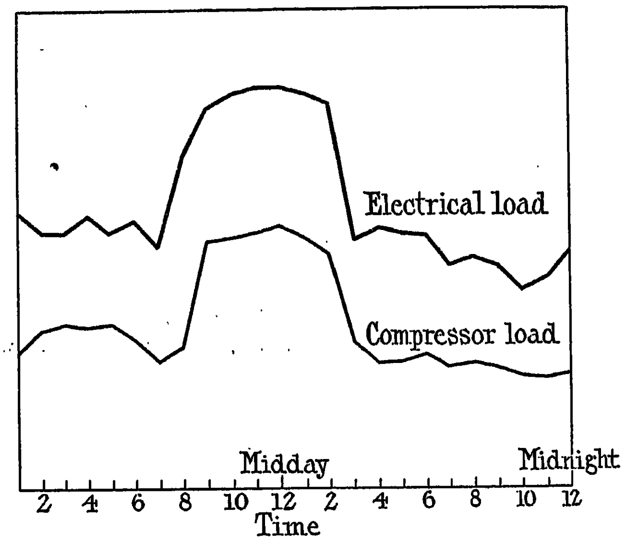

FIG. 4.—Typical load curves for a compressed-air plant and an electrical plant.

Oscillograph records have been taken of these methods of starting, showing the changes of current and voltage. The machine runs up to speed quite smoothly and synchronizes with ease. The whole operation can be carried out by the ordinary unskilled attendant.

Automatic starting and synchronizing by means of a system of contactors appear simple and desirable.

The control of electrically driven compressors is simple. An automatic device controlled by the air pressure closes the inlet valve when the pressure exceeds a predetermined value, and compression ceases, to commence again when the pressure falls by a few pounds per sq. in. and the inlet valve opens and admits air to the low-pressure cylinder.

Electric winders.—The steam winder has been in use for many years and has proved itself reliable and trustworthy, but the electric winder is more efficient, easier to control and easier to maintain in a state of efficiency. Both are equally reliable when of high class and of suitable proportions for their loads.

The case can therefore be settled on running cost so far as the winder is concerned, but the remainder of the plant must influence the choice. If the mine is deep the winder may take anything up to 50 per cent of the total power consumption of the mine. Under these conditions the load on the generating plant is extremely variable and the average load small compared with the peak load. If the plant supplies a single mine, then the diversity factor is low; but if the generating plant supplies a group of mines, then the peaks tend to smooth out and a better diversity factor is obtained. For single deep mines, therefore, electric winding may not be justified, but if the mines can be grouped and either their plants interlinked or power generated at one or more central power stations, the superior economy of the electric winder can be utilized to the fullest advantage.

For shallow mines, particularly where heavy loads can be wound at low speeds, the electric winder is usually two to three times as efficient as the steam winder. Capital charges are slightly higher for electric winders and high-pressure generating plant than for steam-winders and mixed-pressure plant, but the total of running and capital charges is in favour of the electric winder. If power is available at reasonable rates from a reliable supply company, then capital charges will be greatly in favour of electric winding, and the running cost should still be lower than for steam winders.

The chief electrical problem to be solved in a winding equipment is the type of control, i.e. whether it shall be the Ward-Leonard system or an a.c. motor with rheostatic control in the rotor circuit. Secondary problems are those of geared or direct-coupled motors, cylindrical, conical or cylindro-conical drums or Koepe pulleys. Balance ropes have to be considered in the case of cylindrical drums, and are essential with Koepe pulleys. Dealing with the main problem, Stjernberg * gave a mathematical method of analysing electric winding problems and reached a conclusion that if $B = MS/(QT^2)$ exceeded 0·22 Ward-Leonard control was preferable, and indispensable if above 0·3,

where M = equivalent mass reduced to rope = weight in lb. ÷ gravity coefficient,
S = depth of shaft, in feet,
Q = useful load plus friction, in lb.,
T = net time of wind, in seconds.

The expression $B = MS/(QT^2)$ was based on cylindrical drums, with balance ropes, but is equally applicable to cylindro-conical drums, reels, Koepe pulleys or cylindrical drums without balance ropes.

Improvements in the design and manufacture of large double-helical gearing and in a.c. motors since that date have resulted in a.c. winders being permissible for values of B up to 0·25 or even 0·3. In two large a.c. winders recently installed the value of B is 0·292.

* *Journal I.E.E.*, 1911, vol. 46, p. 192.

Another method of deciding on the electrical equipment is to fix limiting values, first for the ratio of the acceleration period T_a to the full-speed period T_f. This ratio should not be greater than 0·5 for reasonable economy for an a.c. motor drive. In addition, the acceleration a should not exceed 4 ft./sec./sec., these figures being actual values in the case of cylindrical drums and average values over the small diameter and scroll for cylindro-conical drums.

If S be the total depth in feet, V the maximum velocity in ft./sec., and T_r the retardation period, which normally equals T_a, we have :—

$$S = V(\tfrac{1}{2}T_a + \tfrac{1}{2}T_r + T_f)$$

Using the ratio of T_a to T_f given above, and $a = r$, we get :—

$$T_a = T_r = \tfrac{1}{4}T, \text{ where } T = T_a + T_r + T_f$$

$$S = 3VT_a = \tfrac{3}{4}VT \,;\; V = aT_a = 4T_a = T$$

$$\therefore S = \tfrac{3}{4}T^2$$

TABLE 3.

Time, T	Depth, S	Velocity	Average velocity, V'
secs.	ft.	ft./sec.	ft./sec.

50	1 875	50	37·5
60	2 700	60	45

S being the limiting depth from which winding can be economically effected in the time T with maximum velocity V.

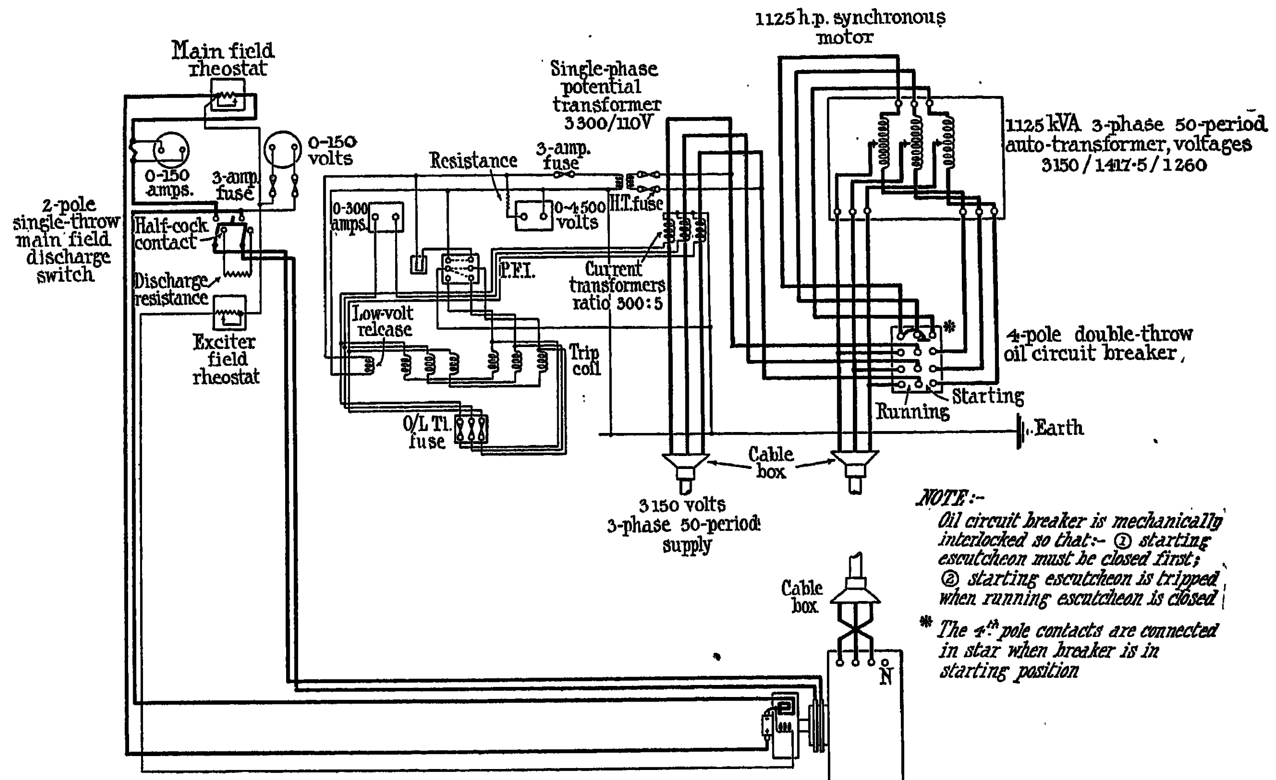
The a.c. motor being inherently a high-speed machine, gearing has been necessary in most cases to transmit the drive from the motor to the drum shaft, the speed of which is seldom higher than 75 r.p.m. or lower than 28 r.p.m. This gearing has in some instances been self-contained with its own bearings, but the two largest a.c. winders in this country at the present time have the spur wheel mounted directly on the drum shaft (which is carried in three bearings) and the pinion coupled to the motor by a flexible coupling of the Bibby type. Fig. 6 shows a normal arrangement for an a.c. winder. Both the double helical and the herring-bone types of gearing have given satisfactory results for some years. Forced lubrication is advisable for the larger sizes.

The speed of the a.c. motor is usually so chosen as to give the lowest energy losses during accelerating and braking. Motors for 250 to 750 h.p. (R.M.S. rating) usually run at 375 r.p.m., 750 h.p. to 1 500 h.p. at 250 r.p.m., and 1 500 h.p. to 2 500 h.p. at 214 r.p.m. The gear ratio, and thus the speed of the drum, can be varied within limits by changing the pinion, but the shaft has to be moved to suit the varying centres. Any large change of drum-speed, therefore, can only be obtained by changing both spur and pinion wheels, and this is an expensive business.

The induction motor is normally a constant-speed machine, its speed variation with short-circuited rotor from no load to full load being only 2 to 5 per cent, but by inserting resistance in the rotor circuit this slip may be increased up to 100 per cent. The speed reduction is proportional to the voltage across the rotor slip-rings, which again is proportional to the torque and resistance in the rotor circuit. Thus the speed corresponding to any particular rotor resistance is not constant, but depends also on the load. Further, regenerative braking in an induction motor is only possible at speeds above synchronism. At any speed below this, to obtain a braking effect the motor must be reversed, and power corresponding to the torque exerted drawn from the line. This power, together with the braking energy absorbed, passes through the rotor to the resistances, and is there dissipated. It is impossible, therefore, to obtain the same delicacy of control as in the Ward-Leonard system.

In high-speed winding, necessary owing to the reduced working hours in mines, retardations of 4·5 and in some cases 6 ft./sec./sec. are necessary to obtain the required output. If normal braking is used, wooden brake blocks last only 4 to 5 weeks and patent fabric linings about double this time. Reverse-current braking is cheaper and more reliable and is used for ordinary coal winding and for lowering men. Regenerative braking is permissible for lowering men for long, slow winds, but reversed current is used to slow down at the ends of the winds. Actually it is safer to use regenerative braking under the above conditions, as it provides a definite limiting speed (5 to 10 per cent above synchronism), rather than to switch off (as is sometimes done) and brake only when the speed becomes excessive. Alternating-current controllers for large motors employ liquid electrolyte, and the resistance is varied in one of two ways; first, moving electrodes; and secondly, moving electrolyte. In the first the resistance is varied by varying the length of liquid electrolyte between fixed and movable electrodes. In the second the resistance is varied by varying the depth of electrolyte in the tank, in which are immersed a number of electrodes. Thus the immersed area is varied, and so the resistance. Each type has its particular advantages. The first lends itself to rapid acceleration, manœuvring and reverse-current braking, the second to uniform acceleration, which can be set for any required rate, and is thus suitable for a fixed and definite rate and load per wind, but it is not so flexible for manœuvring and reverse-current braking. The first method requires the active portion of the electrolyte to be contained in vessels of insulating material. In the second method the electrodes are carried on insulated frames, and the electrolyte in a metal vessel which may be earthed. The electrolyte is circulated constantly by means of a pump, and its height on the electrodes fixed by a movable weir. In

this type there is a danger that when reverse current is quickly applied after a full-speed run the electrodes would be immersed (the liquid not having had time to fall) and, the rotor resistance being low, insufficient torque would be produced in the rotor, resulting in a jerk and damage to the mechanical gear. Again, if the liquid has time to fall, the high voltage produced across the small quantity of liquid in contact with the electrode has a tendency to produce a flash-over inside the controller. This objection is met by providing contactors which introduce a fairly high resistance into the rotor circuit independently of the controller. The relation between forward and reverse torque and resistance in the rotor circuit is an important one and the curves in Fig. 7 show that too high or low a resistance in the rotor circuit results in a reduction of the reverse-current braking effect at full speed, and also show that there is a definite resistance which gives the maximum braking effect at each speed. Heather * was, I believe, the first to point out this fact. He also introduced a special ammeter having a central zero and two elements showing both the magnitude and direction of the stator current and rotor torque in an a.c. winding motor. The present author obtains similar results with a single-phase central-zero indicating wattmeter, the potential supply to which is reversed by contacts on the master controller operating the main contactors. This gives at all times the magnitude and direction of the power supplied to the a.c. motor and is interesting to watch when working regeneratively or with reverse current. The starting and stopping of a.c. induction motors is accomplished by switching " on " and " off " the main current. Reversal of rotation is obtained by interchanging the connections of two of the phases in the case of a three-phase motor, or both phases in the case of a two-phase motor. All this has to be done a great number of times a day, and the switchgear for carrying out these operations has therefore to be of the most robust construction, electrically and mechanically. Both oil-immersed and air-break reversing switches are used. For small sizes oil-immersed direct-operated quick make-and-break switches are satisfactory, but for larger sizes automatic operation is necessary, as the labour of continued reversals is great. Contactor-type air-break switches with powerful magnetic blow-outs are much used and give satisfaction, the wear of contacts being slight. Fig. 8 shows a complete switch of this type. Oil-immersed contacts wear more rapidly, and the oil requires to be frequently renewed. Oil-immersed switches are more compact, and up to 100 amperes on 3 000 volts, if inspected at frequent intervals and the contact faces maintained in good condition, are quite satisfactory. Owing to the considerable mass of the moving contacts and operating mechanism of electrically operated air-break contactors, the force necessary to obtain rapid movement is large and there is a tendency to bounce. Also, the vibration set up by the heavy blows of the closing contacts tends to loosen



FRONT VIEW

* *Journal of the South African Institute of Electrical Engineers*, 1912, vol. 10, p. 157.

fastenings and to fracture small interlocks and mechanism. To overcome this trouble, compressed air has been tried as an operating medium, with very satisfactory results. Fig. 9 shows a section of the operating mechanism. An interesting feature observed in these large air-break contactors is that the arc produced when a current of low power factor is broken is much greater than that from a current of high power factor. Apparently the blow-out coils are less effective when current and voltage are considerably out of phase, as in the case of the no-load current of a low-speed a.c. motor.

that power must be cut off at such a point that the inertia of the moving masses is just sufficient to bring the load to bank with the merest touch of the brakes to hold the load as it drops on the keps. Even when winding coal only, the loads vary considerably (some trams are filled by conveyer, and others by hand), or occasional trams of rubbish have to be dealt with, and it will be seen that it requires considerable skill on the part of the enginemen to judge correctly for each differing load the exact point at which to cut off power. The general tendency is to cut off a little too early, with the result that power has to be switched on again to

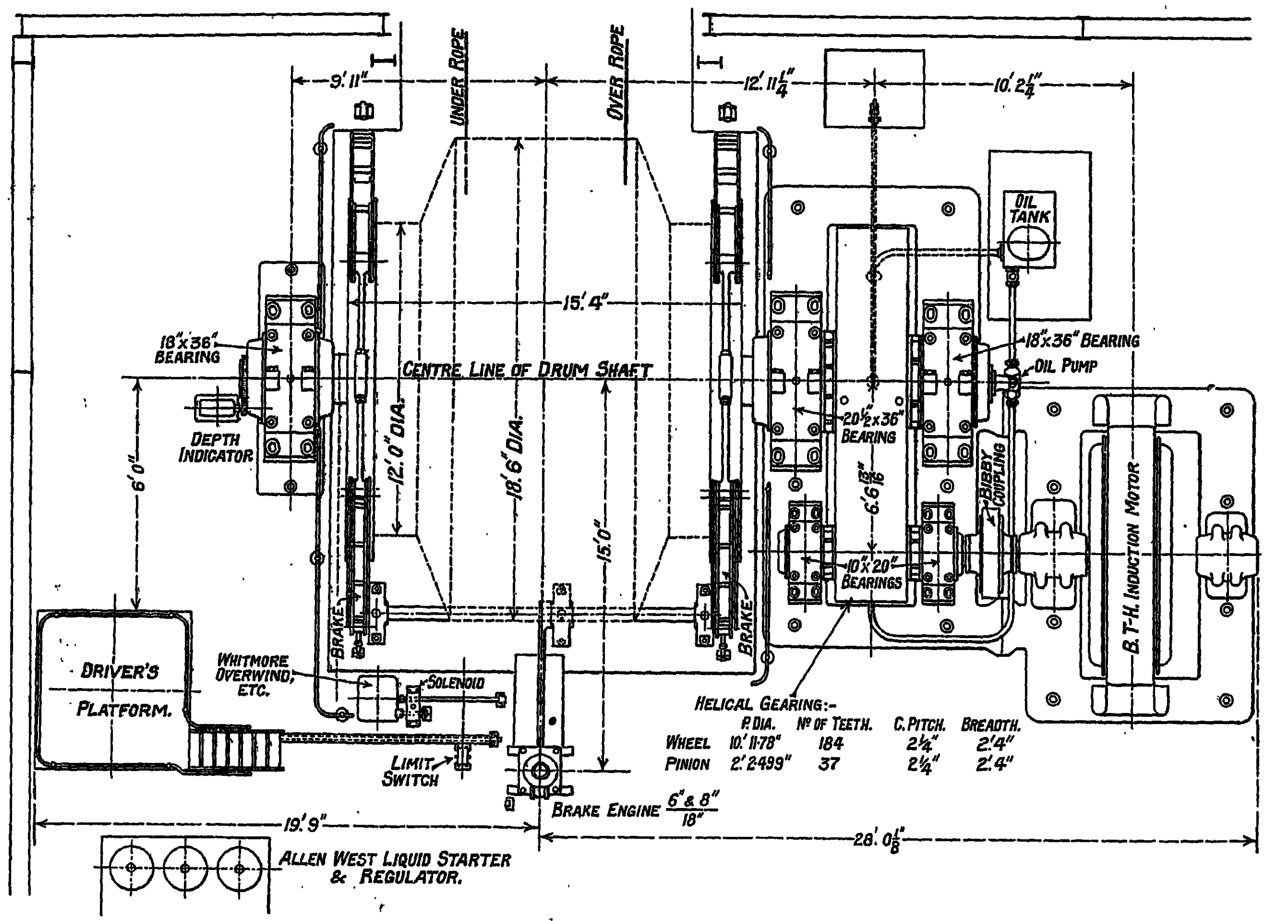

FIG. 6.—Alternating-current electric winder.

In addition to the above consideration in deciding upon the type of winder, the peak-load capacity of the generating station and transmission mains has a great influence. Further, it must be borne in mind that an a.c. winder has a definite maximum speed, which can only be altered by changing the gearing, and its maximum efficiency is only attained at the particular schedule for which it is designed. With all these limitations, however, there is a great field for a.c. winders, from small winders at shallow depths to large winders raising heavy loads at low speeds from greater depths. For maximum efficiency the a.c. winding diagram should be so arranged that no braking is necessary. This means

bring the load to bank. Fig. 10 is a typical wattmeter diagram of such a wind for a cylindrical drum. With a cylindro-conical drum the resulting load on the motor is very heavy, often twice as great as when lifting the normal full cage from the bottom, as the full cage rope is on the large diameter, and the motor receives little help from the empty cage and rope which is on the small diameter. Cutting off too late results in heavy braking.

The advantages of the a.c. system are simplicity, low capital cost, less space occupied, no stand-by losses; and of the Ward-Leonard system, flexibility, ease of control, complete automatic control if desired, lower wear and

tear of brake gear, peak loads on system gradually applied (not instantly as in the case of alternating current) and of shorter duration.

The efficiency varies. For high-speed winds the Ward-Leonard system is usually more efficient; for heavy loads from deep shafts at moderate or low speeds, i.e. where the Stjernberg coefficient is low, alternating current is more efficient. Where it is a question of getting a maximum output from a certain size of shaft with definite limits of weight per wind, the Ward-Leonard system is usually necessary. The two-speed further experience is necessary before mining engineers are prepared to take advantage of the evident improvement possible in the larger sizes.

The d.c. motor is inherently a low-speed machine, and motors of large size to run at speeds down to 30–40 r.p.m. for direct coupling to the drum shaft can be made with high efficiencies. Several large d.c. equipments have recently been installed with geared motors. Fig. 11 shows such a one. Whilst a commercial case has evidently been made out for these, it can only be in first cost. The published efficiency of the geared motors

cascade motor shows a considerable increase in efficiency and reduction of peak loads over the single-speed induction motor, owing to the reduced rheostatic losses. In modern designs this type of motor is run up to cascade speed, then the rotor slip-rings are short-circuited (without breaking the stator circuit), and the motor runs up to full speed. Resistance for control is introduced into tappings in the stator circuit. This type of motor has only been tried in moderate sizes and, as reliability is the essential feature of a winding engine, in this case is 94·5 per cent at 350 r.p.m. Corresponding direct-coupled low-speed motors installed by the author have a full-load efficiency of 92·7 per cent. The gearing losses will be at least 2 per cent when new, and higher when the gears begin to wear, so that the balance of efficiency is in favour of the direct-coupled motor. Reliability and maintenance costs are still more in its favour, as there is only one low-speed bearing to maintain, against two low-speed and four high-speed bearings, a pair of gears and a flexible coupling. These

factors will justify a considerably higher first cost in the case of a direct-coupled motor.

An increase in speed of 30 to 40 per cent is permissible on the Ward-Leonard motor by field control alone, and any desired lower speed can be obtained by fixing a stop on the control lever, or better by a resistance inserted in the Ward-Leonard generator field limiting the armature voltage. Thus the winding speed which gives maximum efficiency for any coal output can be fixed and maintained in a Ward-Leonard equipment, the speed being increased from time to time as the mine develops and the output increases.

Until quite recently Ward-Leonard motor-generator sets have been driven by induction motors. Where the generating plant capacity is small compared with the peak loads, flywheels have been introduced to equalize the loads. The losses in these flywheels are appreciable; to run a 12 ft. 6 in. diameter 30-ton wheel and two variable-voltage generators of 1 100 kW at 500 r.p.m. absorbs between 150 and 210 kW continuously. A large part of this loss is in the induction motor which is running at very low efficiency. Further, to enable the flywheel to give up its energy during peak loads, the speed of the set must be reduced. In induction-motor-driven sets this is usually done by inserting resistance in the rotor circuit of the motor by an automatic device. This reduces the rotor efficiency in direct proportion to the increased slip, and the resulting average efficiency of

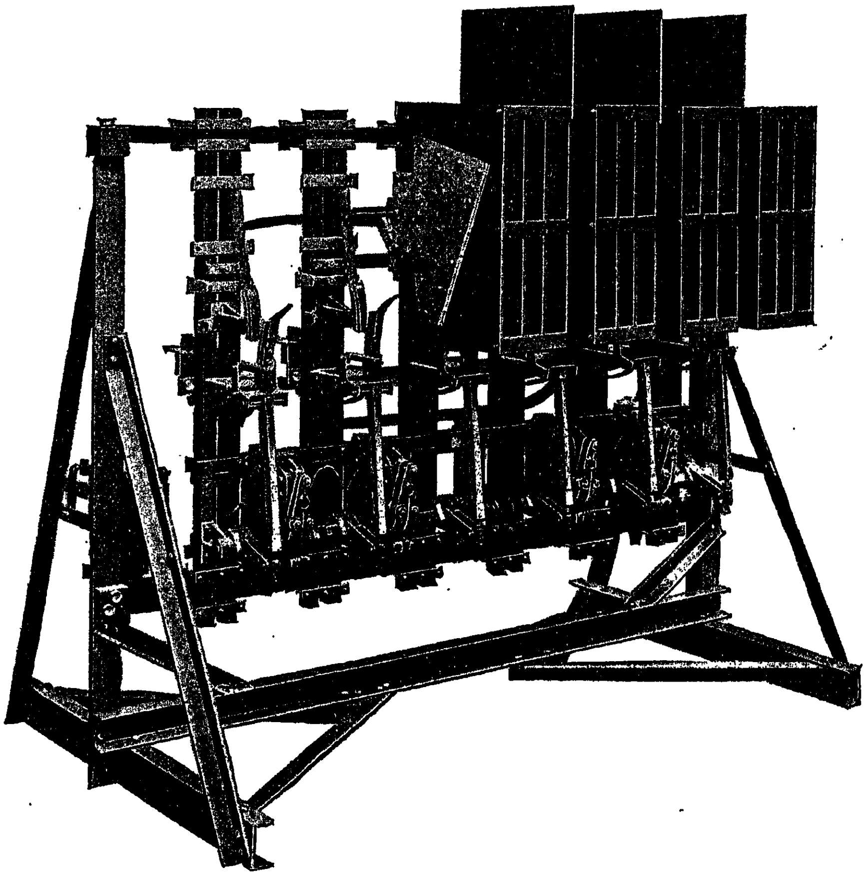

Fig. 8.—Contactor air-break reversing switch.

Table 4.

	Light-load losses	Average efficiency	Peak load	Overall efficiency
	kW	per cent	kVA	per cent
Ward-Leonard generator and synchronous motor ..	80	92·0	3 480	61·0
Ilgner (10 500 V)	205	83·0	3 300	47·0
Ilgner (3 200 V)	150	—	—	—
Ilgner (3 200 V)	115*	—	—	—

* Without flywheel.

the motor over a winding schedule may be as low as 80 or 82 per cent, even in a large machine. If the equipment is run faster than the pre-arranged schedule this may fall to 75 per cent owing to the set being unable to pick up its speed between winds.

Complete equalization for winding schedules raising large tonnage from considerable depths is not feasible, and even partial equalization involves heavy flywheels and correspondingly heavy light-load losses. The author is of the opinion that money can be more suitably spent in increasing the generating plant capacity and in improving the transmission system generally.

If a flywheel with speed variation is not to be used, then the efficiency and reliability of the equipment may be improved by driving the motor-generator set by a synchronous motor. The efficiency of this type of machine will be at least 2 per cent higher than that of an induction motor for similar output. The comparative efficiencies of two equipments of almost equal size, one being of the Ilgner type and the other a plain Ward-Leonard driven by a synchronous motor, are given in Table 4.

The Ward-Leonard set comprises two 1 100-kW 600-volt variable-voltage generators coupled on either side of a 3 250-h.p. 3 200-volt 50-period three-phase synchronous motor designed for 0·8 leading power factor at full load. The main exciter supplying the variable-voltage fields, four motor fields, brake solenoids and other accessories is mounted on an extension of one of the generator shafts and has no outboard bearing. The synchronous motor exciter is mounted in a similar way on the other generator shaft. The whole set runs at 750 r.p.m. This set supplies a winding engine running at 51 r.p.m. and having two 1 400-h.p. motors direct-coupled to a 14 ft. to 22 ft. winding drum arranged for 60 winds per hour, 7·5 tons per wind, giving a normal output of 450 tons per hour from a depth of 650 yards. This can, however, be speeded up to 525 tons per hour if required, without exceeding the B.E.S.A. temperature limits on the various machines.

The Ilgner equipment comprises two 1 035-kW 600-volt variable-voltage generators driven by a 2 000-h.p. induction motor. Two of these sets are supplied at 10 500 volts and the third at 3 200 volts, all three-phase at 50 periods. The flywheels are 12 ft. 6 in. in diameter, weigh 30 tons and are entirely enclosed to reduce windage. The sets run at a full-load speed of 485 r.p.m., and with maximum slip the speed is reduced to 400 r.p.m. The flywheel bearings have forced lubrication and the main bearings on all sets are water-cooled. Excitation is supplied for the Ilgner set by a separate motor-driven exciter of 80 kW with a battery as a stand-by, so that the Ilgner set light-load losses do not include the exciter losses. Each Ilgner set supplies a winding engine having two motors of 1 300 h.p. at 62 r.p.m. direct-coupled to a 14 ft. to 22 ft. winding drum, the output for which they were designed being 60 winds per hour, 6 tons per wind, or 360 tons per hour from a depth of 725 yards.

The overall efficiency is based upon the specified winding schedule. At any lower rate or on an all-day basis the consumptions per ton raised would be still more in favour of the Ward-Leonard set, owing to the lower light-load losses.

The great difference in efficiency is not all due to the relative efficiency of the two systems but is partly due to the winding scheme, the Ilgner set winding lighter loads at higher speeds.

The synchronous motor is of the self-starting and synchronizing type and is started through an auto-transformer with one tapping. The starting current is less than full-load current and the set is run up to speed and synchronized in 60 seconds.

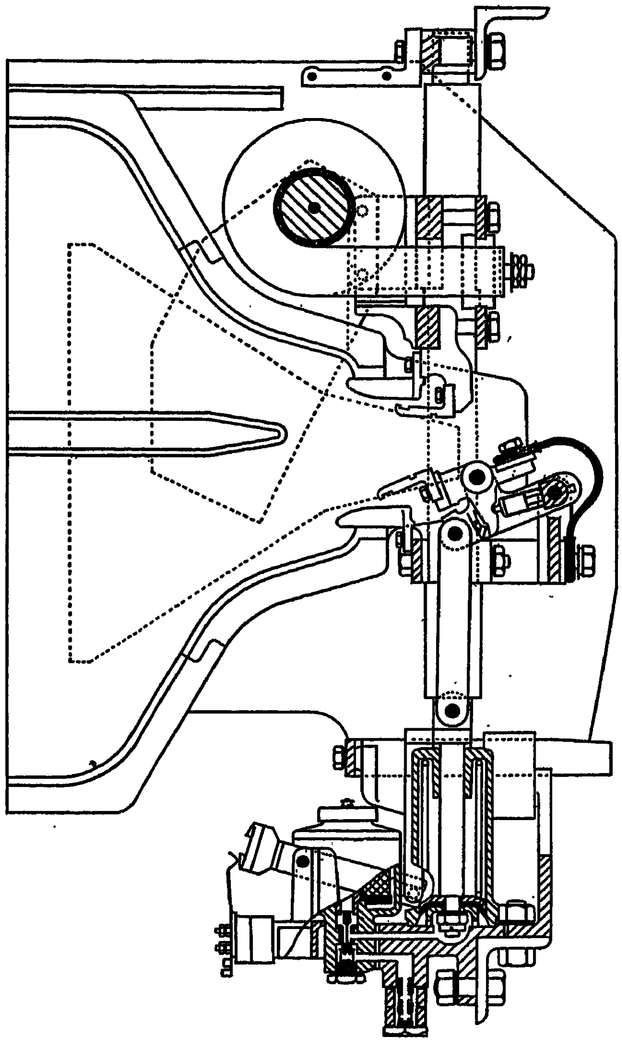

Fig. 9.—Compressed-air-operated contactor.

Advantage has been taken of the improvements in commutation at high speed (resulting from rotary design) to increase the speed of the winder motor-generator sets, and peak loads up to 7 000 h.p. are now dealt with by generators running at 750 r.p.m.

Two valuable and interesting papers on the "Comparison of costs between the Ward-Leonard and Three-Phase Winding Systems" were contributed to the South African Institute of Electrical Engineers, one by Renner in 1911 and another by Ewing in 1916. These refer

to the special conditions existing in South African gold mines, i.e. deep shafts (sometimes inclined) and automatically loaded skips, but the results obtained are easily applicable to our conditions by a few eliminations. For various reasons, balance ropes are not a success in British mines, at least in the author's experience. Of three installations (two alternating-current and one Ward-Leonard) laid out for balance-rope operation, one a.c. equipment ran for only a few months at high efficiency, the balance rope then being damaged beyond repair by a tram falling upon it in the sump. As the gain in efficiency did not represent the cost of a new balance rope every few months, the set now runs without a balance rope. The Ward-Leonard set ran for some years with a balance rope, but the colliery managers, with experience based upon steam winders, or else prejudice, never approved of it and eventually after a similar accident the balance rope was eliminated.

For deep mines and high speeds, cylindro-conical drums are used in preference to balance ropes.

The idea expressed in both the above-mentioned papers—that Ward-Leonard sets must of necessity cost more for maintenance—is incorrect. The maintenance cost of a set of oil-immersed reversing switches on a 1 100-h.p. a.c. winder amounted to £150 per annum; wear and tear on the liquid controller is high owing to the corrosive action of the electrolyte. Slip-ring brushes wear about ⅛ in. in 6 000 hours' operation.

The maintenance of a high-speed motor-generator set consists chiefly of brush renewals. The average wear in 6 000 hours' running of a 750-r.p.m. 1 100-kW set is $\frac{1}{16}$ in. per brush. Slip-ring brushes wear more rapidly, ⅜ in. being the average in 6 000 hours. The wear of the low-speed d.c. winder motor brushes is less than $\frac{1}{32}$ in. in 6 000 hours. In one large set under the author's observation the main motor brushes have not been changed in 11 years and the wear is less than ¼ in. The motor-generator set has also a number of the original brushes still running. The average cost per annum for brush renewals, including labour for bedding, will not exceed £50 for a 1 400-h.p. Ward-Leonard set and winder motor. Bearings appear to run indefinitely on high-speed motor-generator sets. They are mostly flood-lubricated and water-cooled.

The 1 100-h.p. a.c. equipment referred to is gear-driven and, although no figures are yet available for the life of these low-speed gears, an estimate of 20 years appears reasonable.

The average yearly maintenance cost would be as follows:—

An 1 100-h.p. a.c. winder with oil-immersed switches	£250
An 1 100-h.p. a.c. winder with air-break contactors	£150
A similar Ward-Leonard set..	£105

The efficiencies of Ward-Leonard sets have improved since these papers were written; otherwise their findings hold to-day. Briefly these are that a.c. winders will effectively carry out all the operations they may be called upon to do, but that from 50 per cent of their schedule load upwards the Ward-Leonard winder is more efficient in straightforward weight-raising, and for all weight-lowering and low-speed work Ward-Leonard operation is considerably more efficient. In addition the control is safer, smoother and simpler and lends itself to complete automatic operation.

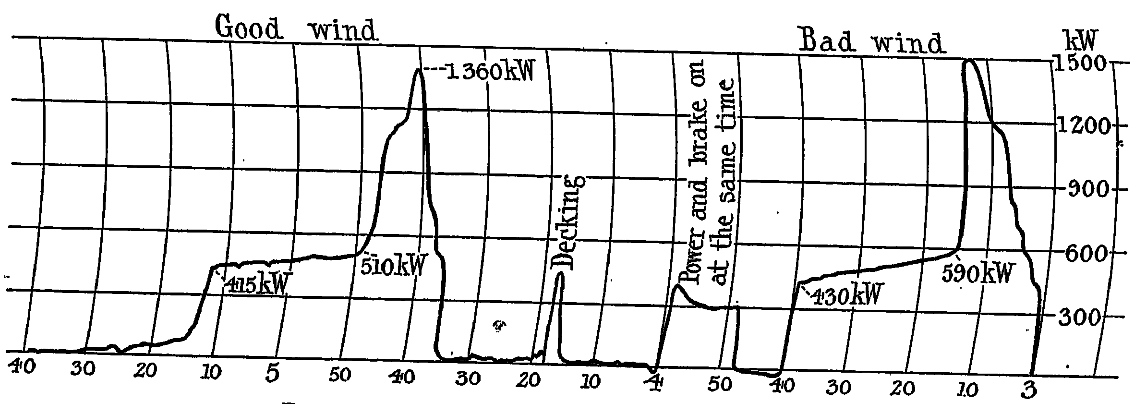

FIG. 10.—Alternating-current winder wattmeter chart.

In the author's experience, winding-engine men taken directly from steam winders require at least 50 hours' practice in a.c. winder control before they can be relied upon, and many months' experience before they can work to a schedule so as to achieve full efficiency. Men taken direct from a steam winder will drive a Ward-Leonard winder with full confidence in an hour or two, and will obtain full efficiency on a schedule in a couple of weeks. The difficult operation of extracting water with a water barrel during sinking operations is mastered in a few attempts on a Ward-Leonard set, but takes twice as long on an a.c. winder, even with a highly skilled driver.

The a.c. winder has a finite maximum output, while the Ward-Leonard set can be speeded up, if required, to the limit of the heat capacity of all the machines. Prices have varied so rapidly in the last few years that a comparison of capital costs is difficult. An approximation based upon a number of recent installations is that the complete Ward-Leonard set, including drum, etc., costs 30 per cent more than an a.c. set for an output of 250 tons per hour from a depth of 600 yards. In all the recent winder equipments for which the author has

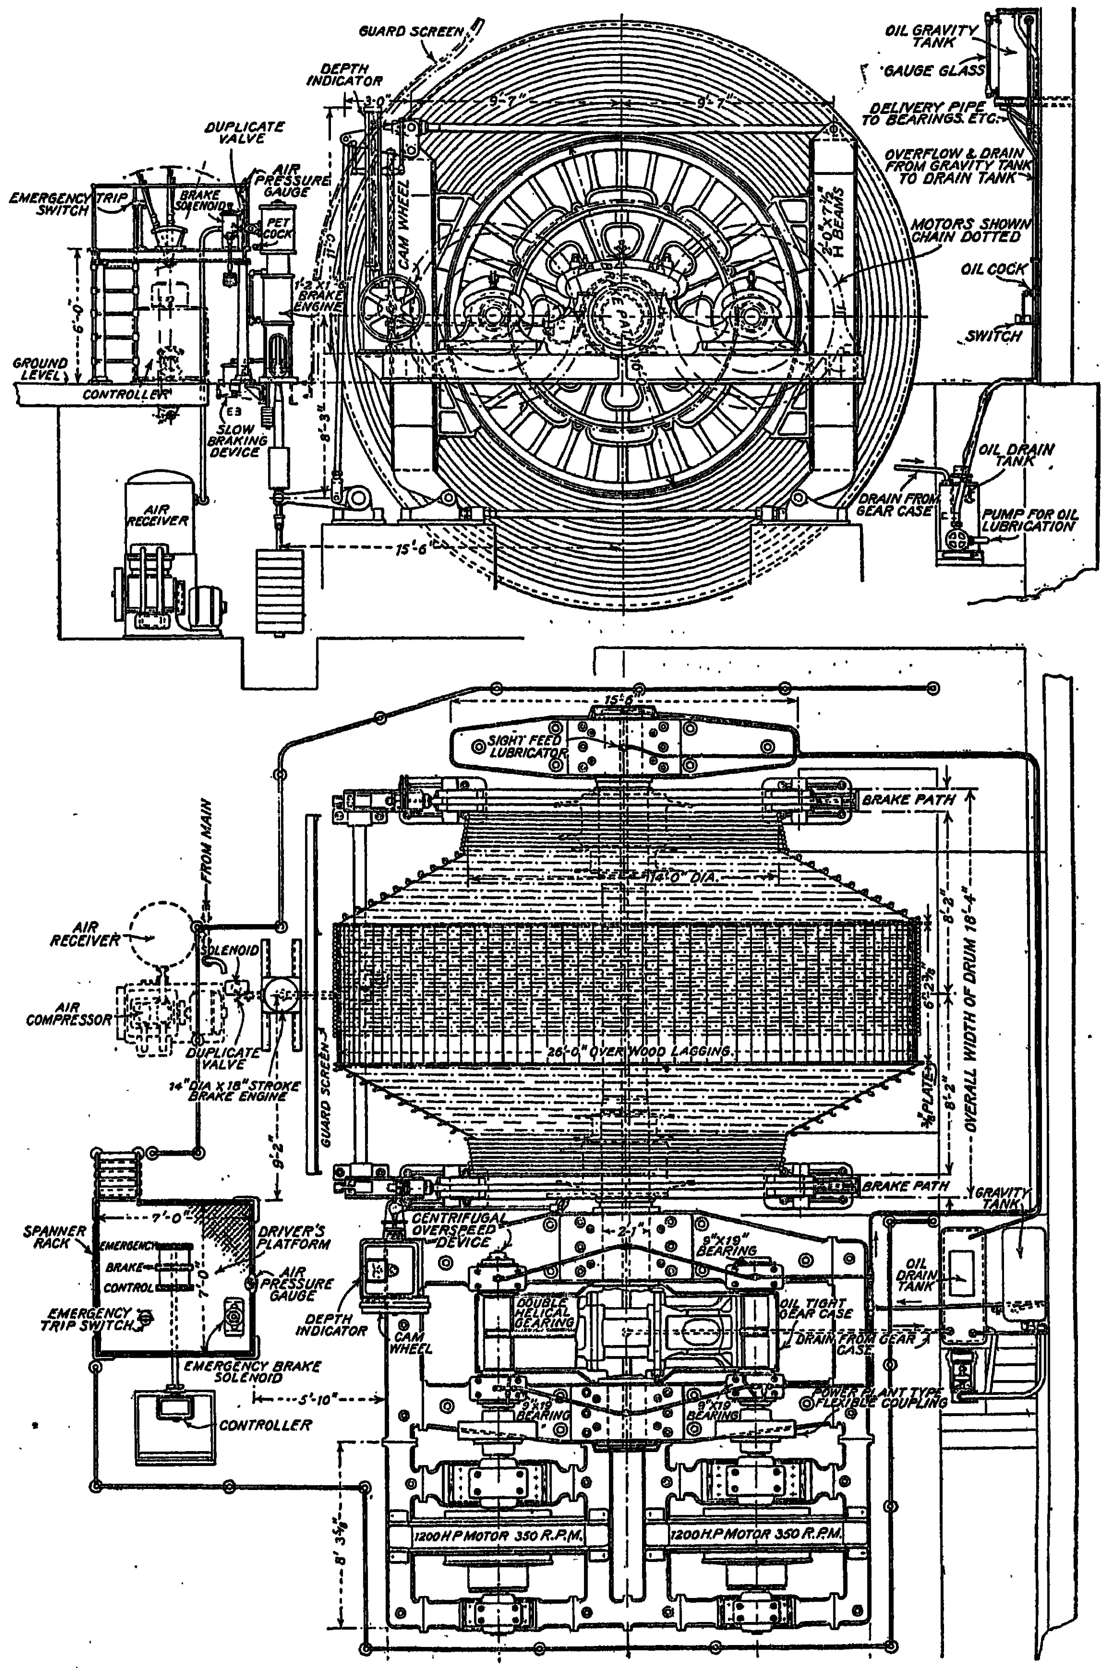

FIG. 11.—General arrangement of the Harworth geared winder.

been responsible, duplicate generators have been provided on the motor-generator sets, each giving half the final voltage. During the sinking and development of the mine, one motor-generator set can thus run two winders at half speed with lower light-load losses and capital costs. Later, when the full output is required, the two generators are connected in series and full speed is obtained on the winder motors, which may also be duplicated if desired. During normal working the winders are run at full speed only during the working shift, and at half speed during the afternoon and evening shifts. These changes are simply and quickly made on a plug board having horizontal and vertical busbars.

An alternative scheme to the usual steam winder and mixed-pressure turbine for isolated collieries has recently been developed, and an equipment is now installed for an output of 3 000 tons per day from a depth of 1 000 yards. The general arrangement is shown in Fig. 11. A Ward-Leonard motor-generator set is driven through gearing by a high-speed turbine. This supplies the two winding motors, the motors being controlled by varying the voltage of the Ward-Leonard generators. A flywheel is provided which takes the peak loads, the turbine governor gear permitting a large range of speed, so that a moderate size flywheel can supply a considerable amount of energy. A valuable feature of this scheme is that full advantage can be taken of the flywheel energy, as speed reduction is not accompanied by a corresponding reduction in efficiency. This plant has been in satisfactory operation for some months and further similar equipments are in progress.

Part 3.

The ratio of winding, compressing and ventilating loads (which may be steam-driven) to pumping, haulage, surface loads and lighting (which are usually electrical) is an important factor in fixing the type of power plant. If the available low-pressure steam from the first three is just sufficient to produce the necessary electricity for supplying the remainder, then it would appear economically sound to install steam winders, fan engines and compressors and mixed-pressure turbines for supplying the remaining power. As, however, the high-pressure steam consumption of mixed-pressure turbines is higher than that of "straight" high-pressure machines, and also as electric winders are twice as efficient as steam winders, and large boiler plants are more efficient than small boiler plants, there are very few cases where a mixed-pressure steam-winder plant can compare favourably with an all-electric plant.

Steam-winder manufacturers usually give consumptions per shaft horse-power or per hour for a given schedule, and ignore stand-by losses. The low-pressure steam from the winders is referred to as a sort of gratuity given to users of steam winders. The heavy high-pressure steam consumption of mixed-pressure turbines is assumed to be useful in maintaining a steady load on the boilers. Figures will be given later in the paper to show that stand-by losses are considerable and, in addition to the smaller boiler plants being less efficient under the varying load, a better class of fuel has to be used than in the large stations.

In conclusion, a few examples are given of actual collieries, (1) steam-operated, (2) electrically operated, and (3) during the transition stage.

The first colliery considered has two winding engines, each operating tandem deck cages raising an average of 50 cwts. per wind, the depth of the shafts being 520 and 450 yards. The engines are of modern type with Corliss valves and governor-controlled cut-off gear. Their consumption per wind calculated from indicator cards is

No. 1 winder .. 175 lb., or 43·8 lb., per shaft h.p.
No. 2 winder .. 166 lb., or 48·2 lb., per shaft h.p.

The pressure is 120 lb./sq. in. and the superheat 425 deg. F.

The fan engine was a rather old vertical type of about 600 h.p. with rope drive.

The three compressors were of the low-speed horizontal Corliss-valve type; two ran during the working shift and one during the remainder of the day. The measured steam consumption of these engines was 28–32 lb. per b.h.p.-hour. All the engines exhausted into a gas-holder type of receiver, and a 2 000-kW mixed-pressure turbo-alternator of modern type utilized the low-pressure steam and generated an average of 86 000 units per week. This set ran only during the working shift.

Average water evaporated by the boilers (three 30 000-lb. Babcock with chain-grate stokers and economizers, and four Lancashire boilers) per week	9 640 000 lb.
Maximum hourly output during the working shift	120 000 lb.
Maximum hourly output during the off shift	60 000 lb.
Average coal consumption per week ..	589 tons
Coal raised per week	12 500 tons
Percentage coal consumption	4·72

11 000 additional units were supplied.

When an electrically-driven fan was installed and the fan engine shut down :—

Water evaporated (average) per week ..	9 124 800 lb.
Coal consumption per week	541 tons
Reduction per week	48 tons
Units consumed by the fan (average) per week	57 000

The compressors, which previously were short of steam, were now enabled to run up to their full capacity, giving a considerably greater output of air.

The compressors were next shut down and the air supplied from the central generating station at the rate of 40 000 000 cubic ft. per week.

Water evaporated per week	4 940 000 lb.
Coal consumption per week	310 tons

TABLE 5.

	Units per week	Units per ton
Present Conditions.		
	kWh	kWh
Winders and mixed-pressure turbines	86 000	6·88
Fan consumption	57 000	4·55
Compressed air	151 700	12·10
Units in addition to those generated by mixed-pressure turbine supplied for colliery washery, etc.	11 150	0·89
Total	305 850	24·42
Estimated Consumption if Winders be Electrified.		
Winders	52 500	4·2
Fan as above	57 000	4·55
Compressed air	151 700	12·10
Colliery washery, etc.	90 000	7·20
Total	351 200	28·05
Comparison with All-Steam Colliery.		
Total coal consumption for winders, compressors, fan engines and mixed-pressure turbine	4·72 per cent of output	
Additional units used over those produced by mixed-pressure turbine	11 150	0·89
Extra compressed air	64 700	5·17
Total	75 850	6·06

The air consumption increased from 8 000 to 9 000 cubic ft. per min. to 15 000 to 16 000 cubic ft. per min. during the working shift, or an average of 70 000 000 cubic ft. per week, the pressure also being increased from 60 lb./sq. in. to 65 lb./sq. in.

The steam winders and mixed-pressure turbines were now the only loads on the boilers, and the Lancashire boilers were shut down, the load being taken on the three water-tube boilers. The light-load losses and auxiliary consumption of these boilers amounted to 10 000–12 000 lb. per hour. Taking the average consumption per wind as 175 lb. for No. 1 winder and 166 lb. for No. 2 winder, over a complete 24 hours the results were as follows:—

Total net consumption for 720 winds of No. 1 winder and 635 winds of No. 2 winder	232 000 lb.
Total light-load losses, feed pumps and auxiliaries for 24 hours	254 000 lb.
Gross consumption, per day, should be ..	486 000 lb.
Actual evaporation, per day	760 000 lb.
Difference, per day	274 000 lb.
High-pressure steam to the mixed-pressure turbine accounted for, per day	224 000 lb.
Left for blow-downs, blowing-off and other unaccounted losses, per day	50 000 lb.

The medium-pressure turbine runs only during the working shift from 7 a.m. to 2 p.m., and the average number of units generated in 7 hours is 14 300, or 2 050 per hour.

The actual high- and low-pressure consumption of steam for winding and generating these units is 58 000 lb. per hour, or an average of 28·3 lb. per unit.

Usually in getting out comparative calculations of steam and electric winding plants the net steam required for winding is taken and then an addition of 12 to 15 per cent made for light-load losses, occasional winds during afternoon and night shifts, and boiler auxiliaries. Actually the average steam consumption during the 7 hours' working shift at this colliery is 480 000 lb., the consumption during the afternoon and night shifts being 280 000 lb. (760 000–480 000), or 58 per cent of that during the working shift. A certain amount of coal-winding is carried out during the afternoon shift from 2.30 p.m. to 4.30 p.m., but when this is not done the evaporation is only slightly reduced. Similar figures for afternoon and night evaporations are obtained from other collieries.

If the steam winders were replaced by electric winders, as they have been at other similar pits, the number of

TABLE 6.

*Comparison of Steam with Electric Winders.**

Winder	Number of winds: Coal	Rubbish	Men	Material	Total	Tons raised: Coal	Rubbish	Consumption per ton of coal raised: Coal	Units	Per cent of output
								lb.	kWh	
Steam	1 572	232	717	244	2 765	6 839	1 200	33·2	—	1·48
Electric	1 650	240	848	250	2 988	7 148	1 240	—	3·7	—

* The figures relate to one complete week's working in each case.

units consumed would be 2·46 per ton of coal raised, or, for men, material, rubbish and coal, 4·20 per ton of coal raised. At 12 500 tons per week this is equal to 52 500 units. The results are summarized in Table 5.

Tables 6 and 7 give actual values for a smaller colliery raising 1 000 to 1 250 tons per day, showing the effect of replacing the steam winder by an electric winder. The fan and compressed-air systems had been converted before accurate water evaporation records were available, but the coal consumption before the conversion was $5\frac{1}{2}$ per cent of the coal raised, with a much lower consumption of compressed air.

Table 7 summarizes all the loads at this colliery.

No. 3 electric winder	1 500	0·21
Fan	28 560	4·00
Compressed air	108 200	15·1
Other colliery uses	26 540	3·71
Total	191 200	26·72

Table 8 shows another gradual conversion. The compressor in this instance was shut down first, the fan afterwards and the winding engines finally. There was no mixed-pressure turbine at this colliery and no water-measuring apparatus. Comparative coal consumptions only can be given. Compressed-air consumptions have in all cases increased since the conversions, due partly to the inadequacy of the steam-driven compressed-air plant and partly to the increased use of conveyers and other air engines.

These results show that wherever accurate records are available, electrification of the whole of the machinery at a colliery can be proved to be a sound commercial proposition. The reduction in pit-head costs resulting from a highly efficient plant is appreciable, although the total cost of power is small compared with the labour costs at a colliery, and the usual method of costing makes it difficult to prove the reductions.

The principal effect of electrification is to reduce the amount of unskilled labour employed at the pit-head, this unsatisfactory and difficult-to-manage gang being replaced by a few skilled hands.

Electrical plant has one special advantage over other types in that the actual consumption of every machine or group of machines can be continuously recorded and any waste checked. Further, electrical plant retains its high efficiency without the constant adjustments and renewals necessary in other machines.

DISCUSSION BEFORE THE INSTITUTION, 19 FEBRUARY, 1925.

Mr. C. P. Sparks: The author refers at the conclusion of the paper to the advantage of being able to obtain exact records. The ease of making exact measurements with an electric drive has done more to enable us to make rapid progress in conversion than any other factor. The main obstacle to progress is the difficulty of comparison with operation under the older conditions. The main reason for electrification is the saving in labour, maintenance and fuel, and the ease of meeting additional power requirements when once an adequate electric supply is available. The author rightly emphasizes the importance of eliminating stand-by losses through the use of electricity, and the results given in the paper confirm the general experience that the saving of fuel by conversion to electric drive amounts to between one-third and two-thirds of the fuel used under the older methods. Dealing with the use of synchronous motors, in view of the importance of maintaining pressure of supply with a heavy fluctuating load on individual feeders, and of keeping down the cost of distribution, the full particulars given by the author of synchronous motors and their methods of control are most valuable. The difficulties of operating with a low power factor were fully appreciated at least 10 years ago. At that time the large system of the Powell Duffryn Steam Coal Co. in South Wales was operating with an output of some 50 million units per annum. The power factor of the stations at that time ranged between 0·7 and 0·8. In view of the progressive fall in power factor with increasing load, the late Mr. George Hann and myself decided that the earliest opportunity must be taken to improve the power factor of this system. The result of the use of synchronous motors on a large scale, driving air compressors, fans and winders through motor-generators, has been to raise the station power factor to between 0·8 and 0·9 with three times the output, now at the rate of some 150 million units per annum. The power factor has been raised and the general pressure on the system much improved, although the system is now operated, owing to its growth, with transformers having higher reactance than when operating on a smaller scale. The author refers to the efforts made to improve the efficiency in winning coal by the use of electricity, but while much has been done much remains to be done. Table 2 shows the average consumption for a typical South Wales colliery, of 32 units per ton of coal raised. The units required per ton vary widely; in some parts of the world the natural conditions are such that coal can be won for the expenditure of a much smaller amount of energy. During a recent visit to the United States I inspected some large colliery undertakings which were operating under favourable natural conditions, and although the whole of the power requirements were supplied electrically the units per ton of coal raised varied from 3 to 5. It would be difficult for us in South Wales to compete with such figures were it not for the fact that these mines are distant from the sea and therefore the question of transport has a material bearing. Of the total of 32 units in Table 2, twenty are used for compressed air, and while I am in agreement with the author as to the efficiency of compressed-air transmission being high, I think that this statement is really misleading, because what has to be taken into account is not only the transmission of the compressed air, but its use; and the compressed-air engine is very inefficient. In my opinion it is most important to improve electrical apparatus and its control so that the use of compressed air can be largely dispensed with. Another thing that is very necessary is better lighting at the face, as this will reduce the risk of accident and at the same time greatly reduce the cost by improving the efficiency of labour. The introduction of the miners' electric lamp with metal-filament lamp has enabled the standard of lighting to be at least doubled in the last 12 years, but there is room for material improvement. In comparing colliery with other power stations, although, of course, every power station should be reliable, reliability is absolutely essential in the case of collieries. One has only to consider the winder, ventilating fans and the pumps to appreciate this point. The author refers to the use of low-grade fuel. In the old days any refuse was used in colliery boilers, but with the improvement of low-grade fuels by washing, and the higher costs of labour to-day, it does not pay to try to burn what I might call dirty fuel, and there is no doubt that the modern tendency, even in the smaller collieries, is to use a higher grade of fuel. The author refers to the advantages which pulverized fuel possesses, but it is doubtful whether the low-grade fuels in their raw form will prove to be suitable for pulverizing. The author refers to the question of reversing switches. These have a heavier duty than any other type, as they have to operate every 45 to 60 seconds. Within the past 2 or 3 years it has been definitely found that, although making these switches larger increases the factor of safety, and although by frequent inspection and changes of oil the risk can be minimized, an oil-immersed switch is not suitable for this work. The best solution is to use a type of air-break switch, as mentioned in the paper. The author draws attention to a point of more than ordinary interest in regard to switches. On page 528 he says: "Apparently the blow-out coils are less effective when current and voltage are considerably out of phase, as in the case of the no-load current of a low-speed a.c. motor." He draws attention here to a matter of great interest to switchgear makers and to users of switchgear generally. The failure of switchgear, which has a large factor of safety when tested under normal conditions, is no doubt due to the greater "arc energy" under the conditions cited. In regard to winders, I entirely agree with the author that the synchronous motor-generator is the right line of approach, especially where the winders are large, as the Ward-Leonard system gives perfect control and is almost essential for the adjustments required during sinking.

Mr. J. A. B. Horsley: The author discusses financial considerations that affect the choice as between steam and electric winders, and describes the technical differences which influence the choice of d.c. or a.c. drive;

but with the exception of a passing reference to the possibility of complete automatic control with the Ward-Leonard system, he makes no reference to the subject of automatic control of the speed during the wind. I submit that such automatic control is of real value and cannot be put aside as a refinement which need not be considered. Methods of automatically controlling the speed are possible with a.c. winders as well as with d.c. winders. I am not referring, of course, to the overwind preventer—that is a statutory requirement—but to some device to control the speed of winding at different stages in the shaft so as to prevent the winding-engine man from increasing his speed beyond that which is safe both in mid-shaft and at either end. During the course of inspection in the Midlands not long ago I saw a recently-installed three-phase winding equipment with which such a device had been incorporated. This was so arranged that if certain predetermined speeds were exceeded the power was cut off and the brakes were applied. I suggested to the engineers responsible that they should devise some means of testing the over-speed preventer by "faking" the controlling rheostat in such a way as to simulate an emergency when running at, say, one-quarter full speed. My suggestion was accepted, both by the users and the manufacturers, and a very simple method has been evolved whereby a spring-return switch is included in the rheostat circuit; when this switch is depressed a certain section of the resistance is cut out so as to enable the automatic device to function at quarter speed as if the engine were really running at full speed.

Mr. J. H. Johnson: I should like to associate myself with Mr. Sparks's remark that the author should not pay too much attention to the relative efficiency of transmission by air and electricity over small areas, but that the question of efficiency throughout the whole system should be considered. It has long been understood and appreciated that over short distances the efficiency of air is higher than that of electricity; but one has to take the whole of the plant as used when making a direct comparison. The author refers on page 523 to the use of the salient-pole synchronous motor. This type of machine has not been largely employed in this country and on the Continent, owing to the fact that it has a somewhat low starting torque and demands a heavy starting current. The auto-synchronous motor or induction synchronous motor has been applied to practically every type of industrial machine at present in use—both in mining and in other industries. The author is rather generous to the salient-pole machine when he refers to an efficiency of 96·7 per cent, compared with the 93·2 per cent for the ordinary induction synchronous motor. If the matter is looked into it will be found that, under ordinary conditions, the efficiency of the former is only about ½ to 1 per cent higher than that of the latter, due mainly to the use of a higher-voltage excitation current. Otherwise the overall dimensions and efficiency remain the same, and the advantages of the cylindrical type are (1) high starting torque at 2 to 3 times full-load torque, (2) automatic synchronizing against full-load torque, and (3) a starting current under ordinary conditions not exceeding the full-load current. The author refers on page 525 to the friction losses incurred in the flywheel of the Ilgner sets. Those can be largely reduced by highly polishing the flywheel and enclosing it in a partial vacuum. The cost of the auxiliary gear is compensated for by the reduced friction losses.

Mr. T. J. Sack: The paper is entitled "Electricity in Mines," but I think that a more suitable title would have been "Electric Power in Mines," as one of the most important uses of electricity in mines is for lighting, and that apparently has been quite ignored. I had hoped to find that some further progress had been made in the lighting of the coal face on the lines laid down by Prof. Thornton in a paper * read before this Institution, in which he suggested that a high frequency of, say, 165 periods, and a low pressure, approximately 25 volts, should be used. It is ridiculous that all this money should be spent on hauling coal and getting it up to the surface, and scarcely any on the actual coal-getter, as far as providing him with better light is concerned. At the present time he works with, in some cases, as low as 0·008 foot-candle on his work. Coal-owners pay £500 000 per annum as compensation for miners' nystagmus, which has been proved to be entirely due to inadequate illumination.† There are a great many limitations to the present design of miners' electric hand-lamp. One of the chief of these is the weight: it has to be limited to 5 or 6 lb. Another factor is the rough usage which these lamps have to withstand. A 2-volt accumulator is the one best fitted to fulfil the foregoing conditions, but 2 volts happens to be the very worst voltage from the bulb-makers' point of view. Owing to physical laws, it is impossible at present to make a really efficient 2-volt bulb that will have a life long enough to satisfy the colliery owners.

Mr. W. C. Mountain (*communicated*): The author has divided his paper under various headings which I propose to deal with in order, and I hope I may be forgiven for introducing into my remarks a good deal of the commercial side of the subject, as I feel, and always have felt, that the introduction of electricity into any enterprise is dependent entirely upon its value commercially. We all know that there are very great opportunities for the use of electricity, particularly in colliery work, but it must not be taken for granted that electricity can be introduced into all sections of colliery work, unless it can be generated or supplied at a price per unit which will render its use economical in comparison with steam, and there are a number of points in the paper with which I propose to deal on these lines.

Boilers.—From my own experience, which has now extended over nearly 43 years (during which time I have been principally engaged upon the development of electrical work in collieries), I have found that probably the most inefficient section is the boiler plant. One finds Lancashire boilers installed in many collieries in considerable numbers and of all ages and sizes, and it is no uncommon thing to find a battery of boilers with a certain number of new boilers having a working pressure of 150 lb. per sq. in., and amongst the battery are several old boilers with a working pressure of probably only 70–80 lb. per sq. in., yet these are retained in use and this

* *Journal I.E.E.*, 1924, vol. 62, p. 481.

† Report No. 65 of The Miners' Nystagmus Committee of the Medical Research Council.

means that the working pressure of the battery is limited to the highest pressure for which the old boilers are suitable. In addition to this, the boilers are generally improperly housed, the boiler flues are in a bad condition, and in very many cases superheaters and economizers are omitted altogether.

Lancashire boilers have necessarily (due to their design) a very limited grate area and consequently, if it is desired to get the utmost steaming capacity out of the boilers, a good coal must be used, otherwise inferior coal will necessitate the use of special fire grates with steam jets, etc., to force the boilers as much as possible. It seems to me that for some reason (which it is difficult to understand) many colliery engineers are prejudiced against the use of water-tube boilers, but they are coming more and more to the front and there is no doubt that if it is desired to burn unsaleable and inferior fuel, it can only be done satisfactorily and economically in water-tube boilers with either induced draught or balanced draught.

The author deals with the use of coke-oven gas to be utilized either in gas engines or under boilers, and this is a subject to which I have given a considerable amount of attention, particularly in connection with a large scheme in the Midlands. It is frequently assumed that the thermal efficiency of gas engines is two or three times as high as that of steam turbines. This, however, is a mistake, and a very exhaustive consideration of the whole subject led me to conclude that the ratio of power which could be obtained with high-pressure steam turbines with gas-fired boilers, to that with gas engines using coke-oven gas, was 10 : 14; in other words, with steam turbines 700 kW and with gas engines 1 000 kW could be obtained with the same consumption of gas. The calorific value of the gas was 400–450 B.Th.U. per cub. ft. and it was assumed that it required 3·75 cub. ft. of gas to evaporate 1 lb. of water at 212° F. into steam at 160 lb. per sq. in. pressure and 150 deg. F. superheat. In connection with this report I prepared some tables which are shown here as Tables A, B, C and D.

These tables are so arranged that the figures can be easily adjusted to suit varying conditions, and the conclusion to which they led me was that it would be far better to adopt water-tube boilers (gas-fired) and steam turbines, in preference to gas engines, as I felt that turbines were much simpler, would require less attention in running and, although the thermal efficiency was not so high as with gas engines, the commercial efficiency, i.e. the cost of current produced, was greater. It would be of interest if the author would give some information on this point, as I think that his company have installed gas engines, also high-pressure and mixed-pressure steam turbines.

As an example of what can be done with boiler plant, I recently inspected a modern installation of Babcock and Wilcox boilers, consisting of four boilers each of 30 000 lb. capacity per hour, and 150 lb. per sq. in. working pressure. They were burning (on chain-grate stokers) refuse coal and dirt which had been lying on the pit-heap for years, together with 25 per cent of small coal of an inferior quality. The result was a saving exceeding £2 000 per month in the cost of steaming, and it was expected that the whole cost of the boilers would be saved in from 1½ to 2 years. The original boiler plant consisted of 18 Lancashire boilers, each 30 ft. long by about 8 ft. diameter. The saving in stokers' wages alone by introducing water-tube boilers with chain-grate stokers, and a proper means of distributing the coal to the boilers, exceeded £50 per week.

Fan driving.—The author refers to the question of driving colliery fans by synchronous motors. I entirely agree with this provided that the fans themselves are driven by ropes or belt, and I think that this method of driving has very considerable advantages as it enables the speed of the fan to be varied by changing the pulleys at very small cost. It is particularly useful where collieries are being developed, and it is only necessary to run the fan at a low speed in the early days. I have used cascade motors designed for two-thirds and full speed. This is a useful arrangement, so much so that in one colliery we found that, although the colliery company estimated that they required the full capacity of the fan at full speed, we ultimately found that at two-thirds of full speed we were able to give them the ventilation they required, i.e. with about half the original water gauge estimated as necessary and two-thirds of the volume of air. I have also used for fan drives ordinary slip-ring induction motors with phase advancers, with very satisfactory results. It is, however, very important, where it is proposed to drive fans electrically, to consider what the cost will be for current, and in connection with a drive of this description—for which a supply had been taken originally from a supply undertaking—the following comparative results between electric drive and steam drive were obtained :—

Capacity of fan, cub. ft. per min. ..	350 000
Water gauge, inches	5
Air horse-power $\left(\frac{350\,000 \times 5 \times 5{\cdot}2}{33\,000}\right)$, say ..	300
Brake h.p. of fan at 70 per cent eff.	425
Units per hour (425 b.h.p. × 830 watts per h.p.)	350
Units per annum (350 × 8 760)	3 066 000
3 066 000 units at 0·5d. per unit ..	£6 387 per annum
3 066 000 units at 0·33d. per unit ..	£4 216 per annum
3 066 000 units at 0·25d. per unit ..	£3 194 per annum

I investigated this to see what the probable cost would be if the fan were steam-driven, with the following result :—

Fan requires, say, h.p.	425
Steam per b.h.p. per hour, lb.	20
Total steam per hour, lb.	8 500
Evaporation per lb. of coal, lb.	7
Total coal per hour, lb.	1 214
Hours running per annum	8 760
Tons of coal per annum $\left(\frac{1\,214 \text{ lb.} \times 8\,760}{2\,240}\right)$, say	4 800
Boiler coal per ton, say	10s.

Approximate cost of a compound high-speed steam

TABLE A.

Cost of Current produced by One 1 000-b.h.p. Gas Engine, and 700-kW Generator with Coke-Oven Gases of a Calorific Value of 400–450 B.Th.U. per cubic foot.

Cost of generating plant with gas-cleaning plant for 700 kW	Load factor	Units produced per annum	Gas per kWh (400–450 B.Th.U.)	Cost of gas per annum, at 6d. per 1 000 cub. ft.	Cost of labour for gas engines, cleaning, plant repairs, oil and stores, and insurance per annum	Cost per unit on capital at 12½ per cent for interest and depreciation (£30 000)	Cost per unit of gas consumed at 6d. per 1 000 cub. ft.	Cost per unit for labour (£2 500)	Total cost per unit generated
One 1 000-b.h.p. engine; one 700-kW alternator; 1 switchboard; 1 suitable power house; 1 crane; 1 gas-cleaning plant; 1 gas holder; 1 starting plant; gas pipes; water pipes and pumps. Total, £30 000.	per cent 100	6 000 000	cub. ft. 40	£ 6 000	3 engineers, 3 labourers, 1 fitter, 1 labourer, etc. £2 500.	d. 0·15	d. 0·24	d. 0·1	d. 0·49
	90	5 400 000	42	5 560		0·166	0·25	0·11	0·526
	80	4 800 000	44	5 250		0·188	0·26	0·125	0·573
	70	4 200 000	46	4 750		0·20	0·27	0·143	0·613
	60	3 600 000	48	4 300		0·25	0·285	0·166	0·701
	50	3 000 000	50	3 750		0·3	0·3	0·2	0·8
	40	2 400 000	52	3 100		0·375	0·31	0·25	0·935
	30	1 800 000	54	2 450		0·5	0·325	0·33	1·155
	25	1 500 000	55	2 050		0·6	0·33	0·4	1·33
	20	1 200 000	56	1 650		0·7	0·335	0·5	1·535

Note: If duplicate plant is installed the increased cost per unit can be ascertained by adding to the unit price for one plant the interest and depreciation on the additional plant.

TABLE B.

Cost of Current produced by One 1 000-kW Turbo-Generator with Two Lancashire or Water-Tube Boilers. Steam Pressure 160 lb. per sq. in. (gauge); Superheat 150 deg. F.; Vacuum 27·5 in.; Coal 12s. per ton.

Cost of generating and boiler plant (1 000 kW)	Load factor	Units produced per annum	Coal per kWh	Coal used per annum	Cost of coal per annum at 12s. per ton	Cost of labour for engineers and stokers per annum, including water and boiler cleaning	Cost per unit on capital at 12½ per cent for interest and depreciation (£2 625)	Cost per unit for coal consumed	Cost per unit for labour (£1 552)	Total cost per unit
One 1 000-kW mixed or high-pressure turbo-generator; condensing plant; power house with crane; main switchboard and coupling cables; steam pipes; cooling plant, etc., £16 000. Two 30 ft. by 9 ft. 3 in. Lancashire boilers with seatings and chimney, £5 000. Total, £21 000.	per cent 100	8 800 000	lb. 3	tons 11 600	£ 6 960	3 engineers and 3 stokers, one each shift, one ashman 1 shift, £26 per week, £1 352 per annum. Boiler cleaning and sundries, £200. Total, £1 552 per annum.	d. 0·0715	d. 0·19	d. 0·042	d. 0·3035
	90	8 000 000	3·2	11 200	6 720		0·079	0·2	0·045	0·324
	80	7 000 000	3·4	10 600	6 360		0·09	0·218	0·053	0·361
	70	6 200 000	3·6	10 200	6 120		0·102	0·237	0·06	0·399
	60	5 300 000	3·8	8 900	5 340		0·12	0·242	0·071	0·433
	50	4 400 000	4·0	7 800	4 700		0·143	0·257	0·084	0·484
	40	3 520 000	4·2	6 500	3 900		0·178	0·266	0·106	0·55
	30	2 660 000	4·4	5 100	3 060		0·237	0·277	0·139	0·653
	25	2 200 000	4·6	3 750	2 700		0·287	0·29	0·169	0·746
	20	1 780 000	4·8	3 750	2 250		0·354	0·3	0·21	0·864

Note: With lower load factor than 50 per cent, cost could possibly be reduced due to reduction in operating staff.

TABLE C.

Cost of Current produced by Two 250-kW Reciprocating Sets (= 500 kW) with Two Lancashire or Water-Tube Boilers. Steam Pressure 160 *lb. per sq. in. (gauge); Superheat* 150 *deg. F.; Vacuum* 26 *in.; Coal* 12*s. per ton.*

Cost of generating and boiler plant (500 kW)	Load factor	Units produced per annum	Coal per kWh	Coal used per annum	Cost of coal per annum at 12s. per ton	Cost of labour for engineers and stokers per annum, including water and boiler cleaning	Cost per unit on capital at 12½ per cent for interest and depreciation (£1 625)	Cost per unit for coal consumed	Cost per unit for labour (£1 552)	Total cost per unit
	per cent		lb.	tons	£		d.	d.	d.	d.
Two 250-kW reciprocating sets; 2 condensers; main switchboard and coupling cables; power house; 2 30 ft. by 9 ft. 3 in. Note: With lower load factor than 50 per cent, cost could possibly be reduced due to reduction in operating staff.

TABLE D.

Cost of Current produced by One 1 000-*kW Mixed-Pressure Turbo-Generator with Receivers and Exhaust Steam Pipes. Steam Pressure* 16 *lb. Absolute* (1 *lb. gauge*)*; Vacuum* 27½ *in.*

Cost of generating plant with exhaust steam, receivers and pipes (1 000 kW)	Load factor	Units produced per annum	Coal per kW per annum	Cost of labour for engineers, assistants oil, water, and repairs	Cost per unit on capital at 12½ per cent for interest and depreciation (£2 250)	Cost per unit for steam, nil. Allowance must be made if H.P. steam used	Cost per unit for labour, stores, etc. (£1 000)	Total cost per unit generated	Exhaust steam used per kW generated
	per cent				d.		d.	d.	lb. per hour
One 1 000-kW mixed-pressure turbo-generator; 1 condensing plant; power house and crane; main switchboard and coupling-up cables; steam pipes; exhaust steam pipes; receivers made from old boilers; valves; grease separators.	100	8 800 000	Nil	3 engineers, 1 assistant, £16 10s. per week. Oil, stores, etc., £142.	0·062	Nil	0·027	0·089	35 approx.
Total, £18 000.	90	8 000 000	Exhaust steam available at all times	Total, £1 000.	0·068	Nil	0·029	0·097	37 approx.
	80	7 000 000			0·078	Nil	0·035	0·113	39 approx.
	70	6 200 000			0·087	Nil	0·039	0·126	40 approx.
	60	5 300 000			0·105	Nil	0·046	0·151	42 approx.
	50	4 400 000			0·124	Nil	0·055	0·179	44 approx.
	40	3 520 000			0·153	Nil	0·066	0·219	46 approx.
	30	2 660 000			0·202	Nil	0·09	0·292	48 approx.
	25	2 200 000			0·25	Nil	0·11	0·36	50 approx.
	20	1 780 000			0·31	Nil	0·13	0·44	52 approx.

Note: If coal used for make-up steam during hours exhaust available, the consumption and cost per kW can be obtained by reference to table of high-pressure turbo costs.

engine with flywheel and one Lancashire boiler 30 ft. by 9 ft. 3 in., including boiler seatings, etc., say £4 000.

Running cost per annum :

Capital cost £4 000	£
Depreciation at $7\frac{1}{2}$ per cent	300
Interest at 5 per cent	200
Coal	2 400
Stokers' wages, including ashmen and boiler cleaners, proportion only, say	300
Oil, stores and incidentals, say	100
	£3 300

Assuming 3 066 000 units required for the electric drive, it means that the comparative cost which could be paid for current would be :—

$$\frac{£3\ 300 \times 240}{3\ 066\ 000} = 0{\cdot}26\text{d. per unit.}$$

I have assumed in this case that the amount of attention required for looking after the engine would be the same as that in looking after the motor. It is usual to arrange fans in collieries so that they can be looked after by the compressor driver.

Air compressors.—The author refers to the use of air compressors and there is no doubt that compressed air is being used very largely in collieries, as in many pits it is impossible (or at any rate unwise) to put electrical machinery into positions where compressed-air plant can be installed. I refer particularly to coal-cutting, conveyers at the face, auxiliary haulages, main haulages, hand-drills, percussive coal-cutters, etc. The vertical types of compressor as made by Messrs. Belliss and Morcom and others are rapidly coming more and more to the front, and are undoubtedly most reliable and satisfactory pieces of machinery, lending themselves admirably to electric driving. It is undoubtedly desirable to have the compressors at the surface, as coal-cutters require clean air if they are to continue to work satisfactorily and it is often very difficult (if not impossible) to get a supply of cold water for cooling the air cylinders underground. In addition, the receivers, if underground, are very difficult to get into position. The synchronous type of motor is undoubtedly the best to use if there is any question as regards power factor, but supply undertakings, in some cases, do not raise any difficulty where the power factor is about 0·8, and under these circumstances slip-ring motors can be installed. I agree with the author that salient-pole motors can be adopted, but it is desirable under all circumstances to take this matter up with the compressor makers, so that they may design their compressor and the method of unloading, etc., to suit the motor. In a number of instances we have found it exceedingly expensive to run electrically driven compressors from an outside supply, and I give as an example what the approximate cost would be for operating an electrically driven reciprocating air compressor :—

·ty of compressor in cub. ft. per min. ..	5 000
·e h.p. of motor, say	1 000
·ning per annum, i.e. 16 hours per 270 days	4 320
Units per annum (1 000 h.p. × 830 watts per h.p. at 90 per cent efficiency × 4 320)	3 585 600
Cost per annum of 3 585 600 units at 0·75d. per unit	£11 205
Cost per annum of 3 585 600 units at 0·66d. per unit	£9 860
Cost per annum of 3 585 600 units at 0·5d. per unit	£7 470

In most cases it will be found much more economical to use steam for operating colliery compressors, and still more economical when the steam can be utilized in mixed-pressure turbo-generators. The following figures will make this clear :—

Assuming that a compressor of the size mentioned (namely, 5 000 cub. ft. per min., 75 lb. working pressure, and requiring 1 000 effective h.p. to operate it) is to be steam driven, this would involve a boiler plant consisting of two Lancashire boilers or one water-tube boiler, capable of evaporating 20 000 lb. of steam per hour and suitable for, say, 150–160 lb. pressure, complete with superheater and economizer, together with feed pumps and piping, steam pipes, suitable housing and a proportion of the cost of chimney, which I estimate at £7 000. The working costs will therefore be :—

Capital expenditure £7 000	£
Depreciation at $7\frac{1}{2}$ per cent per annum	525
Interest at 5 per cent per annum	350
Coal 4 850 tons, at 10s. per ton	2 425
Stokers, ashmen and cleaners, say	500
Insurance, say	50
Repairs	150
Sundries and incidentals	200
	£4 200

The current consumed per annum under similar working conditions would be :—

Units per annum [hours running (4 320) × 830 units per hour]	3 585 600
Cost per unit which consumer could pay to put steam and electricity on same basis $\left(\frac{£4\ 200 \times 240}{3\ 585\ 600}\right)$	0·285d.

The whole question, however, as to whether colliery fans and air compressors should be operated by electricity or steam, depends entirely upon the price at which supply undertakings can supply current, and in order to meet this condition I have (in many agreements which I have made for clients) called upon the undertakings to give the supply at varying rates for the following purposes: fans; main shaft pumps; air compressors; winding; and general work, including haulages, shop machinery, screens, etc. In addition to this, as supply undertakings are generally willing to give a night supply at a lower price than a day supply, separate and reduced rates are agreed under these circumstances.

Electric winding.—The author's description of electric winding (carried out, I assume, at the Powell Duffryn

Co.'s pits) is very interesting to me, particularly as I have been represented by a good many people as an opponent of electric winding. This is an entirely erroneous assumption, but I still maintain that whilst nobody appreciates how thoroughly suited electricity is for winding, it again resolves itself into a question of cost, not only for the electric winder itself, but more particularly the cost of operation. Therefore the use of an electric winder in preference to a steam winder depends upon the cost per unit at which current can be supplied to the winder. When I read my paper entitled "Electric Winding in Main Shafts considered Practically and Commercially," * I finished my reply to a very long discussion with the following words :—

"I admit, as I have done in the whole of my remarks, not only in this meeting but elsewhere, that there is a considerable field for electric winding in small collieries and for small outputs, but I do not think that when coal is cheap, and where the steam has to be generated at the colliery and the winding is heavy, electricity can compete.

"The general conclusions I draw as regards electric winding are as follows :—

"1. For small collieries there is a future for electric winding if the coal used under the boilers is of any considerable value.

"2. In large collieries there is a future for electric winding if the fuel or coal used under the boilers exceed 8s. to 10s. per ton.

"3. Electric winding cannot be economically applied in collieries for very large outputs where the horse-power required for winding is greatly in excess of the horse-power required for driving the other machinery, both on the surface and underground.

"4. In collieries generally, particularly those in which electric winding is adopted, colliery-owners will be well advised to take their current from the supply companies, assuming that they can purchase it at a reasonable price, even if this price is slightly in excess of what they can make the current themselves. The amount of capital required for the generating plant being so heavy, it could usually be applied to much greater advantage in increasing the electric plant or improving other machinery about the collieries."

Since I made these remarks (20 years ago) the cost of electric winders has fallen very considerably. The value of coal at the colliery has risen considerably above the figure at which I then based it, namely 8s. to 10s. per ton, and in addition supply undertakings—in order to assist the adoption of electric winding—have made considerable concessions in the cost of current for winding purposes. For moderate sized electric winders up to, say, 1 000 h.p., it appears to me that the simple winder with either plain drums with balance rope or semi-conical drums is the cheapest and (taken all together) the most efficient type of winder that can be installed, provided it is equipped with suitable control gear of the Allen West or similar type, with three-phase slip-ring motor. For larger winders it is necessary probably to adopt the semi-conical drum with d.c. motors and Ward-Leonard control, but this involves the use of a motor-generator with heavy flywheel, and I very much question whether the efficiency of this apparatus is any higher than that of the simpler type of winder and there are, of course, more links in the chain to go wrong.

Electric winders should not, in my opinion, be run at too high a voltage, and the winding in the stator and rotor, in the case of three-phase motors, should be so designed that only straight bars insulated with mica are used, so that repairs either to the rotor or stator can be very easily and inexpensively carried out. I have seen a very great deal of time and money lost due to high voltage being used on the winding motors, causing breakdowns and stoppages of the pits. My general views as regards the efficiency of the two types of winders can be gathered from the discussion on Mr. Heather's paper.*

I note that the author refers to a winding plant in a colliery in the Doncaster district (I presume he means Harworth) where they have installed an electric winder operated on the Ward-Leonard system by a high-pressure turbine with flywheel, attached to a d.c. generator. This system of winding is, I believe, claimed to be novel, but a proposition on precisely the same lines was put forward by me to a colliery (also in the Doncaster area) about 20 years ago.

Cost of the two steam winders at £6 000 ..	£12 000
The cost of electrical plant, consisting of two generating sets and two winders	£42 000

The total saving in the coal consumption per annum which could be shown at that date was £1 500, which was considered insufficient on an additional capital expenditure of £30 000, and the steam winders were finally adopted. At the present time it is becoming a standard practice in the Doncaster district, where there is no cheap supply of power, to install steam winding plants with mixed-pressure turbines, and also to use steam-driven compressors and fan engines, the exhaust steam being utilized in the turbines. I am fairly confident that this is the most economical scheme to adopt for isolated pits, taking everything into consideration. Of course, I refer to pits of, say, 800 to 1 000 yards in depth and with outputs of about 5 000 tons per day. These remarks do not in any way detract from the suitability of electrical winding for smaller pits and where the conditions are such that they can be economically used.

It would be very interesting if the author would give some particulars in connection with the generating plant at the collieries to which he refers, the cost at which current is being produced at the power station, and also the cost at which it is being charged to the various collieries under his control, because unless one has this information it is quite useless to attempt to decide whether steam winding or electric winding should be adopted. It appears, however (if the author's remarks apply to the Powell Duffryn Co.), that they have an excellent opportunity of producing in their own power station or stations a very large output of current at a very low price, by utilizing their exhaust steam in mixed-pressure turbines, using coke-oven gas and cheap and unsaleable fuel, and under these circumstances no

* *Journal I.E.E.*, 1906, vol. 36, p. 499.

* *Journal I.E.E.*, 1911, vol. 47, p. 609.

doubt the correct thing to do is to use electricity to the greatest possible extent. Some of the author's figures in connection with the operation of the winders approximate very closely to the figures which I assumed in my paper on "Electric Winding" already referred to.

[The author's reply to this discussion will be found on page 563.]

North-Western Centre, at Manchester, 3 March, 1925.

Mr. J. F. Perry: Speaking generally, I am in entire agreement with the views and facts expressed by the author. My own experience confirms the remarks he makes concerning the relative maintenance cost of Ward-Leonard and three-phase winders, and I have found in a large number of cases which have come under my observation that the Ward-Leonard winder is actually very much cheaper to maintain than the three-phase winder. On first thought this seems rather surprising when it is remembered that there are a greater number of machines involved. In practice, however, these machines give practically no trouble and in many cases under my notice have run for years without requiring anything more than the ordinary cleaning and oiling. In the case of a three-phase equipment the stator reversing-switch is called upon to handle heavy currents very frequently, so that it is not surprising that switch contacts and oil require frequent attention and renewal. In this connection it is interesting to note that the maintenance charges for air-break contactors are very much less than for the oil-immersed type of reversing contactors. Then, again, the liquid controller must be provided with a cooling system the tubes of which must be kept clean and free from sediment, and for certain classes of cooling water this feature involves fairly frequent attention. There are one or two points in the paper on which I do not see eye to eye with the author. For instance, I entirely disagree with him with regard to the synchronous motor for driving the flywheel equipments. On page 531 the author suggests that the installation of a synchronous motor to drive the Ward-Leonard equipments for the winders results in a lower operating cost than the common practice of installing flywheels. I cannot agree with the author that money can be more suitably spent in increasing generating plant and transmission systems rather than equalizing individual winding equipments. While conditions certainly exist where this might be perfectly true, the statement needs qualification, as it depends entirely on the proportion that the winder load bears to the total generating capacity of the system to which it is connected. The author identifies his statement with winding schedules raising large tonnages from a considerable depth. In my opinion that is probably one of the exceptions. Heavy fluctuating peaks should be isolated as near as possible to their point of origin, and the addition of a flywheel to the Ward-Leonard equipment will prove a more economical solution than an attempt to absorb the peaks in the power system generally. The actual efficiency, i.e. the kWh per ton hoisted, may be higher, but when viewed as a whole the cost per ton hoisted will certainly be less, as of course the peaks are not capitalized beyond the capital cost of the necessary flywheel. For the conditions outlined by the author I am of the opinion that the Stubbs-Perry scheme would prove more economical than either of the other two alternatives. Some time ago I carried out an investigation to compare the capital and operating costs of a power scheme for a group of eight collieries, (*a*) a central power station to supply power for all purposes, and (*b*) a Stubbs-Perry equipment on each winder, and a central station for the auxiliary load only. The winders in question were large equipments and the average input to the flywheel equalizer equipments was approximately equal to the auxiliary load demand at the colliery. Assuming one 7-hour coal-winding shift per day, the total annual operating cost of scheme (*b*) was 12 per cent less than that of scheme (*a*). For two 7-hour coal-winding shifts per day the difference was reduced to 9 per cent. It was apparent from the investigation that in order to be competitive with scheme (*b*) the load factor on (*a*) required to be 75 per cent, whereas the highest possible with a pure colliery load is about 60 per cent. The author's suggestion to increase the capacity of the generating plant, transmission lines, etc., on account of the peaks, tends to reduce the load factor still further and, apart from any question of capital, reduces the overall efficiency of the whole system. In schemes (*a*) and (*b*) the winders were equalized. If the flywheels had been omitted the capital charges would, I am sure, have been increased out of all proportion to the economies effected on the light-load losses of the wheels. Synchronous motors certainly have the advantage of power factor correction but would not, in my opinion, effect economies of sufficient magnitude to compensate for the interest on the additional capital required if the peaks are reflected on the generating plant. The economic principle underlying the Stubbs-Perry scheme rather emphasizes the foregoing point. The scheme was developed primarily to meet the case of the isolated colliery where winding from great depths was required and no bulk supply of electricity was available. Under these conditions electric winders could only be considered in connection with a power station, and it was not surprising to find that the initial capital cost put the scheme at a great disadvantage as compared with the more gradual development possible with steam engines and mixed-pressure turbines. The introduction of the Stubbs-Perry scheme makes it possible for the electrical manufacturer to compete with the steam-engine builders and offer a scheme which can be developed in easy stages without any reference to the future power scheme required by the colliery for the remainder of the load. By the addition of the turbine to drive the Ward-Leonard generators, winding can commence without any commitments as to a general power scheme, and is therefore financially comparable with the steam engine and mixed-pressure turbine arrangement from this capital

point of view. It has, however, one or two distinct advantages over the above scheme which might be enumerated as follows :—

Given favourable conditions it is cheaper in first cost to install, and unlike the steam engine and mixed-pressure combination the winder load is separated entirely from the remainder of the load about the colliery.

It is also possible to work in conjunction with public supply, the Stubbs-Perry winders relieving the power system of the big fluctuating peaks due to winding, and the power supply taking all the remainder of the steady running load about the pit.

The inclusion of an induction motor on the opposite end of the flywheel equipment to the turbine enables the alternative electric supply, whether from a public supply company or the colliery power station, to act as a stand-by to the Stubbs-Perry turbine and its boiler plant at the colliery. In the majority of cases this feature might also be used to advantage during the non-coal-winding periods as the turbine can be shut down, boilers at the colliery banked and the equipment operated as an ordinary Ward-Leonard equipment from the available supply.

From a large number of investigations I have made I feel convinced that even in the system described in the paper, Stubbs-Perry winders on some of the larger winding equipments would show up to advantage. I should like to ask the author whether the efficiency of 92·7 per cent given for the low-speed winding motor at the foot of page 529 has been verified on the actual machine, because this figure seems to be very high for this type of motor. Unless he can verify this figure his statement concerning the alternative method of gearing d.c. motors to the drum is, of course, misleading. According to the figures given in the paper the efficiencies are practically equal, the difference against a geared equipment being only 0·2 of 1 per cent.

Captain I. Mackintosh : The author has naturally taken the conditions at a large group of collieries, as the group with which he is connected is one of the largest in the country. When he talks of the all-electric pit he has considered it from this point of view, where he has plenty of generator capacity ; but from the point of view of a large single colliery the all-electric scheme has a serious rival in the mixed-pressure turbo set, which will entail winders, and probably fans, being steam-driven, to supply the necessary exhaust steam for the turbo. Of course the all-electric pit has so many advantages that where possible it is the ideal to aim at. Not the least important of its many good features are the ease and accuracy of obtaining running costs, because, if suitable instruments are installed, each particular unit of the plant can be checked and a thorough investigation made of any uneconomical unit in order to put it on a more economical basis ; and by these same instruments any alterations which may have been made can be proved beneficial or otherwise. While agreeing that motors of above 150 h.p. for pump drives should be normally of the wound-rotor type, I am using squirrel-cage motors of a much greater horse-power, and these are not giving any trouble. I should be glad if the author would say in what way he has found the auto-transformer starter so unsatisfactory for starting a pump motor. He is inclined to favour the steam drive to the electrically-driven compressor, but surely a synchronous motor-driven compressor would be a great help in improving the power factor of the system. Again, if the compressors are electrically driven and cutting is done on the afternoon and night shifts, they should be a great help in improving the load factor on the central station. The particular group of collieries with which the author is concerned has a central compressed-air station, with large air pipes going for miles up the Rhymney Valley, a point of interest being that all the joints in the pipe line are welded. I think I am right in saying that this system has given very satisfactory results, and that pipe troubles have been very few, at least until very recently, when a landslide broke up some of the pipes, causing the pits to be closed down for a few days. I have often considered that the ideal compressor job would be to have the compressor as near to its work as possible, in order that there may be as little risk as possible of loss in air pressure ; of course on the other hand it may have been proved conclusively that the central air station is a more economical scheme, and, if that is so, we should be grateful to the pioneers for having the courage to install this scheme. With regard to winding, there is no doubt that the Ward-Leonard system is the best method of electrical drive for avoiding heavy peaks on the central station, but there are so many links in the chain, the failure of any one of which would upset the output for the day. The a.c. motor reduces these links to a minimum, and on a large group of collieries the fluctuation caused by the operation of a number of such winders would probably cancel out, without affecting the central station. In addition, the Ward-Leonard set has a very low power factor, and the converter often runs for many hours on light load. The Ward-Leonard set has also the added advantage of being able to complete the wind by absorbing power from the flywheel if the supply fails. Although I regret to say so, I think that, even in these progressive days, the steam winder is more reliable than the electric winder, and in the case of breakdown could probably be more easily tinkered up to complete the shift. The author refers briefly to switchgear and points out that compound-filled gear will meet most requirements. There is no doubt about this. Compound-filled gear has, however, one serious drawback ; if it has to be dismantled a great deal of time is wasted in melting the compound, and if, on an emergency, it is necessary to remove the gear in quick time, the compound would be a great nuisance. Perhaps the author will say if he thinks it necessary to install gear of this description, or any type of flameproof gear on a screening plant at the surface of a mine, as are apparently required under No. 127 (iii or v) of the General Regulations as to the use of electricity under the Coal Mines Act, 1911.

Mr. G. A. Juhlin : The author places the limit on squirrel-cage motors at 150 h.p., mainly on the basis

that auto-starters are unsatisfactory. It is somewhat difficult to accept this as being a definite limitation on the size of motor of the squirrel-cage type. The company with which I am associated has 3 000-r.p.m. motors of 400 h.p. of the squirrel-cage type in operation. These have been running satisfactorily for eight or nine years. I think it would be a great pity to condemn the type of motor on account of the starter. The author, however, advocates the use of salient-pole self-starting synchronous motors, and has apparently had satisfactory results from this class of motor. It is to be presumed that his experience in this direction includes the type of synchronous motor for which auto-starters are used, and as some of these motors have an output of 1 150 h.p. it would seem that it is possible to obtain auto-starters which are satisfactory in service. With regard to the use of clutches, the author suggests the possibility of the use of a friction clutch. It seems to me that the synchronous induction motor provides a better solution in cases where the full-load pull-in torque is required, as with this type of motor it is possible to dispense with the clutch. Objections are sometimes raised that the air-gap of the synchronous induction motor is not as large as that of the salient-pole machine, but when it is considered that there are millions of horse-power of induction motors in satisfactory operation, there seems to be no reason for objecting to the synchronous induction motor on the score of the small air-gap, as this type of machine has in general a larger air-gap than the ordinary induction motor. It is interesting to note that the magnetic clutch is finding favour in the United States as a substitute for the ordinary friction clutch. The author refers to the salient-pole synchronous motor for driving compressors, and states that it was not until 1918 that it was considered suitable. I think that the reason which retarded the use of the salient-pole self-starting synchronous motor was that the electric supply undertakings would not permit this type of motor to be connected to their mains, owing to the starting current being high. In the United States this type of motor has been in general use for compressor work for many years, and as long ago as 1913 we actually supplied some motors for driving compressors for use abroad. In comparing the efficiency, the author claims an addition of 2½ per cent for the salient-pole machine, as against a synchronous induction motor. It is not clear whether the 93·2 per cent efficiency given for the synchronous induction motor is at unity power factor or at 0·9. The figure appears to be correct if 0·9 power factor is assumed, but in order to put it on the same basis as the salient-pole machine which is given at unity power factor, a figure of 94·2 per cent should be taken for the synchronous induction machine, which only gives an advantage to the salient-pole machine of 1½ per cent. The author also favours the salient-pole machine because it has been found possible to dispense with the bearing between the compressor flywheel and the rotor, due to the large air-gap. We have actually supplied synchronous induction motors with the rotor bolted direct to the flywheel. This of course may not be satisfactory in all cases. The figures given comparing the transmission of compressed air with electrical transmission are of great interest. I believe that similar comparisons were made when the compressed-air plant was installed on the Rand a number of years ago, and the conclusions arrived at were apparently similar to those at which the author arrives in the present case.

Mr. W. A. A. Burgess: It is not clear that the author fully utilizes the sensible heat of the coke-oven gases. That has been found at times to be a very appreciable amount of the waste heat available from coke ovens. With regard to his conclusions as to the burning of coke breeze and coke ashes, he appears to consider it necessary that medium volatile coal should be used to sandwich coke ashes. I have burned many thousands of tons of very fine coke breeze—so fine that it could be blown about—without the use of any other fuel whatever and have done so with chain-grate stokers of the underfeed type. It was found necessary to keep the fire between 9 and 10 inches thick to get the best results, and an efficiency of 56 to 60 per cent was obtained, dependent on the class of coke. Under these conditions the output of the boiler was somewhere about 66 or 67 per cent. We also obtained a large stock of washery settlings of high calorific value (13 000–14 000 B.Th.U.) when dry, but getting the moisture out was the great difficulty. It was found to be quite burnable in conjunction with coke breeze and appeared when dry to be a natural pulverized fuel, and I suggest it may be found possible to use washery settlings in this way. It was singularly free from dirt and really good coal in a very fine state of pulverization. My own long experience of compound-filled switchgear (17 or 18 years) has proved that its use has been amply justified in colliery working as well as in power supply under most onerous conditions. The charge of inaccessibility, so often levelled against metal-clad switchgear, is a myth. It is so made that accessibility, in the sense of access to live conductors, is entirely unnecessary, and the experience of renewal of the extremely small number of breakdowns in the whole of that period has proved that for renewal and extension it is in every respect as flexible as cellular gear and not nearly so dangerous. I have had considerable experience of power factor correction by means of Kapp vibrators, and from a sceptic I have been converted into a firm believer in their use. The particular case which I have in mind was for a 450-h.p. motor on compressor duty. This apparatus gave excellent duty for a period of six years to my knowledge, and required no attention other than the renewal of brushes. The author's remarks in regard to the similarity of compressor load and electrical load have been borne out by my experience in a large dye factory. They ran so closely that every extension of manufacturing plant was guaranteed to bring a similar extension of both services. I cannot entirely agree with the author's sweeping condemnation of oil-immersed contactors. My experience is that that is a matter of design entirely. I know of such contactors which have been in use for a large number of years on very heavy duty, and these have not given any trouble. Some of them have never been touched except for routine examination, and have never been renewed. That does not support the con-

clusion drawn by the author, but his conditions are admittedly onerous and he may not have been particularly fortunate in his selection. I certainly should not like to have in a colliery winding house or engine house an air-break contactor of the design shown operating on a 3 000-volt circuit either by solenoid or compressed air, more especially when the rest of the switchgear installed could be handled without danger. Excellent though the paper is in many respects, it rather belies its title. In my opinion it ought to have been entitled "Electricity on the Surface of Mines," for we are given very valuable information regarding the use of electricity on the surface but none regarding the use of electricity underground. The author appears to pin his faith to the use of compressed air below ground. Now although compressed air is quite suitable in very large bulk, when it comes to be applied to small apparatus and when welded joints cannot be used, the amount of leakage that cannot be detected by any means other than trying to add up the indication of the various metering units, all of them more or less unsatisfactory, is very remarkable. I think there is no need to-day to stress the point that it is perfectly safe to use electricity underground if reasonable care is taken. I am reminded, however, that such care is not always taken and I have seen a case recently of sound gear, sound motors and sound equipment generally, installed below ground—expensive plant and carefully protected cable—but with every cable gland left open to the access of moisture and air, and the gear left in such a condition that it could readily be flooded. One might just as well use compressed air bubbled through water into a bell-jar collector. If electricity is used below ground—and it is being increasingly so used—reasonable precautions need to be taken, and particularly with portable apparatus. The safe use of portable apparatus in mines demands the use of adequate interlocking systems. There are many ways of interlocking a switch with a plug device for a trailing cable so that a plug cannot be put in or pulled out, but when one comes to the motor end it is not so readily done, particularly if the coal cutter or conveyer, or whatever it may be, is some 150 yards away. To meet that condition Mr. Fisher, some years ago, introduced an electrical interlock which at the same time demonstrated the soundness of the earth connection. It had one drawback, however, in that he used full phase voltage to earth—through a resistance, it is true—for his interlock circuit. This meant that when the plug was withdrawn at the motor end it tripped the switch, but if the pilot socket should at any time be making a sufficiently good contact with earth through the body of a man a fatal shock might be received in the event of an attempt to close the switch at the far end, and an insufficient contact with an earthed rope or rail might permit dangerous sparking on a similar attempt. There is now available a similar device which operates in conjunction with an earthed pilot system and gives the desired interlock. There is a low voltage on the pilots, the general arrangement being practically the same as that suggested by Mr. Fisher, except that it embodies a small potential transformer. This system, which is covered by the Williams Rowley patents, is quite efficient but the potential transformer is an added complication and expense. There are now, however, at least two systems which give the required low-voltage interlock without the use of a potential transformer, one being manufactured by Messrs. Reyrolle and the other by Messrs. Switchgear and Cowans. These systems cost little to install and are of great use in mines and also on industrial plants, since they prevent the circuit being broken by a plug under any condition without first opening the main switch. They also definitely ensure that the earthing circuit is complete and perfect. It need hardly be emphasized that it is just as important to be sure that the earthing circuit is complete on industrial plants as it is below ground.

Mr. S. R. Mellonie: Referring to the use of autotransformers for starting synchronous motors, the author has certainly been unfortunate, and his troubles point to defective design. He states that the trouble was due to the arc drawn out from the "starting" contacts held on until the "running" contacts were closed, thus short-circuiting a section of the transformer. When describing the improved methods, he further states that step 5 "short-circuits the transformer." By reading between the lines the author's meaning is clear, but the wording is unfortunate. A method which has been used for the largest synchronous motors employs three oil switches suitably interlocked to ensure correct sequence of operation. The two switches controlling the transformer are tripped out by the operation of closing the main switch. Fig. 5 seems to make extravagant use of overload coils. These are shown coupled two in series and shunted by a time-limit fuse. An objection to this method is that one plunger invariably rises before the other, and the increased impedance so produced may overload the current transformer to such an extent that the resulting secondary current is insufficient to operate the second coil. A single trip coil operating through mechanism is a sounder proposition. The author mentions on page 534 the economical operation of Ward-Leonard sets having duplicate generators and duplicate motors by changing over the armature connections. This is a valuable feature of such equipments, and in a recent installation of two winders any of the four driving motors can be supplied by any of the four generators. This flexibility is obtained by the use of a few knife switches as, for the currents usual (2 000 to 4 000 amperes), plugs are not desirable owing to the difficulty of maintaining a good contact surface. The use of an automatic circuit breaker in the Ward-Leonard armature circuit is an undesirable feature. There appears to be a divergence of opinion on this question, engineers in some parts of the world insisting that the breaker is necessary, and others objecting to it as a dangerous and unnecessary device. The opening of the connection between the generator and the motor prevents the use of any form of regenerative control, and may leave the mechanical brakes in control during the lowering of an unbalanced load. Another alternative is to connect resistances across the motor armature immediately the armature breaker opens. This gives dynamic braking but introduces devices which do not "fail to safety." The

author's opinion on this matter would be a valuable contribution to our knowledge of the subject. Passing to the question of safety devices, one can certainly picture serious accidents due to the failure of this contactor or that small connection. The best policy would seem to be that these devices should be as few as possible, and that they should all fail to safety. Where that desirable characteristic is unobtainable, a second line of defence is justified. The additional cost of such protection does not appreciably add to the capital cost, as the switch and control gear for the average Ward-Leonard controller accounts for about 2 or 3 per cent of the total cost.

Mr. H. Green: One of the objects of the paper appears to be to attempt to disprove the idea that collieries generally are worked inefficiently, so far as the production of power is concerned. As of course the paper merely describes the collieries in which the author is personally interested, it only goes to prove his own particular case; but I think it will be agreed that the collieries mentioned are a very good example of efficiency. If, say, a municipal engineer were to look round the average colliery he would probably be appalled at the apparent waste taking place. He would, however, probably miss one point—that at many pits there is a quantity of unsaleable fuel which is sometimes difficult to get rid of. Therefore, obviously, it should be used for generating power; it would be ridiculous to install modern steam-raising plant for the purpose of saving fuel which is more or less useless. Therefore the old Lancashire boilers remain and give reliable service, and the fuel costs are very low actually. The great point, so far as colliery plant is concerned, is to install plant which will generate power from the most unsaleable fuel. The author gives comparisons for the generation of current by means of gas engines, or, alternatively, using the waste gas under boilers. As a result of experience I should say that, without doubt, the latter is the better method. Any increase of efficiency in the former is very much more than counterbalanced by the reliability and lower maintenance costs of the latter. In connection with the question of power factor correction, the future should always be taken into consideration in laying out a new colliery, and the judicious use of synchronous motors for driving d.c. generators and other plant is always an advantage. There are many instances where d.c. motors can be used with advantage, and this helps to justify the initial outlay for converting sets. I cannot help thinking that we have taken as granted alternating current for transmission, and in consequence the possibility of the generation and utilization of high-tension direct current is being neglected. The author mentions several types of switchgear and controllers. I think there is a field for the application of remote-controlled automatic gear. What I mean is that controllers and starters generally should be absolutely fool-proof. Knowing that often it is anyone's job to start a motor, it should obviously only be necessary to press a button and let the controller do the rest. A particular application of this would be on haulage gears. One man could easily look after, say, two or three haulage gears. Finally, I should like to emphasize what I consider to be a great mistake. We are apt to electrify a colliery piecemeal, by installing a motor here and a motor there. When this is done the resultant saving, so far as fuel consumption is concerned, is nil, because until at least sufficient motor load is added to enable a boiler to be cut off, the stand-by charges remain the same and the diminished steam requirement is not noticed. If any electrification is contemplated it should be of such a nature that a boiler or boilers can be dispensed with. As regards the comparisons between the electrical and compressed-air transmission of power, I hardly consider the figures are fair, because it is unlikely that the compressed-air system would be maintained at its initial efficiency. Nobody seems to worry about air leaks, but an electrical leak would soon assert itself and call for immediate attention.

Mr. A. B. Mallinson: I have used balanced jockey drives for many years and have found them exceedingly satisfactory. I should like to ask the author what power he has transmitted by them. The largest horse-power I have transmitted in ordinary industrial work was 150 h.p. when it was quite feasible to drive at 9 ft. or 10 ft. centres with a ratio of 6 to 1. When comparing the transmissions of compressed air and electricity the author takes 20 000 cub. ft. of air equivalent to something like 3 000 h.p. How would the table of relative efficiency be affected if figures were taken which are more applicable to the ordinary colliery—say 5 000 or 7 000 cub. ft. of air? I should like to ask the author how he expects the colliery proprietor to find the money to pay for equipments such as those shown on the lantern slides. Certainly many collieries to-day cannot find out of their own pockets even a fraction of the money required to install such plant.

Mr. S. C. Lloyd: A maintenance cost of £150 per annum is given in the paper for a set of oil-immersed reversing switches. I rather think the author is referring to the old type of hand-operated reversing switches. The present-day practice is to use reversing contactors, the maintenance cost of which is very small. The figure of £150 given for the reversing switches should be reduced at least to £30 for oil-immersed reversing contactors. Although the maintenance of air-break high-tension reversing contactors is considerably less than with oil-immersed contactors, the initial cost of the air-break type is about four times as great, so that even with the reduced maintenance cost the initial outlay of the air-break switches is not always justifiable, especially on the smaller equipments. With regard to the two types of controllers, the one with the moving electrolyte and the other with the moving electrodes, the moving electrolyte certainly gives automatic acceleration, and the paper clearly describes how this is done—by variation of the amount of electrolyte which passes through the electrolyte chamber. The other type, generally called the pot type, is simpler and not so costly in construction. The automatic acceleration of this type can also be obtained by means of an accelerating device which can now be supplied, so that we can use the pot type of controller to meet exactly the same conditions as the type in which the electrolyte is moving.

Mr. G. S. Corlett (*communicated*): It is interesting to note what rapid progress has been made in the electric mining industry during my own business experience. I well remember putting in, some 40 years ago, a small lighting plant at the George Pit (one of the many under the author's control) where the generator was a Gramme dynamo of about 2 kW capacity at 100 volts, and where all the details were very bad from a present-day standard. It is almost worth while to pause a moment to compare the conditions then and now: then, broadly speaking, there were no motors underground; to-day in round figures they total 1 million h.p. Then the technical knowledge available was minute in quantity and limited to the select few; now, as matters of everyday routine, oscillograph records of the starting current of motors are taken. The paper is obviously based on the conditions existing at the group of collieries with which the author is associated, and generally in South Wales, but these conditions are not to be found elsewhere. For example, the amount of gas given off there is enormous, and consequently the standard on which the amount of ventilation is based is the dilution of this gas to a sufficient extent to render it harmless. In many districts the amount of gas given off is so small (there are still many pits worked with naked lights) that the standard of ventilation is entirely different, namely, sufficient to provide a cool and healthy atmosphere for the workmen. A good many years ago I obtained the following figures relating to a Welsh colliery which is now, but was not then, controlled by the author's company: Ventilating current 300 000 cub. ft. per min., percentage of gas in the main return never less than 2½. This means that not less than 7 500 cub. ft. of free gas was given off every minute, and often more. Under such conditions it would be an act of criminal folly to reduce the fan speed at the week-ends. On the other hand I find it quite a safe commercial proposition, in many collieries where I am buying current, to reduce the fan speed during the week-ends and holidays, and obtain an appreciable saving in costs. The author gives under certain specified conditions 32 units as a reasonable consumption per ton of coal raised, and he allows 20 units out of these to furnish the necessary compressed air. In large numbers of collieries within my personal knowledge there is either no compressor at all or only a small one for operating rock drills and the like. At the moment I cannot put forward figures applying to some other district, but I know that they would be widely different. The paper suggests by its whole tone that the real problem of supply to collieries is narrowed down to two aspects of the case: (*a*) Complete electrification with high-pressure turbos, and (*b*) partial electrification with mixed-pressure turbos. A third alternative, and one which has increased and is bound to increase still further, is the public supply, and, in the case of the smaller collieries and single ones, such a supply is appreciably cheaper than a private supply. The convenience alone of being able to switch on any individual motor when wanted, without reference to any other plant, is often sufficient under certain circumstances to justify the preference. It must, of course, be remembered that groups of collieries of the magnitude and extent as the author's are few and far between, and probably nowhere else in Great Britain would be found another group where the same amount of generating and transmission plant would be required or justified. In a great majority of cases the groups are small, and there are very large numbers of individual pits, some large, some small, but in my view very many of these could be best furnished with power from the public mains. Nevertheless I freely admit that in no branch of engineering is it more dangerous to dogmatize; each individual case must be considered on its merits. In conclusion, I should like to point out that many of the problems—such as whether electrification shall be adopted or not, and if so to what extent—are determined not by engineering considerations, the estimated savings per annum or the other advantages that would accrue, but by finance conditions only. The average loss per ton of coal raised in Lancashire, Cheshire and North Wales for the last quarter was approximately 11¼d., and it is not difficult to understand the reluctance of colliery proprietors to spend money. If, as is often the case, there is only sufficient capital available to equip the interior of the mine, then obviously the supply must be obtained from an outside source.

[The author's reply to this discussion will be found on page 563.]

North-Eastern Centre, at Newcastle, 9 March, 1925.

Mr. S. A. Simon: The paper, together with the discussion, should show what may be considered to be the best present-day practice, and should indicate the trend of further development and formulate the more immediate questions which electrical engineers will have to solve in the interests of mining. As electrical engineers we are, I suppose, all in agreement with the author's conclusion—that the electrification of the whole of the machinery at a colliery can be proved to be a sound commercial proposition. The figures given by the author, and other similar figures which may emanate from the discussion, should be of very material assistance to the electrical engineer in carrying his points. The great need of the coal-mining industry in this country at present is reduction of cost, particularly of the cost of labour. Means must be found of increasing the output of coal per man employed, and it is the task of electrical engineers to devise the means by which electricity can assist in this consummation. This should be constantly kept in view so that the record of the discussion may be of the greatest value to electrical manufacturers and contractors, as well as to those actually engaged in the operation of the mines. It seems to me that the tables in Part 3 of the paper require amplification. In comparing steam-driven with electrified collieries, comparisons are made of the percentage of coal raised used for power on the one hand, with kilowatt-hours per ton on the other. I have

endeavoured to bring this comparison to a common denominator. To do this I must assume a coal consumption per kWh. I have first assumed 3 lb. Taking Table 8 I find that initially when raising 4 650 tons per week the equivalent coal consumption was 6·97 per cent. After the steam compressor was shut down the equivalent coal consumption was reduced to 6·79 per cent, and after the fan engine was electrified the equivalent coal consumption was further reduced to 5·6 per cent for the same output (4 650 tons) of coal. After complete electrification the equivalent coal consumption was increased to 7·68 per cent with an increased output to 5 700 tons per week, and the hypothetical consumption for this output with the original steam plant supplemented by electricity would have been 10·68 per cent. If a smaller equivalent coal consumption per electrical unit is assumed, the figures work out correspondingly more favourably for electrification. The most significant point is that after complete electrification, with an increased coal output, the percentage consumption is increased. The paper shows that more compressed air is used for conveyers and other air engines. This will doubtless account for the whole increase, but presumably there will be considerable saving in labour costs, and some indication should be given of the comparative value of such saving to set against the increased power consumption. I should imagine that it would be more than a mere reduction of unskilled labour at the pit head. May we take it that the increased output of practically 25 per cent was obtained without increasing the number of men employed? Table 5 when treated on similar lines shows a marked economy for electric drive, viz. 3·75 per cent equivalent estimated consumption with electrified winder against 5·53 per cent with an all-steam drive. It is not clear what is meant by the sub-heading "Present Conditions" in this table. Table 6 shows a very marked economy of electric winding compared with steam winding, and Part 2 of the paper shows that the electric winder has thoroughly justified its use. The system in which the exhaust steam from the steam winder is utilized in a turbine can only be considered for isolated cases and during transition periods. A very strong case has been made out for the Ward-Leonard winder without power-equalizing flywheel. With increasing capacity of generating plant this is a more or less expected result—as the peaks will be of comparatively less account—and, moreover, it is probable that in new pits the whole winding cycle is being laid out for the most advantageous electrical drive, whereas in earlier electrifications the electrical equipment had to be made to suit conditions which were essentially laid out for steam winding. It is interesting to observe the large proportion of power used for compressed air in South Wales pits. Naturally the figures for this district with shallow mines, where there is no objection to using electricity at the face, are very much lower. I have seen figures as low as 8·46, and for a large group of Durham pits with a moderate amount of water the figure works out on an average at 11·54. Other figures are 6·9, 10 and 13·5. No doubt if compressed air could be replaced by electrical drive in South Wales the figure of 20 units per ton would be reduced to 6 or 7. I appreciate that conditions in South Wales are such as practically to preclude electricity in places where compressed air is now used, and I am not one to advocate the indiscriminate use of electricity in places where Regulation 132 applies. On this account, therefore, I can understand the omission of any reference to electrical coal-cutters, face conveyers, etc. At the pits with which I am connected, electrically-operated face conveyers have been in use for many years and their use latterly has been considerably extended. They are of the scraper type driven by 9-h.p. squirrel-cage motors through Hele-Shaw friction clutches and chains. I am somewhat surprised, however, that no mention is made of main haulages amongst the more important loads to be dealt with. Main and tail type haulages are largely in use, and the methods of drive have not changed essentially from the types installed 15–20 years ago. I have found that a rope drive has worked very satisfactorily both above and below ground, and I now favour this arrangement in preference to direct gear. For larger haulages at medium pressures, contactor-type stator reversing-switches have lately been used with much success, although in the earlier types with large low-speed motors trouble was experienced on the blow-outs. The use of contactor reversing-switches has both lightened the labour of the attendant and reduced the heavy cost of upkeep of reversing controllers on larger motors. The rotors are controlled by means of liquid starters. Turning to power factor correction, I am inclined to agree with the author that in new installations synchronous motors are probably the best means of obtaining the requisite leading wattless kVA. It is particularly interesting to learn that such motors have been applied to Ward-Leonard winders, and if this is really satisfactory there should be a wide scope in this direction on large systems. A certain amount of prejudice has arisen against the use of synchronous motors for driving fans, due to the difficulty of starting of some early types of salient-pole machines. The synchronous induction motor has overcome this difficulty. In cases where the installation is complete, and suitable drives for synchronous motors are not available except by scrapping existing induction motors, the electrostatic condensers are eminently suitable and give satisfactory results. An advantage is that they can be obtained in small units and placed close to the motors the power factor of which is to be corrected. I am informed that in certain pits each small motor is provided with its own condenser, and the air-gap is made very wide. In regard to the power station, an eminent mining engineer, recently speaking of electrical costs, ruled the private generating station altogether out of consideration, and, basing his arguments on the rates usually charged by the supply undertakings, he maintained that it was more profitable to drive the winder, fan and compressor by steam. I think that the author has amply justified the private generating plant, and along with it the complete electrification of the above-named capital units of plant, but a little more information would be desirable in regard to load factor, cost of production, etc. This discussion should prove the economic possibilities and limitations of the private station. One peculiarity of the colliery generating station is its ability to utilize

all sorts of fuel and particularly the low grades. The time may come, however, when the supply undertakings may have to take low-grade fuels from the collieries, as a consideration for the collieries taking a supply.

Mr. S. Burns: I was rather surprised to hear the author state that in his experience the energy consumption per ton of coal raised by means of an a.c. geared winder is usually found to be appreciably in excess of the estimated energy consumption. Such is not the case in this coalfield and one wonders why it should be so in South Wales. It may be that there is a disparity in the weights of conveyer-filled and hand-filled tubs, with a consequent variation of the net unbalanced load from time to time, but this should not present difficulty where the torque/time cycle is arranged to take account of the heavier lift as a normal condition of working. The disparity in weights cannot be great, and it follows that the braking peaks when lighter loads are being decelerated cannot differ appreciably from the braking peak of the normal winding diagram. The author has mentioned the Stjernberg coefficient and the correction to which recent improvements in winder design have rendered it subject. That formula is related primarily to cylindrical-drum winders operating with tail ropes of a weight per unit of length equal to that of the winding rope and so is equally applicable in the case of winders operating without tail ropes, but where the drum profile has been arranged to compensate for the effect of overhang of the winding rope throughout the winding cycle. It is a formula which may only be applied with circumspection in the case of other arrangements of drum profile and, what is more important, it neglects to take into account the economic aspect of the problem. It is no sufficient justification for the choice of a particular type of winder that it can be shown to be the most efficient arrangement in terms of energy consumption per trip. What is required is the arrangement of plant which will be most economical in terms of total winding cost per ton of coal raised. The energy consumption bill is an important item, but so also are Imperial taxes, local rates, interest, depreciation, insurance, inspection, maintenance and stores. For example, I recently took out a set of "average" winding conditions for Northumberland and Durham. The average value of B is $0 \cdot 167$ and the Stjernberg coefficient, therefore, serves as an indication that an a.c. geared installation is likely to be satisfactory. The coefficient does this but no more. Given a schedule of definite winding data, it is not difficult to decide which of four or five alternative arrangements of plant is the most economical, but the problem seldom presents itself in so simple a fashion. There at once arises the question as to whether it will be better to install a complete new winder, probably to the rear of the existing winding engine, or whether the existing mechanical parts should be converted to electric drive. At this stage there may be complication because, whereas with the new winder one is free to determine suitable drum dimensions, it may well be that the dimensions of the existing drum are such as to render a direct-current motor and Ward-Leonard control desirable. This is not an exaggerated statement of the problem and my object is to show that close reliance cannot be placed upon the Stjernberg coefficient when a choice is to be made upon economical grounds in circumstances which are to be met regularly in everyday practice, if rarely in technical analyses. It is proposed shortly to install in this locality an a.c. geared winder, although the value of B is $0 \cdot 358$. The circumstances are similar to those I have described and it would be difficult to imagine a case more likely to be favourable to Ward-Leonard control upon the score of relative efficiency (for the value of B is high). Similarly the Ward-Leonard control alternative is likely to be favoured in respect of capital cost and, therefore, of annual capital charges (for the cost of the complete new a.c. geared winder with bicylindro-conical drum is naturally somewhat higher than that of the electrical equipment only of the Ward-Leonard conversion alternative). As a matter of fact the Ward-Leonard arrangement is only more economical than the a.c. geared plant in the ratio of $1 \cdot 31$ to $1 \cdot 29$. The difference is so little that the final choice may well be influenced by some local circumstance of no importance in itself—in this case a matter of convenience only—and which certainly is not taken into account by the Stjernberg or any other formula. The author mentions the Harworth main winder in particular. This plant is arranged upon the Stubbs-Perry principle and also embodies Ward-Leonard control, but it is not to be supposed that because it is a Stubbs-Perry winder it must of necessity be a Ward-Leonard-controlled winder. Briefly the Harworth main equipment embodies a turbine, gears, flywheel, d.c. generator and d.c. winder motors, but the Stubbs-Perry principle would still apply were the equipment to comprise turbine, gears, flywheel, three-phase alternator and three-phase winder motor. With the latter arrangement the alternator and motor would, of course, be solidly electrically coupled, and in such a case the variation of frequency consequent upon flywheel speed fluctuation is not a matter of inconvenience, since this can quite well be taken into account when plotting the speed/time cycle of the wind. I think it will be found that the value of B for this winder is $0 \cdot 291$ and I have sometimes wondered why an a.c. geared installation was not chosen. I do so still in view of the author's statement that in the case of two large a.c. geared winders at present being installed in this country the value of B is $0 \cdot 292$. The author's experience with tail ropes has been unfortunate and is a disappointment to those of us who hold to the view that these should be employed upon every occasion where their use can be shown to be beneficial to the energy diagram. There is much to be said for them even in conjunction with drums of special profile, for if by that means the ratio of larger to smaller diameters of the drum can be reduced, then appreciable reductions in weight and cost will result.

Mr. R. W. Mann: It is interesting to note that the author obtains such a very high efficiency from the belt drive of fans with jockey-pulley arrangements, and I should hardly have expected that this arrangement would have given such results as to have been equal, let alone superior, to a high-class helical-gear reduction, the efficiency of which might be anything from 94 to 98 per cent, depending upon the type of gear. The author refers several times in the early portion of the paper to the comparative advantages of the syn-

chronous motor of the salient-pole type, with or without pole-face windings, as against the synchronous induction motor. As he states, this question has been dealt with in earlier papers read before the Institution, the discussions on which appear to show that the synchronous motor was slightly more efficient than the synchronous induction motor, and, while this is true, it would appear to me that too much consideration can be given to these problematic little differences in efficiencies, even on continuous running plant, and more particularly plant which is not constantly fully loaded, e.g. colliery plant. Take, for instance, Fig. 1. The sizes of the machines are not given, but from the curves I should expect them to be about 450 kVA, the comparative efficiency of the synchronous induction motor being 1 per cent lower, as is usual for machines of this size and upwards. This lower efficiency is almost entirely due to the extra losses in the secondary winding caused by the larger mean turn of the coils than those of a salient-pole machine. It follows, therefore, that at low loads (with constant power factor and hence reduced excitation) the efficiency becomes almost the same as that of the salient-pole machine. The author states that the advantages of the motor shown in Fig. 2 are (1) higher efficiency and (2) normal voltage excitation. The first I have dealt with, but I do not quite follow the line of argument with regard to the latter. Owing to the series-parallel arrangement of the d.c. windings it is quite probable that the excitation voltage would be somewhat higher than that in the case of the synchronous induction motor, but not very much, due to difficulties of design, say, between 35 and 40 volts as against say 25 on a synchronous induction motor. There is, so far as I can see, little advantage to be obtained from the higher voltage. I should be glad if the author would say what is the excitation on this particular machine. The motor has certain disadvantages not mentioned by the author, viz. (1) extra complication, including a switch on the rotor for altering the windings from the starting to the running position, and (2) the machine is an expensive one for British manufacturers to build, costing considerably more than the synchronous induction motor. This fact is not, perhaps, obvious because of the advantages which accrue to our foreign competitors due to cheaper labour and material. Whilst the actual reliability of the two types of machine may be very similar, the author himself refers to a greater possibility of trouble with the starting gear of a salient-pole synchronous motor than with that of a synchronous induction motor which, after all, differs practically not at all from the ordinary starting gear of a slip-ring induction motor with which colliery staffs have more experience. There is, however, another, and to my mind very important, advantage of the synchronous induction motor over the salient-pole machine, and that is that while in both cases as compared with a slip-ring motor there is an additional link caused by the necessity of the d.c. exciter for the field, with the salient-pole machine, in the event of a breakdown on the exciter, the complete unit is useless. With the synchronous induction motor, however, the unit can be run as an ordinary slip-ring induction motor without any d.c. excitation at all, the only limit to this application being where the lagging power factor of the machine as an induction motor is lower than the corresponding leading power factor for which the machine was designed. This is, however, very rare, as most synchronous induction motors are built for at least 0·8 leading power factor at full load, and the power factor of an induction motor is not likely to be less than 0·8 lagging. Quite apart from the above, a synchronous induction motor complete with its switchgear is cheaper than a salient-pole machine complete with its switchgear, and it is a case for serious consideration whether the problematic saving in efficiency justifies the additional cost of the dearer machine. Dealing now with electric winders, it would appear that the author is of the opinion that for single, deep mines electric winding may not be justified, presumably on account of the relationship of the peak load to the rest of the colliery load. This difficulty can, however, be overcome by the application of the turbine-driven Ward-Leonard system which the author describes later in his paper. The larger the winder, the greater the economy over a steam winder, which is the other alternative. The author drew attention during the reading of the paper to the fact that, on the turbine-driven Ward-Leonard winder which he describes later, a second equipment had been ordered, and that it had been found necessary to add an induction motor to the end of the motor-generator set of the second equipment. This is not the case. It will be apparent from a consideration of the scheme that external braking must be provided, regenerative braking only being possible to that extent necessary to bring the flywheel up to full speed and no more. To effect the necessary braking, it is possible to consider either a water-wheel brake or an eddy-current brake similar to that which was fitted to the first equipment and which has given every satisfaction, or an induction motor provided with d.c. excitation. This latter arrangement has been adopted in the second equipment, due not to the disadvantages of the eddy-current brake but to the advantages of the induction motor as a brake, inasmuch as the power system at this colliery has now developed and the induction motor can be used as a stand-by to run the motor-generator set for light-load winding or occasional trips without the necessity of starting up the turbine and flywheel. I fully agree with the author that comparative costs favour electric winders and high-pressure generating plant as against steam winders and mixed-pressure generating plant, and I endorse his view that where power is available from a supply undertaking at reasonable rates, taking everything into consideration, still greater economy can be shown for electric winding. Referring to a.c. versus Ward-Leonard, Stjernberg's conclusion, from his mathematical analysis, was based upon the point of his graph where the value of MS/QT^2 was such that no braking was necessary. This does not necessarily represent the dividing lines between the a.c. and Ward-Leonard systems, and with Stjernberg's own diagrams I should not, under certain circumstances, consider the braking excessive resulting from a value of $MS/QT^2 = 0\cdot3$ with $V \div S/T = 1\cdot5$. To my mind, the tendency of to-day is to use a.c. winders right up to the limit where the respective efficiencies in conjunction with the respective capitalized charges

make the Ward-Leonard an economic necessity. With regard to a.c. motor speeds, the inertia referred to drum varies as (gear ratio)^2 and, whilst of course it depends upon individual designs, I find that the inertia of the rotor drops in roughly the same ratio within reasonable limits. With modern gearing, therefore, there is no harm in using higher-speed motors than those which the author gives, with their consequent better performance figures and lower capital cost. Whilst I agree that a.c. winders do not have the same delicacy of control as Ward-Leonard winders, I am convinced from a fairly wide experience of a.c. winders that, within the limits of their economic application, the control with or without reverse-current braking is all that can be desired for ordinary service. Dealing with the question of braking on a.c. winders, whilst there are, of course, occasions where excessive braking necessitates the use of reverse power, one finds that these cases are the exception rather than the rule for the conditions which prevail in Northumberland and Durham, and normal methods of braking, i.e. wooden brake blocks or patent fabrics, have given quite good service. The following figures are the averages taken from a number of local steam and a.c. winders, from 2 to 500 h.p.

System	Average life of lining	
	Wood	Ferodo
Alternating current . .	2–3 months	12–18 months
Steam.	3–4 months	18–24 months

With regard to the controllers for a.c. winders, it is now possible to incorporate the advantages of automatic acceleration with the advantages of flexibility for manœuvring of a metal-pot type of controller, and I should say that it is very doubtful whether the weir type of controller will be used in future modern equipments. The author's method of indicating reverse-current power is ingenious and interesting. I do not agree with him that even in small winding equipments direct-operating reversing switches are satisfactory. I have seen many types of such switches and I consider that any reasonable increase in cost is a very good exchange for the reduced manual effort required to operate contactor-control reversing switches. When mentioning the automatic control of Ward-Leonard winders, I presume that the author is referring to semi-automatic control given by cam-operated gear—the present-day practice. The question of complete automatic control has been given much consideration, and as far as I am aware there is no completely automatic winder in existence. There would appear to be two chief considerations in the design of an automatic winder—advantages and engineering difficulties. The first is a question of the Coal Mines Act, and I should imagine it doubtful whether permission could be obtained for a locked-up winder house and for the cages to be controlled from bank by the banksman; without such saving it is difficult to see the advantage. Were there any possibility of such permission being given, then I imagine that greater attention would be paid to the engineering difficulties, the chief of which would appear to be double-decking and the design of a motor which would have an exact straight-line characteristic of speed against load during the slowing down of the motor to rest, essential for repetition decking with varying loads. In short, the cam control of a Ward-Leonard winder might perhaps be called an emergency measure eminently desirable but having its counterpart with arrangements that can be and are regularly made for a similar effect on an a.c. winder. The author refers to high- and low-speed d.c. machines, and I can assure him that quite a definite commercial case has been made out for higher-speed d.c. motors on Ward-Leonard-controlled winder equipments. When one takes into consideration, using the author's own figures, that the low-speed motor without gear is only 2 per cent more efficient, while the overall efficiency of the winding cycle may be round about 60 per cent, one really must agree that commercialism must be given room, especially as it can show a very large difference between the capital cost of the low-speed d.c. motor and a high-speed d.c. motor plus gears, the latter being the cheaper. With regard to the maintenance of the additional bearings, my experience is that there is little or nothing in it, and I am in agreement with the author when he says later in his paper that high-speed bearings appear to run indefinitely. The author's comparison between a Ward-Leonard and a Ward-Leonard–Ilgner winder is interesting. It is, however, to my mind impossible to make a generalization from one special case—the application of either of these systems is one necessitating a close study of particular conditions. While agreeing with the author as a general principle that the generating plant should be increased in preference to installing an Ilgner set, there are many cases where it is impossible, and also many cases where the necessary supply network to keep voltage-drop due to peaks within reasonable limits makes the Ilgner set an economic necessity. It is difficult to analyse Table 4 without many more particulars, but there are one or two outstanding features. The motor driving the motor-generator set is of 3 250 h.p., the corresponding peak being approximately 4 000 h.p., or 1¼ times; a system which will take a 3 250-h.p. motor obviously does not require the help of a flywheel for a peak load 1¼ times the rated load. In the next case the motor driving the motor-generator set is of 2 000 h.p., and even with a flywheel the peak is 3 800 h.p., or 1·9 times the normal, so that if the flywheel is doing any equalization at all, the peak without it may have been 2½ times. In the light of the foregoing remarks, this is a case where a flywheel is probably needed. The comparative overall efficiency conveys practically nothing, due to the different net loads. I had a case recently where an extra deck, adding two tubs of coal to the net load for the same output, resulted in halving the size of the equipment put in, with a consequent saving in overall efficiency and cost. It follows that two winders with net loads of 6 and 7½ tons respectively cannot be fairly compared. With regard to balance ropes, in the early days there was a certain amount of opposition to their use, undoubtedly due to steam-

winder experience. Now, however, their use has been demonstrated to be satisfactory, even on cylindro-conical drums, provided a suitable rope suspension shackle is used, with the result that I have no hesitation in suggesting their use where the resulting economy warrants it. The application of the Koepe system in this district in four cases has done much to bring about the foregoing result. The author supplies some valuable data when he gives the actual steam consumptions of modern steam winders. A certain amount of data exists for older winders, but the figures put forward by the manufacturers of modern steam winders are undoubtedly optimistic when compared with the author's figures. In conclusion I should like to say that I prefer the straight a.c. winder for every possible case where it is an economic proposition. There are close on a hundred such plants in this area and I feel that it is on these lines that the coal industry can be best served as a whole.

Mr. A. B. Maclean: In Table 2 the author gives some average figures for the current consumption per ton of coal raised at a modern colliery, and, as he points out, the figures apply specifically to South Wales conditions. It may therefore be of interest to give similar figures for collieries in the Northumberland and Durham coalfield. In Table E such figures are given with information as to some of the essential features governing the total consumption. The figures in this table are derived from meter readings taken over 12 months, three meters being used on some of the circuits and the mean value taken. Accurate coal output and pumping figures have been obtained from the collieries. It has not been possible in all cases to get meter readings to give a complete subdivision of the units, but estimated figures in those cases where meter readings were not obtainable are given in Table F.

TABLE E.

Consumption of Current for Completely Electrified Collieries.

No.	Output,* in tons per day	Depth	Ratio † of water to coal	Consumption, in units per ton					Remarks
				Ventilating	Pumping	Winding	General supply	Total	
		ft.							
1	637	800	1·2	1·27	1·00	2·23	3·66	8·16	Moderate amount of compressed air used
2	1 073	478	1·8	2·07	1·41	4·20		7·68	No compressed air
3	940	720	1·37	2·47	1·11	3·32		6·90	No compressed air
4	4 650	1 170	3·12	—	—	—		21·5	Group of 6 pits. Large amount of compressed air used

* Actual total outputs for the year 1924 have been taken and divided by 250.

† Ratio of total tons of water pumped to total output in tons of coal.

The units per ton given under the heading "General Supply" include the current taken by the compressors used in cases 1 and 4. It will be noted that in cases 1, 2 and 3 the total consumption per ton is very much less than the figures quoted by the author for South Wales. This is due mainly to the shallower shafts and to the fact that in case 1 very little compressed air is used, and in cases 2 and 3 none at all. In case 4 the consumption is relatively high owing (1) to the greater depth of shaft, (2) to excessive pumping, and (3) to the large amount of compressed air used.

TABLE F.

No.	Ventilating	Pumping	Winding	General supply	Total
1	1·27	1·00	2·23	3·66	8·16
2	2·07	1·41	1·32	2·88	7·68
3	2·47	1·11	1·99	1·33	6·90
4	4·27	5·14	3·21	8·88	21·5

[**Mr. W. C. Mountain** also took part in the discussion. The substance of his remarks will be found on page 538 in connection with the discussion before the Institution.]

[The author's reply to this discussion will be found on page 563.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 11 MARCH, 1925.

Mr. W. W. Wood: So far as the technical points dealt with in the paper are concerned, I am in agreement with what the author says, but I must criticize his statement that there are very few cases where the mixed-pressure steam-winder plant can compare favourably with an all-electric plant. His own figures in Table 5 show that, whatever may be the result at the Powell Duffryn Co.'s collieries, in very many collieries the steam winder and mixed-pressure turbine would be the best commercial proposition. In Table 5 there is a comparison between the number of units of electricity required to supply a colliery with an electric winder, and the actual amount of steam used to supply both a steam winder doing the same work and a mixed-

pressure turbine generating electricity. The units generated by this mixed-pressure turbine are given and we therefore have sufficient data to compare the amount of coal used in each case, provided we know how many pounds of coal are required to generate one electrical unit. Unfortunately, the author does not give any particulars enabling me to estimate either his cost of electricity or the pounds of coal he requires to generate 1 kWh—presumably at the Powell Duffryn Co.'s collieries the latter is a very low figure and one that could very seldom be obtained by any other group of collieries. We cannot tell, therefore, what the financial results of electrifying the winder would be at the Powell Duffryn collieries, but we can see from the author's figures what would be the results at an average colliery. The average amount of coal used for the larger generating stations (exclusive of the three largest) of this country for 1924 was about 3 lb. of coal per unit generated. An average colliery may be able to do better than this, though generally the results are not so good. I have, however, assumed that $2\frac{3}{4}$ lb. of coal is required to generate one useful unit, and by this I mean a unit which can be used for driving the winding gear or other productive plant, and not including the units required for condenser, auxiliary apparatus or loss in transmission. The total units generated will be considerably in excess of the useful units and I think that the figure of $2\frac{3}{4}$ lb. of coal per useful unit is as good as can be expected in most collieries, as a normal daily performance. On this basis, taking the author's figures we get the following results:—

Total high-pressure and low-pressure steam required to supply both the steam winding engine and the mixed-pressure turbine (author's actual figure) per hour ..	58 000 lb.
Total ditto required per week of 42 winding hours, 58 000 × 42 equals ..	2 430 000 lb.
Coal required per week to generate the above steam (based on the figures on page 534)	332 000 lb.
Units per week generated by waste and live steam from the above coal in addition to the winding	86 000
Of these units apparently all were not available for useful work, and these we have to deduce from further figures as follows:—	
In Table 5 the total units generated by the mixed-pressure turbine are given as	86 000
Plus units from an external supply ..	11 150
Total	97 150
These were necessary to supply the colliery washery, etc., while if the winders were electrified the author gives the units required for the washery as	90 000
	7 150
By subtraction we see that 7 150 units were apparently used for the turbine auxiliaries and that the useful units supplied by the mixed-pressure turbine were 86 000 — 7 150, equals	78 850

If the steam winder were replaced by an electric winder, it would be necessary to supply from an external source 78 850 units, which were previously obtained from the mixed-pressure turbine, in addition to the units required for the winding gear. The total units therefore required would be:—

Electric winder (author's figure)	52 500
Extra units owing to shut-down of mixed-pressure turbine	78 850
Total additional units required ..	131 350
Coal required per week to generate these units on the basis of 2·75 lb. of coal per useful unit	361 000 lb.
Extra amount of coal required per week to supply the colliery if electric winder is used as compared with steam winder and mixed-pressure turbine, is 361 000 — 332 000	29 000 lb.

We see from the above figures that if it requires $2\frac{3}{4}$ lb. of coal to generate one useful unit, then the substitution of an electric winding gear for a steam winder and mixed-pressure turbine, in the case cited by the author, would involve an extra coal consumption of about $12\frac{1}{2}$ tons per week. In addition to the extra coal there would be of course a considerable cost per annum in the interest and depreciation on the extra capital required by the more costly electrical scheme. As the author gives no figures of present-day capital costs, I do not propose to discuss this, but I would point out that the capital required for the electric winding gear is only part of the cost. In addition to this the generating plant must be increased to supply the extra demand both of the electric winding gear and of the plant which was previously supplied by the mixed-pressure turbine. As the electric winding gear makes a big demand for its peak load, the additional capital required for the generating plant is a large amount and more than offsets the saving due to the fact that the mixed-pressure turbine would not be required. It will be well to note also that the auxiliaries for this larger generating plant would take considerably more power than those for the mixed-pressure turbine, and would work on a worse load factor. I think it is obvious, therefore, that in a number of cases the steam winding gear and the mixed-pressure turbine are undoubtedly the correct plant to install, and it would be necessary to generate at an extremely low coal consumption per unit in order to make electric winding the better proposition. Every case of this kind must be worked out on its merits, taking into consideration (1) the cost of generating or buying electricity, (2) the cost of coal used under the boilers for raising steam, and (3) the capital cost of each scheme. My present partner, Mr. Mountain, went very fully into this cost for the electric winder versus the steam winder in the paper which he read before the Institution in 1906, and showed that at that time there were few cases where the electric winder

was best, owing to the small value of the coal which was used for raising steam, and to the high capital cost of the electric plant. It was generally realized that the electric winder would require less coal to be burnt under the boilers for a given work than would a steam winder, but the value of the coal saved was so little that it was not sufficient to offset the extra interest and depreciation required on the costly electrical winder. Since that date conditions have altered considerably and there are more cases to-day where the electric winder may be the right equipment than when the paper was read, but on the other hand the developments of the mixed-pressure turbine is a factor tending to increase the number of cases where the steam winder is the better proposition. I do not wish it to be thought that either Mr. Mountain or myself is an opponent of electric winding—that is by no means the case—but we feel it is never of advantage to the industry to install plant which does not give the best commercial results, and consequently it is desirable to treat every case on its merits, taking into account the numerous factors which affect the financial result, the only one of interest to the mine owner. During the discussion with regard to the efficiency of compressed-air transmission, reference was made by several speakers to the loss which occurred in the underground distribution of this power. A short time ago I had to make some tests of the leakage of air at a colliery, and in this particular case I found that while about 4 000 cubic feet of free air was being supplied to the pit in question, of this amount 1 500 cubic feet of free air was escaping without doing any work. This is by no means an isolated instance and shows a leakage of about 37 per cent during times of heavy load. When the load was reduced, with the leakage still remaining constant, the loss increased to nearly 50 per cent. In Table 4 the author gives particulars of the power required to run a Ward-Leonard generator when driven by a synchronous motor as 80 kW, whereas if driven by an induction motor the light-load loss is 115 kW. I should like some further explanation of these figures as I do not understand how the induction motor could take so much more power than the synchronous motor to do the same work. Is there anything abnormal in the machine referred to ?

Mr. D. Weir: I am interested to note that the author questions the advisability of running ventilating fans at low speed during stop-days and at week-ends. If the advantages of such a procedure are indeed doubtful it would seem ill-advised to install variable-speed motors for fan drives when a constant-speed machine of much superior operating characteristics might be used. As the author suggests, the increase of fan speed as the mine develops can be arranged for very simply by altering the ratio of the drive. The author's statements as to the higher efficiency and better all-round operation of the salient-pole type of synchronous motor as compared with the synchronous induction—or auto-synchronous motor, as it is sometimes called—are welcome. So much attention has recently been drawn to the synchronous induction motor that engineers are apt to overlook the claims of the older and more robust type of synchronous motor with salient poles. The salient-pole machine suffers from the disadvantage of not being able to start up against a heavy torque, but in the cases of air compressors and other drives where high starting torque is not required there would appear to be no justification for using the synchronous induction motor when a more satisfactory machine of higher efficiency is available. Reference has been made to the use of salient-pole synchronous motors in America for driving colliery fans, the torque being reduced at starting by closing the air outlet. Baffling of the fan outlet has been used for varying the air volume, and it only seems necessary to carry this a step further to permit of the use of salient-pole machines for fan drives. It would be interesting to have the author's views on the feasibility of applying this scheme to mine-ventilating fans in this country. Provided inexpensive arrangements could be made for baffling the fan outlet, the scheme would appear to have much to recommend it. It is stated that a complete Ward-Leonard winder (presumably with direct-coupled motor) costs about 30 per cent more than a geared induction motor winder. My experience has been that this figure is nearer 75 per cent. Apart from the reduction gearing, the mechanical equipments for the two systems are practically identical. On the other hand the Ward-Leonard system requires roughly three machines of the full winder capacity, one being a very large low-speed motor, as against one moderately high-speed machine in the case of the induction motor winder. When the larger winder house and the high cost of the cable work are taken into account, the cost of the Ward-Leonard winder may easily approach twice that of the geared induction motor winder. It is somewhat surprising to learn that the balance rope is not looked on with favour in South Wales, in view of the increasing popularity of this device in other districts. In addition to the economy in energy consumption, there is a considerable saving in the initial cost of the drum if by using a balance rope a parallel drum can be used in place of the more costly and much heavier cylindro-conical drum. The author exhibited a lantern slide showing a "pot" type of liquid controller in which the customary arrangement of vertically moving electrodes is retained. All such arrangements suffer from the disadvantage of inefficient circulation of the electrolyte. The heated liquid in rising by convection from the region between the moving and fixed electrodes is baffled in its flow by the upper electrode. A considerable advance has been made in a recent design of "pot" controller in which the electrodes move approximately in a horizontal path, thereby permitting free circulation of the electrolyte by convection. Heaviness of operation is a further disadvantage of the orthodox design of controller, necessitating in some cases the use of an air engine to assist the driver. In the new design referred to, this defect is overcome by swinging the moving electrodes in pendulum fashion and balancing them with a spiral spring which avoids the objectionable inertia of balance weights.

Mr. Christopher Jones: I suggest that the title of the paper should be amended to read "Electrical Power Plant at the Colliery Pit Head," inasmuch as the author does not refer to the use and application of

electricity *in the mine*. I personally should have welcomed some description of the plant used underground, together with the system or the troubles (if any) experienced on such a very large colliery undertaking. The author's remarks regarding fuel and water conditions are very much to the point and I am in agreement with him. He refers to the question of the improvement of power factor. This subject was considered by my company about 12 years ago when it was decided to install static condensers on the low-tension system at surface and underground substations. These have justified their installation from every point of view. In another instance when the question of conversion of a steam-driven ventilating fan to electrical drive came up for consideration, it was decided to install an induction synchronous motor drive direct coupled to the fan. This has been in continuous use for about 4 years without a moment's trouble. The author refers to speed reductions of ventilation fans at week-ends or stop-days which necessitate variable-speed motors or other mechanical speed-reducing devices, and his jockey pulley device is very interesting. I should like to ask him if he has had any experience with the Williams-Janney variable-speed gear and if he has considered such gear in connection with his undertaking for winding, fan or haulage drives. I agree with him that speed reduction at week-ends, etc., is a questionable economy, bearing in mind also the colliery manager's responsibility as to safety of the mine, and I doubt whether the mining regulations permit of such speed reductions. My own colliery manager confirms the author's views that it is safer to maintain full volume of air at all times, and this practice is in force. Mention is made of the unsatisfactory method of starting up squirrel-cage motors by means of auto-transformers. In this connection I would say that in my own case motors up to 70 b.h.p. only are allowed. These are started up by auto-transformers and no trouble has been experienced. The size of this type of motor is also governed by the capacity of the generating station and, in the case of bulk supply from an outside source, by the rules of the supply undertaking; these are in some cases very stringent in regard to the use of squirrel-cage motors. On page 522 the author states that the four most important loads are pumping, ventilating, winding, and air compressing. I presume that the author regards this as being applicable to his own undertaking, otherwise I disagree with him. At the collieries under my charge electricity is used on the surface for ventilating, haulage, pumping, screening and other works drives, *but no winding*. For underground purposes electricity is used for coal-cutting, pumping, haulage, auxiliary winding gear, compressor drives, other than conveyers, rock-head drills, punchers, and small haulage gears up to 10 h.p. which are compressed-air driven, electrically driven compressors being installed inbye. It would be of interest to hear the author's views regarding inbye compressors. The units generated at the colliery station for all power purposes during drawing hours average 3 per ton of coal raised, 70 per cent of the coal drawn being got by electrically driven long wall and arc wall coal-cutters. On page 536 the author refers to the advantage of the use of electricity in that the consumption of every machine or group of machines can be continuously recorded and any waste checked, the electrical plant retaining high efficiency without the constant adjustment and renewals necessary in other machines. Apparently here again the author refers to pit-head drives, as a large number of compressed-air machines must be used when analysing the curves shown. In view of the author's admission in regard to the advantages of electricity, will he say why compressed air is used on such a large scale and how he obtains the best results from such machines? I cannot understand his statement that the principal effect of electrification is to reduce the amount of unskilled labour employed at the pit-head, and I should be glad if he would amplify his remarks on this point.

Mr. G. M. Harvey: In the summary, the author states that the object of the paper is to show that the mining electrical engineering industry cannot rightly be charged with employing wasteful and unscientific methods, and the paper shows what high efficiencies can be obtained by means of the latest developments in electrical machinery scientifically applied to mining conditions. I would ask, however, whether there is not too great a tendency to strain after the last 1 per cent of efficiency, possibly at the expense of reliability, which is of greater importance in colliery working from the point of view of the management. A stoppage of one hour on the main haulage supplying a shaft from which, say, 2 000 tons of coal are being wound per shift, will mean a loss in revenue to the company of £300 or more, and will counterbalance several decimal points of efficiency in the motor. The author refers to the practice of washing low-grade fuel, and states that this should be done if the ash content exceeds 10 per cent. It would be interesting to know whether he has proved this practice to be economical, as it would appear that the cost of washing would more than outweigh the extra efficiency gained. It is common practice to burn, with ordinary hand-firing arrangements in Lancashire boilers, low-grade fuel having an ash content of up to 30 per cent. On page 522 the author states that auto-transformers are unsatisfactory for starting large squirrel-cage motors. Has he had any experience of the type of auto-transformer starter in which successive tapping voltages are applied to the motor during starting, thus gradually increasing the applied voltage by a number of stages? Once the difficulty of changing from step to step without open-circuiting or short-circuiting the transformer windings has been obviated, I believe that these starters give satisfactory service up to about 200 h.p. at least. The statement on page 524 with regard to the efficiency of transmission of compressed air is rather startling, and I think that the author might have emphasized the fact that this applies to surface transmission only. For transmission below ground, along shifting roadways, with bends every few yards and the ever-present possibility of damage from the collier's pick, transmission by compressed air cannot hope to compete with the electric transmission of energy. It would have been useful if the author had carried his comparison of compressed air and electric transmission somewhat further, and given the relative efficiencies of the three systems in practical

use, viz. (*a*) steam-driven compressors on the surface and air engines at the coal face, (*b*) electric generators on the surface and electric motors at the coal face, and (*c*) electric generators on the surface, electrically-driven compressors at suitable points below ground, and air engines at the coal face. The efficiencies of these systems are roughly as follows: (*a*) 25 per cent, (*b*) 60 per cent and (*c*) 15 per cent. The very large proportion of power taken by the compressing plants in the colliery referred to in the paper is, I think, an admission that we have not yet arrived at complete safety from shock and explosion in the use of electricity in an explosive atmosphere. In South Wales generally, one finds the electric cables terminating at points a few hundred yards inbye from the shaft bottom, whereas in more favoured districts, such as the Midlands, where we have not to deal with large quantities of explosive gases, the electrical installation extends to the coal face, and compressed air is used solely for percussive rock drills. The portion of the paper dealing with electric winders contains a very large amount of information, and goes to prove—if proof were needed—the intricate nature of the problems with which the mining electrical engineer has to deal, and the folly of attempting to handle such problems without a very full knowledge of mining conditions. It would be instructive if Table 6 could be completed by filling in the blank spaces in the last three columns, utilizing the pounds of coal burnt per unit generated by the electrical plant. Without these figures the comparison is incomplete.

Mr. H. Jack: The paper is of great value for the comparative data it gives based on actual tests and costs. I think that the author has proved the great advantage of running a group of collieries by means of a modern high-pressure steam-turbine-driven electric power station and the general use of electric motors. The consideration, then, of the best type of electric motor for each duty is important. I note that the author is not in favour of using the squirrel-cage type of motor for driving centrifugal pumps where the horse-power exceeds 150. This is contrary to the experience of some engineers in large mines abroad. I consider that the squirrel-cage motor, properly designed and constructed, is the most robust type of electrical machine, and that with substantially built auto-transformer or star-delta starters, squirrel-cage motors up to at least 1 500 h.p. could be used for driving centrifugal pumps and would give maximum reliability. The author was one of the first in this country to realize the great advantage of installing synchronous motors, both of the salient-pole type and the cylindrical-rotor type. At the same time he has wisely only installed motors of the synchronous type, where the output of the motor was of sufficient magnitude to make a substantial improvement in the power factor of the system. The type of synchronous motor shown in Fig. 2 is interesting, but from a manufacturing point of view it tends to be costly. One cannot use for its manufacture the developed pole dies of the salient-pole squirrel-cage type of synchronous motor, or the developed rotor dies of the induction motor. The synchronous induction motor with cylindrical rotor can be made with the dies developed for the ordinary induction motor. For this reason I do not think that the salient-pole motor with slip-ring type winding in the pole face is likely to be generally adopted by manufacturers. Where a starting torque of full load or greater is required, or where it is necessary to pull into synchronism against a torque of full load or greater, the cylindrical-rotor type of synchronous induction motor is being generally adopted. It is the cheapest type of synchronous machine for heavy starting duty, but its efficiency is at least 2½ per cent lower than that of the salient-pole synchronous motor. As regards the Lenix belt drive adopted by the author for driving fans, I should like to know the maximum horse-powers and speeds for which this type of drive could be used and what is the approximate life of a belt. Although for a considerable number of years the salient-pole synchronous motor has been adopted in the United States for practically all air and ammonia compressor drives, the extent of its use and success is not yet realized in this country. For starting duties up to at least half full-load torque, and where unity or leading power factor is required, the salient-pole synchronous motor is the ideal machine. As regards the method of starting I think that the best form of starting apparatus is on the lines of the Korndorfer arrangement described in the paper. With such a method the supply to the motor is never broken during the starting period. I hardly think that it is necessary to have all the 6 steps given on page 525. There is no apparent advantage in starting with the auto-transformer neutral open. The real advantage in being able to open the neutral of the auto-transformer is that one can pass from the tap connection to a choke-coil connection; on short-circuiting the choke-coil connection the motor gets the full line voltage. This avoids any sudden rush or kick of current such as is obtained if the tap connection from the motor is broken and the full line voltage then switched on to the motor. Further, I think that it is better, wherever possible, to synchronize the motor, i.e. close the field switch, while the motor is still running on the tap voltage. The author considers the characteristics of the induction motor in dealing with the control of a.c. winders. I think that the late Dr. Steinmetz was actually the pioneer in developing fully the characteristics of the induction motor. In Fig. 7 the author gives the well-known speed/torque curves of the induction motor. When considering the control of an a.c. winder motor the value of the curves would have been enhanced if the author had extended them to include regenerative working and had also given curves with greater external resistance. Curves showing the stator and rotor currents throughout the range of speed and for the various values of rotor resistance would also be of assistance in considering the control. His statement that too high or too low a resistance results in a reduction of the reverse-current braking effect at full speed is only correct where the resistance inserted is such as to give maximum braking torque at full speed. A further increase or decrease of this resistance would then lower the torque. This is a contingency that would practically never arise, as one would always have sufficient external resistance to keep the torque below its maximum value. With the external resistance

values corresponding to the curves of Fig. 7 the stator currents on reverse-current braking would all be approximately equal to short-circuit current, and the motor should not be run at such high values of current. If the motor is running with the proper external resistance value to give a braking torque of less than maximum torque, then to obtain an increased braking torque at full speed the amount of external resistance should be reduced.

[The author's reply to this discussion will be found on page 563.]

East Midland Sub-Centre, at Nottingham, 24 March, 1925.

Mr. L. G. F. Routledge: Table 1 is interesting in that it should dispel any illusions in the minds of those who still place their faith in gas engines owing to their high thermodynamic efficiency. There is, I believe, a 7 500-kW gas engine now being installed at works not far from this Centre, and the results of its working will be awaited with great interest. I should like to ask the author what are the various percentages for interest, depreciation, etc., which he allows under the head of capital charges in line 5 of Table 1. Questions of economical fuel consumption have not yet been seriously tackled in the Midlands. Most of the collieries have hand-fired Lancashire boilers, but some of them are now seriously going into the question and some results should be available for comparison in the course of the next year or two. On page 522 the author mentions power factor improvement and briefly dismisses the static condenser. It may be of interest here to state what has been done in the way of power factor improvement at a group of collieries with which we are connected. The author's conditions are more or less peculiar to South Wales, and the centres of gravity of his electrical load are, generally speaking, on the surface at the collieries. In this district electricity is taken to the coal face both for machine cutting and conveying, and the electrical centre of gravity usually lies somewhere between the pit bottom and the coal face. It is obvious that synchronous motors of small size cannot be introduced into the mine, and it is here that the static condenser shows to advantage. Table G gives some particulars of static condensers installed at this group.

Table G.

Capacity of static condenser	Date installed	Type	Cost of repairs and maintenance per annum
kVA			£
81	Oct. 1913	Old original type in 50 μF units	8
115	Feb. 1917	Old original type in 50 μF units	3
56	April 1919	Tank type	Nil
95	April 1919	Tank type	Nil
65	Oct. 1924	Tank type	Nil

We dispense with switchgear where possible and connect direct to the stator circuits of induction motors. Two of the above are connected to the stator circuits of small motors driving ventilating fans; the others are inbye. When the 115-kVA condenser was installed about three miles from the generating plant, while the load remained steady the weekly consumption of units was reduced by 840. This showed a saving of 17 per cent on its capital cost, taking into account only the costs of coal and water ruling at the time of its installation. At this group of collieries we installed in 1914 a salient-pole motor to drive a screening plant. This motor released three induction motors for other jobs and enabled an increase in transformer capacity to be avoided. It seems rather an extraordinary drive for a synchronous motor, but it was the only one available and something had to be done at the time. A synchronous induction motor of moderate size drives a fan installed in 1920. Mr. Weir, in reading the paper on behalf of the author, showed some interesting diagrams of fan drives by salient-pole motors in America and mentioned a starting torque of 50 per cent of full-load torque. I should like to ask how this is done, and what is the starting current. It is difficult under existing conditions in this country to get a starting torque of 30 per cent of full-load torque with reasonable starting current. I am afraid also that colliery managers would not agree to shut off the fan drifts while starting the fan. Some figures which we have obtained for motors to drive a 3 000 cubic-feet-per-min. air compressor at a synchronous speed of 250 r.p.m. may be of interest as they do not bear out the author's statement as to the immense superiority of the salient-pole motor. The figures given in Table H were obtained over 12 months ago. The

Table H.

	Induction motor	Synchronous induction motor	Salient-pole motor
Capital cost ..	100	118	132
Power factor ..	—	0·85 lead	0·85 lead
Full-load efficiency	93 %	92·2 %	92·5 %

Table J.

	Induction motor	Synchronous induction motor	Salient-pole motor		
Capital cost	100	130	135	142	150
Power factor	0·82	unity	unity	unity	unity
Full-load efficiency	94	93·8	93	92·5	94

figures of capital cost include main switch and starter and an allowance for saving on the compressor bed in the case of the salient-pole motor. The figures of efficiency are not strictly comparable with the author's as they are at 0·85 leading power factor. Some figures recently obtained in connection with a second 3 000-cubic-feet-per-min. air compressor at the same speed are given in Table J. The above figures are from various makers. The figures in Table K, however, are

TABLE K.

	Induction motor	Synchronous induction motor	Salient-pole motor
Capital cost ..	100	114	132
Power factor ..	0·82	unity	unity
Full-load efficiency	92·5	93·8	94

from the same maker. Taking the cost of the induction motor in Table J as 100, the induction motor in Table K costs 108. The figures in Table L are also

TABLE L.

	Induction motor	Salient-pole motor
Capital cost	100	98·5
Full-load efficiency ..	92·5	93
Full-load power factor ..	0·8	unity

from one maker. This is the most expensive induction motor offered and the cheapest salient-pole motor.

In connection with Part 2 of the paper the following figures may be of interest as showing how conditions vary in different parts of the country. At a group of collieries near Nottingham where the whole of the plant with the exception of winders and locomotives has been electrified, the figures are as follows :—

	Units per ton raised
Ventilating fans	2·72
Pumping	0·21
General pit use	4·15
Compressed air	—
	7·08

If the winders were electrified the consumption would be approximately 2·5 units per ton raised, making a total of 9·58 units per ton raised. These are very old pits with thin seams a long way out. The average depth from the surface is 300 yards and the coal raised per pit is about 1 000 tons per 7-hour shift. The figure 4·15 includes screening, washing, workshops, coal-cutters, haulages, and a few face and gate conveyers. At another pit in South Yorkshire drawing about 2 200 tons per 7-hour shift from a depth of 630 yards the figures are :—

Winders	Steam
Fans	Steam
Compressed air	2·1 units per ton raised
Inbye haulages	1·1 units per ton raised
Pumping	0·1 unit per ton raised
Washing	0·8 unit per ton raised
Screens, shops and other uses on surface ..	2·4 units per ton raised
	6·5

If the winders and fans were electrified the total would be about 13 units per ton raised. I should like to ask the author if he has any motors with Boucherot rotors, and, if so, what are the starting torques and currents obtained with them. I agree with him that it is very questionable economy to install variable-speed or cascade motors for fan drives. I have known one or two cases where two-speed motors have been installed and only run on top speed, due partly to the desire to maintain the full volume of air at week-ends and partly to the difficulty of finding suitable men to change the speed of the motor in question. The examples of the Lenix drive shown on the lantern slide were extremely interesting, as indicating what can be done in economizing space and making what is apparently a very simple and reliable arrangement. What does the author consider to be the maximum horse-power that can be transmitted by this method? I quite agree with the author's remarks on the economy of the electric winder, and under suitable conditions where the colliery only runs one 7-hour shift the steam winder with mixed-pressure turbine has no case against the electric winder, although of course the Ward-Leonard equipment is more favourable the longer the coal-turning period. As a matter of fact there are cases in this district with steam winders already existing where it is false economy to install mixed-pressure turbines as against high-pressure sets. In considering electric winding each case must be judged on its merits. Where there is an unlimited power supply without risk of excessive voltage-drop, Stjernberg's coefficient is a very useful way of analysing the problem, but this cannot apply to those collieries with small generating plants and transmission systems where new generating sets and increased capacity of transmission lines would have to be installed to supply a.c. winders. The value of the paper would have been enhanced had a table of rope and drum diameters and life of ropes been included. Mr. Weir mentioned several cases of drums from 12 to 13 ft. dia. on the small diameter with ropes of 2 inches dia. and larger. What type of ropes are these and what life is obtained with them? The author mentions fully automatic control with the Ward-Leonard system, but I should like to ask whether he has tried fully automatic control. It was pointed out that a way of complying with the regulations and keeping all the plant in one engine room is to keep the winding engine man in a cabinet. Why not in the case of Ward-Leonard control move him to the pit bank where he could have absolute control over the cage and save the time of signalling

between pit bank and engine house? A better alternative in those cases where electro-pneumatic decking is in use would be by an extension of the decking plant control lever to make him operate both the decking plant and the hoist. Has the author had any experience, where automatic keps are in use, of the keps being pulled away when there is a certain amount of slack rope above the cage? If so, how does he guard against this contingency? With the Ward-Leonard control and semi-automatic cam gear, does an engine man ever pull his lever back and stop before the ascending cage has reached the keps? If this happens with a cylindro-conical drum, will the slight movement of the control lever enable the motors to exert sufficient torque to raise the loaded cage on to the keps, and, if not, how is this difficulty overcome without waste of time? Mr. Weir explained that there is a spring attachment to the control lever which enables it to move sufficiently to give the motors creeping speed, but this does not explain whether that movement enables the motors to exert sufficient torque to lift the loaded cage on the large diameter of the drum. On page 529 the author compares the efficiency of the direct-coupled low-speed d.c. motors with the higher-speed geared motors on the Harworth colliery winder. Taking the capital cost of the whole equipment, including flywheel set, exciter, control board and complete winder (excluding foundations, buildings and cables) as 100, the cost with low-speed direct-coupled motors would have been 123, or, taking the mechanical and electrical parts of winder only as 100, the equipment with low-speed motors would have cost 142. Apart from considerations of reliability, maintenance costs, etc., the efficiency of the motors and gears on the Harworth winder could drop to 75 per cent before the direct-coupled motors would show a saving on the score of efficiency only, so that there is here a large margin for repairs and maintenance. It may be of interest to compare the corresponding steam consumption (running light) of the flywheel set given at the top of page 530, with the Harworth flywheel set. This set when running light takes 3 650 lb. per hour (including allowance for condensing plant) with 150 lb. per sq. in. steam pressure, 100 degs. F. superheat and 28 in. vacuum (actual figures, bar. 30 in.). The flywheel weighs 22 tons, is 12 ft. in diameter, has two 875-kW d.c. generators and eddy-current brake, gears, turbine, etc., and the stored energy at 750 r.p.m. is approximately 83 million ft.-lb. The estimated stored energy in the author's set at 500 r.p.m. is 55 million ft.-lb. Assuming 180 kW input to induction motor, 10 per cent loss on transmission, 96 per cent generator efficiency, and similar steam conditions, would give 3 000 lb. of steam per hour. This is 26 per cent in favour of the steam-turbine-driven flywheel set. This could, of course, be considerably improved by increasing the pressure and superheat, but owing to there being boilers already in existence the plant was handicapped to that extent. This plant is not yet operating under anything like its full-load conditions, viz. 300 tons per hour from a depth of 940 yards, so that it is impossible yet to give any actual figures of results of working. The coal being raised at the present time is just under 400 tons in the 24 hours. The author's application of the synchronous motor to drive the Ward-Leonard equipment is extremely interesting and further information about his device for keeping a steady power factor on the motor during the large fluctuations of load would be welcome. With regard to Part 3 of the paper, I quite agree with the author that the stand-by losses are more considerable than they are usually thought to be. It would be interesting if the calorific values of the fuels were given. At the group of collieries previously mentioned where there are four winding engines exhausting to atmosphere and only a small proportion from two engines going to a mixed-pressure turbine, the fuel consumption remains steadily year by year in the region of 3·5 per cent of the coal raised, but this may be due to the fact that it may be of much higher calorific value than the 4·72 per cent mentioned in the paper, owing to the boilers being mostly hand-fired Lancashire boilers. The whole of this group of collieries is electrically driven from a central generating station at the central mine of the group. Only the winding engines are steam-driven. In conclusion I should like to ask the author why he has gone to so much trouble to reduce the starting peaks on his compressor motors when he has so many large a.c. winders on his system.

Mr. A. D. Phillips: I notice from Table 2 that a very large proportion of the energy used in the South Wales coalfields is apparently for compressor purposes, and I gather from Mr. Weir's remarks that this is accounted for by the fact that the colliery managers and engineers will not have electricity used at the coal face. In the Midlands I believe that there is very little compressed air used for this purpose and that electricity is generally favoured. I should therefore be interested to know whether the different policy adopted in South Wales is due to different conditions or whether it is dictated to some extent by prejudice. I gather from the paper that electric winding is fairly extensively used in South Wales and, from the figures given, this type of winder apparently shows a considerable improvement in efficiency over the steam winder. In the Midlands the practice is again the reverse, and I should like to have the author's views as to whether in this case this is due to prejudice on the part of the Midland colliery owners. From the figures put forward as to the efficiency of electric winders it seems to me that if these figures are correct any colliery owners who fail to adopt electric winding in connection with the new coalfield development in Nottinghamshire will find within the next 5 to 10 years that their equipment, although comparatively new, is entirely out of date.

[The author's reply to this discussion will be found on page 563.]

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE, AT LIVERPOOL, 20 APRIL, 1925.

Mr. R. F. Bull: Referring to the author's opening remarks, I would say that in Lancashire also efforts have been made to achieve efficiency. In 1899, electrical energy was generated for lighting, haulage, coal-cutting, etc. In 1903, steam turbines driving three-phase alternators were installed, and in 1913 two sets of electric winders were ordered with Ward-Leonard-Ilgner control by the same colliery company. On page 522 the author refers to the pulverizing and burning of inferior coals. Can he give any figures comparing the cost of burning similar coals, not pulverized but hand-fired, in Lancashire boilers? Is the winder referred to in Table 2 an a.c. or a d.c. machine? At a Lancashire colliery, completely electrified except for one winding engine, the units per ton (not including the electric winders) were as follows:— Air compressors 12, fan 6, other plant (surface and underground) 7; total 25. This colliery is in its early development stages. At another colliery, completely electrified with the exception of its steam winding engines, the total units used vary from 8 to 10. The low figure is due to the very small amount of compressed air used. Does the author find any extra wear on the motor bearings with the Lenix drive, and has he experienced any trouble with the belt not gripping after it has been out of commission for some time? Referring to the two-speed motors, it would seem that three speeds are really necessary—the middle speed for ordinary running, low speed for week-ends (if required) and high speed in case more air is required in the mines due to a sudden outburst of gas. On page 524 the equivalent h.p. for 6 396 cub. ft. per min. at 75 lb. per sq. in. is given as 1 038. The comparison seems hardly fair to the reciprocating set unless the steam consumption of the turbo compressor is taken when it is developing 6 396 cub. ft. of free air per minute. Can the author say what is the running cost per 1 000 cub. ft. of air, comparing the turbo compressing plant, pipe line, etc., with electric transmission and reciprocating compressors? Fig. 4 shows typical load curves for a compressed-air plant and an electrical plant. The scale of loads is not given, but it appears that one or more 40 000 cub. ft. turbo compressors have to be started up and shut down before and after the day shift respectively. I should imagine that this is not very good practice for large turbines. The author refers to the automatic air-controlled inlet valve on the vertical compressors, which is closed when the pressure exceeds a predetermined value and compression ceases, to commence again when the pressure falls by a few pounds per square inch. There is another type of control gear for electrically driven compressors, consisting of rotary unloading valves on the suction sides of the high-pressure and low-pressure cylinders. These valves can be adjusted to operate one after the other so that the load can be taken off and put on gradually, to reduce shocks on the compressors and sudden variations on the power station. It would be interesting to know what air meters the author uses, also if he has had any trouble with his pipe line due to water, expansion, or contraction. There is a great demand for air meters at a reasonable price for placing in branch mains to check the flow of air to various districts. How does the winding-motor control compare with the synchronous-motor-driven converter set against the flywheel set from the point of view of accelerating and retarding quickly? Referring to Table 1, I should be glad if the author would state whether the installation working with steam at 350 lb. per sq. in. pressure and 700° F. results in any considerable saving.

Mr. E. W. Ashby: Curves are given in the paper comparing the efficiency of motors of geared and direct-driven winders. The system dealt with in the paper will have a high power factor owing to the liberal use of synchronous machines, but I think it would be of interest to those who use ordinary induction motors to compare power factor for high-speed and low-speed winding motors. Regarding Mr. Bull's remark about the cascade motor, I have handled inquiries for these over a period of six years, and three-speed motors are often asked for. Taking a single-wound cascade motor having two speeds of 500 and 333 r.p.m. (50 periods), the third speed with this winding would be 1 000 r.p.m. The top speed would thus be too high to meet the conditions set out by Mr. Bull, and to obtain a third speed of 600 r.p.m. a second stator winding is necessary. This increases the cost by about 20 per cent over that of a two-speed machine. The additional speed is well worth the extra outlay, but in the majority of cases the colliery engineer decides on the two-speed motor.

Mr. H. Pryce-Jones: I should like to ask whether the Stubbs-Perry scheme, the details of which Mr. Perry has given, can be used as a straight a.c. equipment. The drop in speed necessitated by the giving up of the kinetic energy of the flywheel would of course result in a frequency variation, which in turn would have an adverse effect upon the electrical efficiency of the generators and winder motors. If an a.c. equipment has been utilized in this arrangement, how does its overall efficiency compare with that of a Stubbs-Perry scheme operated upon the d.c. Ward-Leonard principle?

Mr. T. Hodge: The paper is in my opinion rather in the nature of a treatise on "Electricity *at* Mines," than "*in* Mines," and although the author gives some very interesting figures in regard to the production of power and the methods of its application, I am sorry that the transmission of it has not been touched upon more with reference to underground purposes. Has the old trouble of the cores of the pit-shaft cables being squashed together by the clamps holding the cable, and the consequent short-circuits, been entirely overcome? What progress has been made along the main roads to ensure that cables are impervious to damage in case of falls of roof, or at such times as the tubs or wagons threaten to bring all the props along with them on their journey? In view of the reports of fatal accidents, would it not be possible or economical in the case of distributors to transform down to a safe voltage within a reasonable distance from the coal-

cutters? With regard to the motor on the coal-cutter, and its trailing cable, does the author consider that it will ever be safe in the light of recent developments to use it in any working place where safety lamps are necessary? It is pleasing to see what strides have been made in the use of electricity for winding, but I fear that there will not be a large field for electric winders in England in the future, mainly on account of capital cost and the depleted state of the coalfields. I was surprised to read on page 524 that the transmission losses with electric power and compressed air are so nearly equal. With regard to the latter part of the paper dealing with the amount of unskilled labour, I do not see that electrification can affect much economy, since the few skilled labourers require a higher rate of pay. In addition, they might at times be more difficult to manage than some of the unskilled. Is not the principal effect of electrification a higher plant efficiency?

Mr. C. Rettie: I do not quite understand the system proposed for small collieries and should like some explanation on this point. For instance, I was always under the impression that the Ward-Leonard, Ilgner, or cascade system was far superior to any other, no matter what size the colliery happened to be. What, for instance, becomes of the peak loads in the system proposed by the author? With regard to the economies gained by the use of electricity in mines, I have always laid down in other directions that economy is not always the deciding factor, but rather the ability to do things more safely and better. With regard to mine signalling, as the driver does not see what is going on in the shaft he depends entirely on reliable signalling apparatus, and this, in addition to providing safety, must affect the economical working of the mine.

Mr. E. M. Hollingsworth: Unfortunately, for financial and other reasons, the colliery companies in this area have not seen their way to adopt the progressive policy of the South Wales owners, and, as in the case of the Powell Duffryn Co., with the excellent results given in the final part of the paper. The advantages of electrical working generally in the mines are well known, but outside the South Wales area there are very few cases where electric winding has been adopted. That part of the paper dealing with winding is therefore of great interest, particularly the comparison of the merits of the a.c. and d.c. systems, and the control apparatus. The author has not hesitated to apply synchronous motors to drives for which a few years ago such motors would not have been considered suitable, and his experience goes to show that the synchronous motor is satisfactory and, of course, is of great value as regards power factor improvement. Is any great progress being made in the direction of the replacement of compressed air by electricity at the coal face, also what recent improvements have been made in the direction of reducing risk with electrical machines in gassy mines?

The Author's Reply to the Discussions before The Institution and at Manchester, Newcastle, Birmingham, Nottingham, and Liverpool.

Major E. I. David (*in reply*): I propose to deal with the various points raised, under separate headings.

Boiler fuel.—Mr. Sparks, Mr. Burgess and others refer to the various fuels burnt under colliery boilers. I agree that it does not pay to burn dirt; but coke breeze, washery slurry, froth flotation slurry and other difficult but clean fuels can be and are being burnt by blanketing or mixing with other fuels. Mr. Burgess also refers to burning coke breeze alone, and other low volatile fuels with thick fires, but he obtained only 55–60 per cent efficiency and outputs of 60–67 per cent of the boiler rating. I would point out that by the blanketing method average efficiencies of 82 and 100 per cent boiler outputs with 12–13 per cent CO_2 are being continuously obtained. This replies also to Mr. Harvey's question in regard to coal-washing. With 30 per cent ash in hand-fired boilers an efficiency of 55–60 per cent would be a good result. Coal-washing is not expensive—it is the loss of weight in the removed dirt that makes the principal difference in the cost of washed and unwashed coal. If people would buy on calorific value and burning properties, all small coals would be washed and railway carriage on ashes saved.

Mr. Mountain's long experience in mining electrical engineering makes his extensive contribution to the discussion of the greatest value. I agree with all his remarks on boilers. The old fallacy of the reserve steam capacity of Lancashire boilers still deludes people into installing them where steam winders are used. The largest steam winder at present installed takes 800 lb. for one wind, and this weight of steam would hardly make a visible movement in the water gauges in the necessary bank of water-tube boilers. In comparing gas engines and gas-fired boilers, Mr. Mountain takes a boiler efficiency of 70 per cent only, whereas I take 82–85 per cent; otherwise our results are identical. For my comparative figures I refer him to Table 1. His tables giving generating costs under various conditions are interesting, but the size of units taken is very small compared with the power equipment of a modern group of collieries. The capital costs in Table A are very high, also the labour cost; gas at 6d. per 1 000 cubic ft., calorific value 450 B.Th.U. per cub. ft., is equivalent to coal of 12 500 B.Th.U. per lb. at 31s. per ton and is too high. A charge of 4d. would be more reasonable. The coal costs and labour charges in Tables B and C are again high owing to the small plant. Table D is based upon the assumption that low-pressure steam costs nothing, but I cannot agree to this assumption. I consider that the cost of steam to the high-pressure engine and the low-pressure turbine should be charged in proportion to the heat-drops in the two machines. This is normally 50 : 50. On this basis, taking the low-pressure steam consumptions of the mixed-pressure turbine as double that of the high-pressure turbine, the cost for steam would be the same for each machine. This would make the costs per unit of the mixed-pressure machine practically the same as those of the high-pressure

machine in Table B. The condition that the available low-pressure steam exactly corresponds to the load during working and night shifts is most unusual, and high-pressure steam is required to bridge gaps in the low-pressure steam supply. Mixed-pressure turbines are normally extravagant on high-pressure steam and, in my experience, units generated by mixed-pressure turbines cost more than those produced by high-pressure turbo units. Further, double quantities of steam require double the amount of condensing water, and this is usually a further objection to mixed-pressure turbines. Pages 534 and 535 and two of the lantern slides exhibited show that there are other losses in connection with steam-winder mixed-pressure turbine equipments and that where electric power is available at a moderate cost per unit, or can be produced for coal consumptions of less than 3½ lb. per unit, the complete electrification of winders, fans and all other machines is justified.

Mr. Routledge's remarks on the large gas engines (presumable for blast-furnace gas) and coal economy in the Midlands are interesting. In Table 1 interest is taken at 6 per cent, amortization at 15 years for plant, and 25 years for buildings, etc.

In reply to Mr. Bull, I have no figures for hand-fired Lancashire boilers but have burned coals down to 9 per cent volatile in pulverized-fuel equipments. The efficiencies were no better than those obtained by the sandwich method on a chain-grate stoker with balanced draught. I would refer Mr. Bull to the last paragraph on page 521 for a reply to his query in regard to high-pressure and high-temperature steam.

Switchgear.—Mr. Burgess and Capt. Mackintosh agree with my appreciation of compound-filled switchgear. I find, as they do, that it is just as easy to change a compound-filled transformer chamber as a set of current transformers in a cubicle, and in all other directions it is equally flexible. I strongly recommend its use in screening plant, owing to its immunity from dust troubles.

Winder switchgear.—Dr. Garrard, Messrs. Sparks, Mountain, Perry, Weir, Maclean and others are evidently in agreement with me in regard to winder reversing-switches. After one million operations of the compressed-air-operated air-break type, the contacts show only 7/1000 in. of wear, and the maintenance cost is nil.

In reply to Mr. Lloyd, my figure of £150 per annum refers to a number of oil-immersed reversing-switches, both hand- and contactor-operated, and is an average figure. Oil renewals alone on one contactor switch amounted to £10 per month. The air-break air-operated contactor is actually cheaper than an oil-immersed type of equal capacity, but takes up slightly more room.

In reply to Mr. Burgess, my experience of oil-immersed contactors covers the four principal makers and extends over 13 years. On a winder which makes or breaks a magnetizing current of 100 to 120 amperes at 3 300 volts 6 to 8 times a minute for 8 hours, the contactor must be examined daily and the oil changed at least once in four weeks. There is no difficulty in housing air-break contactors in the basement of an engine house in a suitable stone cell with interlocked doors. Air-break contactors are used on trains where the space is far more confined.

Power factor correction.—Mr. Routledge accuses me of dismissing the static condenser as hardly worth consideration. Far from it. I refer on page 522 to my contribution to the discussion on Kapp's paper where I recommend the static condenser for use in the very conditions he specifies and give an instance of the economies effected by the installation of a 235-kVA 3 300-volt three-phase 50-cycle condenser. His figures confirm mine.

Power utilization.—Messrs. Maclean, Routledge and Bull give comparative figures for the consumption of electricity per ton in various districts. I have collected these into Table M and have included those given in Tables 2 and 7.

TABLE M.

Units per ton raised.

District	Winder	Fan	Pit use	Pumping	Compressed air	Total
Table 2	4	3	1·5	3·5	20	32
Table 7	3·91	4	3·71	—	15·1	26·72
No. 1	3·88	3·04	1·71	1·01	16·57	26·21
No. 2	8·08	3·70	0·64	10·01	27·50	49·93
North-East Coast—						
No. 1	2·23	1·27	3·66	1·00	—	8·16
No. 2	1·32	2·07	2·88	1·41	—	7·68
No. 3	1·99	2·47	1·33	1·11	—	6·9
No. 4	3·21	4·27	8·88	5·14	—	21·5
Midlands and Yorkshire ..	—	2·72	4·15	0·21	—	7·08
Lancashire	—	6·0	7·0	—	12·0	25·0

In the case of the North-East Coast, Nos. 1, 2 and 4, the units for pit use include the power used for compressed-air production. General pit use in the South Wales table does not include a washery, coal-cutters or conveyers. The Midlands appear to be fortunate in having a very low pumping load. No. 1 colliery is an old one in which a portion of the conveying and cutting

is done by compressed air. The depth is moderate and there are a number of horses underground. No. 2 colliery is a deep colliery in which the whole of the output is conveyed by compressed-air-driven conveyers and there are no horses underground. Mr. Routledge's figures form a very interesting comparison with Tables 2 and 7. Ventilation is naturally a heavier load in the gassy South Wales seams in the proportion given, i.e. 4 to 2·72 units. The figure of 4·75 per cent of coal consumption in Table 5 includes steam engines, fan engines, compressors and mixed-pressure turbine. The figure for winders and mixed-pressure turbine alone is 2·48 per cent, whilst for winders, mixed-pressure turbine and fan engine it is 3·15 per cent, which is probably better than his figure of 3·5 per cent, owing to the higher boiler efficiency. The calorific value of the fuel varies from 12 000 to 13 000 B.Th.U. per lb.

In reply to Mr. Bull, the winder in Table 2 is Ward-Leonard controlled, as this is a necessity for an output of 300 tons per hour from a depth of 700 yards.

Pumping and pump motors.—In reply to Mr. Routledge, I have a number of motors running with Boucherot rotors up to 150 h.p. at 1 500 r.p.m. They take about $1\frac{1}{2}$ times full-load current to start against normal turbine pump torque and run up to speed very smoothly.

Fans.—In reply to Mr. Juhlin, I suggest the possibility of the use of a clutch for fans or compressors but do not advocate its use. I agree that the synchronous induction motor is the most suitable for fan drives and have installed over 20 in the last two years.

Mr. Jones refers to Williams-Janney gear. I think it is quite unnecessary for fan drives, as all requirements are met by single-speed or two-speed motors with 15–20 per cent higher efficiency, but there is a limited field for its use in haulages and small winders.

Mr. Bull requires a three-speed fan motor. This would mean some sacrifice in efficiency and reliability.

In reply to Mr. Routledge, the figures for American fans starting with drift doors closed are only of use to show what can be done by co-operation, but in this country such tests are improbable for the reason he states.

Fans; Lenix drive.—In reply to Mr. Mountain, the Lenix drive is more efficient than a rope drive, takes half the space and has a range of speed up to 12/1. The maximum power transmitted by the Lenix drives shown in the lantern slides is 600 h.p. at 120 r.p.m. at the fan shaft.

Fans; special salient-pole high-starting-torque motors.—Mr. Jack and Mr. Mann are correct. The type of motor in Fig. 2 is expensive and unnecessary. All requirements can be met by the induction or salient-pole types. I agree that it is better to synchronize (i.e. close the field switch) on salient-pole machines on the tap voltage, as this reduces the current carried and broken by the switch contacts to a very low value (at unity power factor) with correspondingly increased life. If Mr. Mann will examine Fig. 1 he will find that the horse-power is given clearly in the diagram on the bottom line. This diagram refers to a synchronous induction motor. The voltage of excitation of the salient-pole motors is 110 volts.

Fans; comparison of steam and electric drive.—Mr. Mountain's figures for steam-driven and electrically-driven fans can be compared directly with Table 8 of the paper, as the fans are identical in size. My figures are actual results of several years' operation. He does not debit the electrical equipment with any capital charges. In Table 8 the actual costs for motor starter and Lenix drive were £1 400, giving a yearly charge of £175. No spare boiler plant is allowed in his steam equipment. This would add considerably to his capital costs. The actual steam equipment in Table 8 consisted of two Babcock boilers and a low-speed drop-valve rope-drive engine. The coal consumption was 6 500 tons per annum. At Mr. Mountain's figure of 12s. per ton, as taken in his power cost tables, this amounts to £3 900 per annum. Maintenance, capital and other charges amount to £1 600 per annum, making a total of £5 500 per annum. For the same quantity and water gauge the units consumed by the same fan electrically driven were 2 100 000 per annum. Deducting the capital charges for the electrical equipment, £175, from the total cost for the steam fan, £5 500, leaves a yearly charge of £5 325 for the electrical units, or a permissible charge of 0·6d. per unit.

A fan, being a 100 per cent load factor load, is very desirable, and, when added to the other electrical loads, has a great effect on the colliery load factor. Taking Mr. Mountain's own figures in Table B, a normal load factor for other loads at a colliery would be 30 per cent, excluding compressed air, or, in Table B, 2 600 000 units per annum. Adding the above fan load of 2 100 000 units gives 4 700 000 units, improving the colliery load factor to 53 per cent and reducing the unit cost from 0·653d. to 0·47d. Further, the fan drive is, as shown elsewhere, particularly suited for a synchronous motor or other power-factor-improving drive and, in my opinion, should be one of the first machines electrically driven.

Compressors and compressed-air transmission.—Mr. Sparks, Mr. Johnson and others refer to the efficiency figures given for compression and transmission of air for use underground and suggest that these figures are misleading. I assumed that it was general knowledge that compressed-air engines without interheating can only recover from 20 to 25 per cent, and with interheating 30 to 35 per cent, of the energy used in compressing the air. Therefore compressed air will only be used where it is inadvisable to use electricity. Progress in mining methods and improved ventilation will open up more places where electricity is permissible, and we must put up with the inefficient but otherwise satisfactory air engine while we make our air-compressing and transmission plant as efficient as possible.

In reply to Mr. Harvey, Mr. Wood and others, comparative efficiencies for compressed-air production and transmission were given to the pit-head only. At this point the equipment usually passes out of the hands of the electrical engineer. Leakages below ground are seldom less than 15 per cent and often more than 50 per cent of the total volume. Part of this is used for ventilation.

Mining electrical engineers are aware that with reasonable precautions and properly designed apparatus it is safe to use electrical machinery underground, but under the Coal Mines Act it must be shut down when gas is present, whereas compressed-air machinery can continue to operate and its exhaust

helps to purify the working place. Leakage underground is a bugbear, but careful attention to the total consumption of a colliery, combined with week-end pressure-drop tests, can keep the engineer informed of the extent of the leakage. I agree with Mr. Burgess as to the absolute necessity of care in maintenance, even when the most adequate apparatus is installed.

I do not agree with Mr. Johnson that it has long been appreciated that air transmission is more efficient than electrical transmission over short distances. Eminent mining and electrical engineers, including a number of contributors to this discussion, have been surprised at the efficiency achieved in compressed-air transmission.

Mr. Mountain appreciates what many other speakers have not done, viz. that compressed-air power is a necessity in certain places. The efficiency figures given on page 524 refer to a Bellis and Morcom compressor and I endorse Mr. Mountain's appreciation of these machines. Wear and tear of all parts of inbye compressors is excessive and they are not to be recommended. Further, their diversity factor cannot compare with that of surface or central-station machines. Mr. Mountain suggests that the makers should be consulted with regard to the type of unloading device to suit the motor. When this was done in 1919 they all required 100 per cent starting torque. The experiment referred to on page 523 was made as a result. Mr. Mountain overlooks the fact that salient-pole synchronous motors not only improve power factor but at unity power factor are at least 2 per cent more efficient at full load and 20–25 per cent more at light loads than induction motors. My remarks on fan drives apply equally to Mr. Mountain's figures for compressor drives.

In reply to Mr. Bull, the comparison of the two types of compressors is taken at full output in each case. The running cost of the electrically-driven sets is about 10 per cent higher than that of the steam turbo type and pipe line, owing to the higher efficiency and lower maintenance cost of the latter. No difficulties result from the practice of running one steam turbo-compressor for 7 hours per day. A number of other turbines have to be run during the working shift period only.

Both B.T.H. and Kent indicating and recording air meters have been in use for some years with satisfactory results. Siemens-Halske meters are also used; these have an electrical recording device. Water traps are used in low places on the air mains, and no trouble has been experienced due to water or expansion, though very few expansion joints are fitted.

In reply to Capt. Mackintosh, the figures on page 524 show the superior efficiency of steam-driven turbo-compressors of large size over electrically-driven sets, but the group of collieries cited have over 12 000 h.p. of electrically-driven compressors (mostly with synchronous motors) for the very purpose which Capt. Mackintosh suggests, i.e. to balance the load between the electrical and air systems and to improve the power factor generally.

Mr. Simon suggests that if electric power were used instead of compressed air the average figure given in Table 2 would be reduced from 20 units to 6–7 units. I would go further and say 4–5 units.

Compressor drives.—Mr. Johnson and Mr. Juhlin doubt the comparative efficiencies given for salient-pole and induction type synchronous motors. The efficiencies are test-figures of two machines of the same horse-power and speed at unity power factor, each by the maker who most strongly advocates the competing type. They are directly coupled to compressors. The salient-pole machine has given no trouble, but the induction type machine has been shut down with various troubles for 25 per cent of its time. I do not agree that a difference of only ½ to 1 per cent is usual, and I would refer Mr. Johnson to my contribution to the discussion on Carr's and Kapp's papers referred to on page 522.

Mr. Routledge's figures for the relative costs and efficiencies of synchronous induction and salient-pole motors do not agree with mine, which are for larger lower-speed machines, necessitating a double winding on the induction-motor rotor. Corresponding figures of machines of the size he gives, obtained two years ago, were, at unity power factor :—

Induction motor	Synchronous induction motor	Salient-pole motor
92·5	93	94·5

Compressor drives; auto-starters.—Mr. Juhlin and Capt. Mackintosh appear to think that I am prejudiced against auto-starters. After several years' trouble with the starting apparatus on two 1 000-h.p. 1 500-r.p.m. squirrel-cage pump motors, these were altered to slip-ring machines and there has been very little further trouble. With regard to the 1 125-h.p. salient-pole machines, I would refer Mr. Juhlin to page 524 where it is specifically stated that the chief trouble lay in the auto-transformer. Three different makes have given trouble, so it is not confined to any specific design.

In reply to Mr. Routledge, no special effort has been made to reduce the starting peaks on compressor motors; the oscillographs were taken and other tests made with the object of eliminating breakdowns in the starting gear.

Mr. Harvey's suggestion of a number of stops for auto-transformers would not prevent the troubles on the smaller sizes, which are principally due to sheer abuse. For large machines the ideal starter would be an induction transformer with a short-circuiting switch.

Electric winders.—Mr. Horsley and Mr. Mann refer to automatic control. Two of the a.c. winders illustrated in the lantern slides have electrically-operated control of the type they refer to, but I prefer the well-tried Whitmore or profile mechanical device. Either of these gives continuous control of speed throughout the wind, and sensitive overspeed setting. In addition, I fit overwind switches in the headgear in case of failure of the speed-control drive, as in the recent Cwm Colliery accident. The brake application should be graduated during the high-speed portion of the wind, but instantaneous in case of overwind. I do not see any reason why future electric winding plants may not be fully automatic, combined with automatic decking under the control of one man in an enclosed cabin at the pit-head. I have not tried full automatic control on a Ward-Leonard winder. The spring connection in the cam gear allows sufficient movement to produce full torque at "dead" low speed.

Mr. Mountain still appears to be doubtful about the advisability of electric winding. I agree that his conclusions Nos. 1 and 2 of 20 years ago still hold, but there is very little coal available to-day of a lower value than 12s. per ton. His conclusion No. 3 must be modified in view of the enormous increase of the colliery loads other than winding. In Table 2 the winder units are only 12 per cent of the total loads, and even the peaks do not exceed 25 per cent of the average load. His conclusion No. 4 is true of isolated collieries, but if by joint ownership or co-operation a group of collieries can run a large central station or stations, interlinked with waste-heat stations, then a supply company can only compete by virtue of its greater diversity factor. Another factor which tells greatly in favour of centralized power supply and complete electrification is the increased cost and decreased output of labour. Small steam plants are notoriously extravagant of labour, and the costs of this item are seldom given proper consideration in comparative estimates.

In spite of Mr. Mountain's statement with regard to the standard practice of installing steam winders and mixed-pressure turbines in the Doncaster district, no less than five large electric winders have been installed there and three more are on order in the last two years. Further, no steam winder in the country has an output or efficiency equal to that of the Ward-Leonard set described on page 531, i.e. 525 tons per hour from a depth of 650 yards with an efficiency of 64 per cent. This rather disqualifies his statement that electric winders are only suitable for small outputs. I can assure Mr. Mountain that the unit costs in the stations to which I refer are such as to justify considerable capital expenditure in electrifying winders, fans and compressors. A small proportion of these units is generated by waste heat, i.e. gas engines or mixed-pressure turbines. The units generated by mixed-pressure turbo-alternators (which are properly charged with the cost of heat units in the steam supplied to them) cost considerably more than those generated by modern high-pressure turbo-alternators.

Mr. Perry does not agree with my conclusion that it is better to spend money in increasing the generating plant and transmission system than to install flywheels. He speaks from the manufacturers' point of view. My conclusion is based upon several years' operation of a system having nearly 40 large electric winders connected to it, including the two largest flywheel winding sets, the two largest Ward-Leonard sets and the two largest a.c. winder sets in this country. The peak loads which cause the most disturbance in the system are those from the flywheel sets. Referring to Table 4, although the Ward-Leonard output is 12½ per cent higher, its peak load is only 5 per cent higher, due to the very much higher overall efficiency. The assumption that the introduction of a flywheel produces a uniform load demand is never borne out in practice, even when working at full schedule output. Large winders have peaks extending over periods of 15 to 26 seconds, and for complete equalization the flywheel must give out 25 000 to 35 000 kW-seconds (a very different quantity of energy from that required in rolling-mill Ilgner sets). Speed is regained during the braking and banking periods, which may be 30 to 40 seconds. The result is that energy is imparted to the flywheel at low efficiencies of the driving induction motor. Further, the usual slip regulation of 10–15 per cent reduces the motor efficiency during the peak-load period by a corresponding amount. Even without a flywheel the light-load losses of an induction-motor-driven set are 50 per cent higher than those of a synchronous motor at unity power factor, and with a flywheel 100 per cent higher. The extra cost of a 30-ton flywheel complete with shaft, bearings, etc., is about £5 000. The extra cost of generating plant to carry the Ward-Leonard peak would be £2 000 if the actual peak kW were charged for, or nothing if R.M.S. kW were taken. Flywheels are useful for dealing with peak loads of ½ to 2 seconds' duration, but I am of the opinion that peaks of 15 to 25 seconds are better transmitted to the generating plant and thence to the boilers. Mr. Perry advances the Stubbs-Perry scheme as a solution of heavy winding problems, even for a group of collieries. As only one Stubbs-Perry equipment is in operation at the moment and the second set has been ordered with an induction motor as an auxiliary drive to save power in the non-coal-winding shift, I do not propose to discuss the system at the present time but await with interest the operating results. The figure given for the direct-coupled d.c. winder motor on page 529 is the average test figure of several motors of similar output and speed.

Capt. Mackintosh's objections to the Ward-Leonard winders (apparently including a flywheel) that they must be unreliable because of the "number of links in the chain" is not borne out by practice. In 13 years' operation there have only been three stoppages exceeding 15 minutes on two large Ilgner sets. Owing to the arrangement of motors and generators in pairs only one of these stoppages (a fire in the engine room) shut down a winder completely. My experience is that an electric winder is more reliable than a steam winder.

In reply to Mr. Johnson, the actual kW absorbed by a 12 ft. 6 in. diameter 30-ton flywheel running at 485 r.p.m. is about 35. This can be reduced by 50 per cent by the methods Mr. Johnson suggests, but the vacuum-producing apparatus will absorb a portion of this saving.

Mr. Burns and Mr. Mann favour a.c. winders for all purposes. I have found in every case that the consumption per ton for a.c. winders is higher than the calculated figure, more particularly in large equipments dealing with peaks of 2 500 to 3 000 h.p. Loads vary greatly; a tub of rubbish may weigh 75 per cent more than a tub of coal, and Fig. 10 shows what happens with only 12½ per cent variation of load. Their remarks are based upon experience of winders of much smaller size, i.e. 200–500 h.p. and more uniform loads. My conclusions are based upon a very large number of winders in all parts of this country and abroad, and on direct observation of nearly 40 winders of sizes varying from 100 h.p. upwards. Some of these have been in operation for 20 years. This paper refers only to larger machines which I considered would be of greater interest, and more particularly to those with novel features such as the synchronous-motor-driven Ward-Leonard sets or the compressed-air-operated air-break contactors.

The Stjernberg formula or the alternative Table 3 can only be used as a preliminary guide. Up to 500 h.p. (R.M.S.) only exceptional circumstances should necessitate Ward-Leonard; above 1 500 h.p. an a.c. winder is possible on only few systems. The total cost per ton raised is the final factor.

Mr. Mann does not think reverse-current breaking necessary. If he works with Stjernberg coefficients of 0·3 and upwards he will find it an absolute necessity on equipments of 750 h.p. and upwards.

Mr. Burns replies to Mr. Pryce-Jones's query that the Harworth-Stubbs-Perry equipment might have had a.c. control without apparently altering the efficiency.

With regard to the second Stubbs-Perry equipment, out of Mr. Mann's lengthy explanation the fact which I stated emerges, viz. that an induction motor is included with this set to run the motor-generator for light-load winding or occasional trips.

Mr. Mann's analysis of Table 4 overlooks the fact that in the synchronous-motor-driven Ward-Leonard set voltage-drops due to peaks can be corrected by varying the power factor of the load demand. Provision is made for this automatically in my patented device. He further states that a system that can carry a 3 250-h.p. motor can carry a peak of 4 000 h.p. Surely it can also carry a peak of 4 500 h.p., and a flywheel is unnecessary on the Ilgner set.

I have nothing to add to my remarks on tail ropes. I appreciate their advantages and would install them if the mining engineers would accept them.

Mr. Mann's remarks on pot and weir type controllers are very gratifying to one who has for many years favoured the pot type in spite of strong opposition. The two largest a.c. winders in this country have pot-type controllers and air-break contactors and have been running for three years without a hitch.

Mr. Weir questions my figures on the comparative costs of Ward-Leonard and a.c. winders, and Mr. Routledge also questions my figures on geared and ungeared Ward-Leonard main motors. My comparison is based upon a number of actual installations and I cannot agree that a complete Ward-Leonard set costs 75 per cent more than a geared a.c. set.

Here are comparative figures :—

	A.C.	Ward-Leonard	Geared Ward-Leonard
Mechanical parts	67·7	48	67
Electrical parts, including cables	32·3	87	70
	100	135	137

My comparison is made with a single main motor in each case but duplicate generators on the Ward-Leonard motor-generator set.

With reference to Mr. Routledge's comparison of geared and direct-coupled winder motors, taking his ratios and analysing them mathematically on the basis of the proportional costs of electric and mechanical equipment from some 30 tenders, the results are as follows :—

	Single motor	Double motor
	Per cent	Per cent
Percentage value of whole cost, electrical and mechanical gear, of main motor	32	37
Percentage of value of winding portion only, mechanical and electrical	47·8	54·3

From this it would appear that in the case of the double-motor equipment the price of the high-speed electric motors would have to be less than one-third of the price of the low-speed motors, and in the case of the single-motor equipment less than one-fifth. These are impossible values. He must have compared a very expensive type of low-speed motor with a very cheap high-speed motor. It will be seen from the average of a number of tenders that the geared Ward-Leonard equipment was slightly more expensive than the direct-coupled set. I adhere to my opinion that a direct-coupled motor, of equal efficiency, is worth 20 per cent more than a high-speed motor and gearing, and I have not yet been offered a high-speed equipment 10 per cent cheaper than a direct-coupled set. I cannot follow Mr. Routledge's statement with regard to relative efficiencies, as the geared and direct-coupled equipments are exactly equal in efficiency at 105 per cent full load, and the direct-coupled machine has a higher efficiency at all lower loads and a slightly lower efficiency at the higher loads. For the normal winding schedule the efficiencies are practically identical. Again, in comparing the steam consumption of the Harworth flywheel set with that of the Britannia equipment, he has apparently taken the input on light load for the Britannia set and increased it for comparison with the Harworth set in the ratio of the flywheel stored energy. As the actual losses in the flywheel amount to only 35 kW, as will be seen from Table 4 by comparing the third and fourth figures in col. 2, this is hardly fair. A more correct estimate would be as follows: The stored energy of the flywheel is 70 million ft.-lb. and not 55 million as he takes. The light-load losses of the modern 3 200-volt Ilgner set without flywheel are 115 kW, and with flywheel, increasing in the proportion of 70 to 80 million, 156 kW. Losses in transmission are considerably under 5 per cent, as this set is within a mile of the principal power house. Taking the steam consumption per kW which he uses, the actual light-load consumption of this set would be 2 300 lb. per hour, against the Harworth consumption of 3 650 lb. per hour, or 37 per cent lower instead of 26 per cent higher as he states. With a modern Ward-Leonard equipment still more favourable results would be obtained. I do not think that the time is opportune

to discuss the merits of the Stubbs-Perry scheme; this should be postponed for a couple of years, when experience of the actual operating results will be available.

In reply to Mr. Bull, owing to the more uniform speed of the synchronous-motor-driven Ward-Leonard set, control is more definite as compared with that on the Ilgner set, which has a 15 per cent speed-drop.

In reply to Mr. Ashley, the usual power factor of large geared winder motors at full speed is 0·80 to 0·84. A direct-coupled a.c. motor running at 72 r.p.m., under my control, has a power factor of 0·55 at full load. Another of 60 r.p.m. in the South Wales district on a 25-cycle circuit has a power factor of 0·6–0·65.

Mr. Routledge confirms the economy of electric winders as compared with steam winders and mixed-pressure turbines for the 7-hour shift. Where two-shift or even three-shift operation is the custom, as in parts of the Doncaster field, the light-load losses for the steam equipment have less effect and the economy of the electric winder is not so marked, but out of several hundred equipments which I have calculated I have not found a single instance where the steam-winder mixed-pressure turbine equipment is more efficient than the electric equipment, and the operating costs of two collieries almost identical in every respect from the point of view of depth, output and class of coal, one with steam winders and the other an all-electric equipment, show that the electric equipment there effects a very appreciable economy. Anyone who has seen a large steam winder and a large electric winder in operation cannot but be struck by the smooth and simple operation of the electric equipment as compared with that of the steam equipment.

In reply to Mr. Hollingsworth, the capital cost of a completely electrified colliery, together with its proportion of a centralized power scheme, is less than that of a steam-winder mixed-pressure equipment complete with boilers, plant, etc., and, as the figures given show, the operating costs are considerably less. The difference in the light-load losses of the synchronous motor and the plain induction motor for winder motor-generator sets is purely a question of light-load losses. The magnetizing current is practically constant in the induction motor, with resulting high core loss and appreciable stator copper loss at light loads. The synchronous motor runs at unity power factor with minimum excitation low core loss and stator and rotor copper losses. For the same shaft horse-power the induction-motor consumption is nearly twice that of the synchronous motor.

Comparison of steam and electrical collieries.—Mr. Wood supports his partner Mr. Mountain in his championship of the steam-winder mixed-pressure turbine equipment for collieries. He takes *some* of the figures given in Table 5 of the paper and presents a case for a steam-winder mixed-pressure turbine equipment. If this is typical of the methods employed for calculating the coal consumption of collieries, then it is not surprising that colliery owners still install steam winders in spite of the proved greater efficiency of the all-electric equipment. His figure of 3 lb. per unit does not agree with that given in the Electricity Commissioners' Report for the year ending March 1924. Excluding group A, groups B and C, consisting of 36 stations of 200 to 50 million units per annum, have an average consumption of 2·33 lb. per unit generated, but I will take his figure of 2·75 lb. to avoid controversy. He takes a 42-hour week, omitting the men-winding periods, the afternoon and evening shifts and

	Mr. Wood's figures	Actual running figures
H.P. and L.P. steam per hour passed through M.P. turbine, lb.	58 000	58 000
Boiler auxiliaries, condensation, blow-downs, steam blowers, etc., average per hour, lb. ..	—	12 600
Total for 6 coal-winding shifts in one week, 42 hours, lb. ..	2 430 000	2 960 000
Average steam evaporated during afternoon and night shifts, including boiler auxiliaries, etc., per hour, 15 700 lb. over 102 hours	—	1 600 000
Sunday evaporation, M.P. turbine not running	—	380 000
Total steam evaporated by boilers in week of 168 hours, lb.	2 430 000	4 940 000
Coal consumption per week at 7·12 lb. per lb. of coal, lb.	342 000	694 000
tons	152·5	310
Alternative consumption for electric winders, etc.		
Electric winder units	52 500	52 500
Extra units owing to shut-down of M.P. turbine	78 850	78 850
Total additional units required	131 350	131 350
Coal at 2·75 lb. per unit, lb.	362 000	362 000
tons	161·5	161·5
Mr. Wood's calculated extra coal for electric winder proposition .. .. .. tons	9·0	—
Actual reduction in coal consumption by installing electric winders .. .. tons	—	149·5

occasional winds. He also omits all reference to boiler auxiliaries, blow-downs, condensation, etc. I repeat the actual figures already given on pages 534, 535 and 536 compared with Mr. Wood's estimated figures, including the items that he has overlooked and correcting one or two of his small errors. The average boiler efficiency was 74–75 per cent, giving an evaporation of

7·12 lb. per lb. of coal. Babcock boilers with chain-grate stokers and induced draught were used. The winding engines and mixed-pressure turbine were modern engines of the highest class.

That is, instead of an increased consumption of coal of 9 tons (corrected from 12½) as calculated by Mr. Wood, there will be a reduction of 149·5 tons per week based on the present actual coal consumption and the electrical consumption of the winding engines of similar collieries, i.e. 2·46 units per ton net or 4·2 units per ton gross.

In reply to Mr. Harvey, I agree that the choice of the most efficient and suitable winding equipment is a matter for experts. Tables 2, 5, 6, 7 and 8 can be completed by taking a coal consumption per unit to suit the size and load factor of the plant under consideration.

Miscellaneous.—Mr. Sparks and Mr. Sack consider that I have ignored lighting. Professor Thornton last year read a paper * devoted principally to this subject, but we still await the transformers to give the 150 cycles which he advocated. As the power taken for lighting is only ½ of 1 per cent of the total power produced, it is not of great importance in the general scheme of "Electricity in Mines." Further, the same objections are raised to electricity for lighting as for power in certain places. Lighting at the pit bottom and wherever possible has greatly improved in recent years, particularly in regard to the wiring and type of fittings. Miners' lamp bulbs are not so very inefficient as Mr. Sack suggests; 1·5 to 1·8 watts per candle is usual. I agree that 2 volts is too low, as contact and other resistances absorb too high a proportion. A 4-volt lamp is now on the market. Miners' nystagmus has not been finally proved to be entirely due to inadequate illumination. One school of thought attributes it to gases occluded from the coal. Again, replying to Mr. Sack, more than 75 per cent of the compressed air produced is utilized by the actual coal-getter in cutting and conveying.

* *Journal I.E.E.*, 1924, vol. 62, p. 481.

In reply to Mr. Simon, a very large proportion of the underground haulages in South Wales are electrically driven, but the load factor of haulages is very low, varying from 3 to 5, and the proportion of total power taken barely 2½ per cent. I agree that contactor-type reversing-switches reduce the labour of operation considerably, and I have introduced them in several heavy-duty haulages.

Mr. Hodge raises a number of questions. With regard to shaft cables, British-made paper-insulated cables seldom give any trouble. I have not had a 3 300-volt shaft cable fail for many years. Where roof-falls are frequent, double-wire armouring and either steel piping or double D troughing are necessary. Progress in design and improvements in ventilation and other mining methods will eventually allow electricity to be used in every part of the mine.

Mr. Phillips compares the conservatism of the Midlands and South Wales. At present the combined objections of the mines inspectors, colliery managers and miners prevent the extensive introduction of electric mining in the steam-coal measures in South Wales, but electricity is used at the face in house-coal and anthracite collieries. It appears that a similar prejudice exists against electric winding in the Midlands. This prejudice is supported by the absence of any large public supply company or any attempt to group collieries, and also by the fact that accurate records of the steam and coal consumption of steam-winder mixed-pressure equipments are rarely available. A grouping scheme is now in progress, so that electric winding may now have a chance to develop.

Mr. Sparks and Mr. Harvey refer to the importance of reliability in mining plant. The minimum-wage operation is another factor which makes it of the greatest importance. Efficiency is of no value if it is obtained at the expense of reliability.

REPORT OF THE COUNCIL FOR THE YEAR 1924–1925, PRESENTED AT THE ANNUAL GENERAL MEETING OF 7 MAY, 1925.

CONTENTS.

REPORT.

The Council, at the Fifty-third Annual General Meeting of the Institution of Electrical Engineers, present to the members their Report for the year 1924–25, covering approximately the period from 1st April, 1924, to 31st March, 1925, and, in doing so, desire to put on record their gratification at the continued progress and prosperity of the Institution, and also to thank the many members who have so freely placed their services and knowledge at its disposal.

(1) Membership of the Institution.

The changes in the membership since the 1st April, 1924, are shown in a table given in Appendix A.

The following table shows the growth of membership for the last few years:—

Year	Membership	Increase or decrease
1915	6 811	− 234
1916	6 676	− 135
1917	6 613	− 63
1918	6 667	+ 54
1919	7 023	+ 356
1920	8 146	+ 1 123
1921	9 449	+ 1 303
1922	10 275	+ 826
1923	10 911	+ 636
1924	11 415	+ 504
1925	11 743	+ 328

The membership of the Institution still shows an increase which, although much smaller than those of the years immediately following the war, is very satisfactory.

(2) "Chartered Electrical Engineer."

The Council think it useful to include in this Report the contents of a letter which was despatched to all Members and Associate Members on the 5th May, 1924.

Under Bye-law No. 9, which has received the sanction of the Privy Council, every Member and Associate Member of the Institution is entitled to describe himself as a "Chartered Electrical Engineer."

The privilege is one which attaches to the individual member, and if that is borne in mind, little difficulty will arise in making a legitimate use of the title. For example, when the names of all the members of a firm are printed separately on the letter paper of the firm, it would be appropriate that those of them who are Members or Associate Members of the Institution should have the qualification "M.I.E.E." or "A.M.I.E.E." added to their names, followed by the title "Chartered Electrical Engineer." But this should be done in such a way as to make it quite clear that the title applies

individually to certain members of the firm and not to the firm itself.

Similarly, those directors of a company who are Members or Associate Members of the Institution may legitimately make the same individual use of the title "Chartered Electrical Engineer."

The privilege being an individual one, a Member or Associate Member of the Institution should not append the title "Chartered Electrical Engineer" to his signature when he signs a letter or other document on behalf of his firm or company.

A Committee, presided over by the President, has been appointed by the Council to deal with any cases of doubt or difficulty which may arise in connection with the use of the above designation, and all such cases should be referred to the Secretary, who will bring the matter before the Committee for their decision.

The Council feel confident that they will receive the support of the members in preserving the strict use of a title which carries with it an honourable distinction.

(3) Unauthorized Use of the Letters "A.M.I.E.E."

It recently came to the knowledge of Mr. J. Orchiston, the Local Honorary Secretary and Treasurer of the Institution for New Zealand, that a person in that Dominion was falsely representing himself as being a member of the Institution and using the letters A.M.I.E.E. Legal proceedings having been taken, a conviction was secured and the offender was fined £5. The Council have expressed to Mr. Orchiston their appreciation of his action in the matter.

(4) Members Practising as Consultants.

The attention of the Council was recently drawn to an advertisement of a Local Authority in which Chartered Electrical Engineers were invited to submit, in competition with each other, their terms for professional advisory work.

In the opinion of the Council such a proceeding is undesirable and not in the best interests of Local Authorities requiring advice. The Council would consider it to be a breach of professional etiquette for a member of the Institution to reply to such an advertisement.

Where the names of a sufficient number of qualified consultants are not known to a Local Authority, the President of the Institution will always be willing to submit the names of qualified electrical engineers for the purpose.

A statement to the above effect appeared in the issue of the *Journal* for January 1925 (p. 153).

(5) Mascart Medal.

In April 1924 the Council received an intimation from the Société Française des Electriciens to the effect that the Society had founded a Medal of Honour to be called the Mascart Medal, in memory of that eminent French scientist, the Medal to be awarded triennially to scientists or engineers distinguished for their work in pure and applied electricity, whatever their nationality.

The Society also intimated that the first (1924) award of the Medal had unanimously been made to Monsieur A. Blondel, and requested that members of the Institution be informed of the founding of the Medal and of its award to Monsieur Blondel.

(6) Examinations.

The Associate Membership Examination was held in April and October, 1924, in London, Belfast, Birmingham, Cardiff, Glasgow, Manchester and Newcastle-on-Tyne, and also in Spain, New Zealand, South Africa and the Argentine. The candidates examined included a number of officers of the Corps of Royal Engineers, who sat for the examination for the purpose of qualifying for "Engineer Pay."

For the purpose of qualifying for "Signal Pay," officers of the Royal Corps of Signals were also examined by the Institution in the "Theory of Electrical Military Signalling" at the Signal Service Training Centre, Maresfield Park Camp, Sussex, in August 1924 and February 1925.

A certain number of candidates submitted theses and papers during the year in lieu of the Examination.

(7) Honorary Members.

The Council have pleasure in recording that, as announced at the Ordinary Meeting on the 6th November, 1924, they have elected Sir Oliver Lodge, D.Sc., F.R.S., to be an Honorary Member of the Institution.

Sir Oliver Lodge became a Member of the Institution in 1889 and was Chairman of the Birmingham Local Section in 1901–2, and Vice-President of the Institution in 1902–4.

There are now ten Honorary Members.

(8) Honours and Distinctions Conferred on Members.

Knighthood.

Longbottom, B. (Member).

C.M.G.

im Thurn, J. K., Capt. R.N. (Member).

(9) Faraday Medal.

The fourth award of the Faraday Medal has been made by the Council to Sir J. J. Thomson, M.A., O.M., F.R.S., Honorary Member.

(10) War Memorial.

The War Memorial Book containing the biographical notices of the 162 members of the Institution who fell in the war of 1914–1919 was published in April 1925, and copies have been presented on behalf of the subscribers to the War Memorial Fund to the nearest relative of each fallen member. It is a large post-folio volume ($15\frac{1}{2}$ in. × 10 in.) bound in special buckram, and contains 345 pages of letterpress set in twelve-point old-style type and 159 portraits.

The biographical notices are preceded by a historical introduction entitled "The Origin and Causes of the Great War, 1914–1919," written by the editor of the Book, Lieut.-Col. W. A. J. O'Meara, C.M.G., R.E. General Service maps of the battle fronts mentioned in the book are included in a pocket at the end of the volume.

Additional copies of the book have been printed,

which will be on sale to members and the public at the price of £2 2s. each, and the proceeds will go to the War Memorial Fund. A specimen copy can be seen in the Library.

The Council again desire to take this opportunity of expressing their appreciation of the very thorough and able manner in which Colonel O'Meara has edited the volume.

(11) Deaths.

The Council regret to have to record the death of the following 68 members of the Institution during the year :—

Honorary Member.

Heaviside, O., F.R.S.

Members.

Awoki, D.
Bainton, J. R.
Bastian, C. O.
Bhering, F.
Birks, L.
Bonnor, G. F.
Bradfield, W. W., C.B.E.
Brown, C. E. L.
Cappel, Sir A. J. L., K.C.I.E.
Carr, Col. G. A., R.E.
Cook, D.
Hayward, R. F.
Hunter, W. D.
Jensen, J. L. W. V.
Langdon-Davies, W.
Madgen, W. L.
Markby, W.
Martin, T. C.
Oi, S.
Pletts, J. St. Vincent.
Robertson, W. S.
Sullivan, H. W.
Tamaki, B.
Tasker, W. H.
Thompson, P. S.
Walmsley, Prof. R. M., D.Sc., F.R.S.E.
Wordingham, C. H., C.B.E.

Associate Members.

Balsillie, J. G.
Bedford, A. L.
Bowman, H. M.
Brander, G.
Bullock, H. J.
Canning, R. W.
Chamen, A. D.
Conning, W. D.
Cooke, R. R.
Dearling, G. S.
Dutta, S. K.
Farrar, R. R.
Fleming, G.
Forder, E.
Gill, R. F. H.
Gordon-Campbell, W. F.
Hale, C. P.
Hedley, E.
McMorrough, F.
Richardson, O. A.
Robertson, J.
Robinson, W. M.
Rorke, Major A., M.C., R.E.
Sergent, R. S. B.
Toppin, W. A.
Utting, Major S.
Woodfin, N. C.

Graduates.

Crook, E. R.
Gerry, L. F.
Todd, W. M.

Students.

Gibb, C. J.
Grute, L. H.
Mitton, A. R. D.
Nisbet, C.
Slattery, L.

Associates.

Cuff, J. C.
Drummond, Sir H. H. J. W., Bart., Brig.-Gen., C.M.G.
Moulsdale, W. E.
Ogilvie, Sir A. M. J., Colonel, K.B.E., C.B., V.D., R.E.(T.).
Powles, W.

(12) Institution Building.

A very large number of kindred societies have continued to hold their meetings in the Institution building during the past twelve months and it has been a pleasure to the Council to have been able to grant the use of the premises for this purpose.

(13) Papers.

For the information of members and to remove any possible misapprehension, the Council think it desirable to include in this Report an outline of the procedure followed in connection with papers.

The final decision in regard to the acceptance or rejection of a paper lies in the hands of the Papers Committee, which consists of the eight Chairmen of the Local Centres and seven other Members of Council. Each paper received is submitted to two or more referees, and care is taken in selecting these referees that they should be in a position to consider the subject matter of any particular paper from the point of view of the general body of members rather than from a highly specialized aspect.

These referees do not see each other's reports, but their reports, together with the paper, are submitted to a member of the Papers Committee, who at the beginning of the session is selected to be the Committee Referee for all papers falling under the particular subject allotted to him. The Committee Referee next reports to the Papers Committee, which comes to a final decision after consideration of all the reports.

As regards the obtaining of papers, the Papers Committee is in close collaboration with the Committees of the Local Centres and the Sectional Committees of the Institution. It may be useful to state here that there are five Sectional Committees and that they deal with the following subjects respectively : Lighting and Power, Traction, Telegraphs and Telephones, Electricity in Mines, Electro-Chemistry and Electro-Metallurgy.

The selection of papers for the Wireless Section is in the hands of the Wireless Section Committee.

The Council take this opportunity of expressing their grateful thanks to the Chairmen of Local Centres for their regular attendance at the meetings of the Papers Committee, thereby ensuring efficient contact and co-operation between the Committee itself and the Committees of the Local Centres in the important question of papers.

The Council will be pleased to consider any constructive suggestions that may occur to members for the improvement of the papers read before the Institution, either as regards subject matter or method of presentation.

(14) Meetings.

During the past twelve months, 365 meetings have been held in London and the Local Centres by the members, the Council and the various Committees. A detailed statement is given in Appendix B.

The Premiums awarded by the Council for papers will be announced about the time of the Annual General Meeting.*

* See Institution Notes, page 613.

(15) LOCAL CENTRES AND SUB-CENTRES.

Reports from the Committees of the Centres and Sub-Centres indicate that the attendances at the meetings and the interest in the discussions have been well sustained.

The President has attended functions or meetings at the Centres at Birmingham, Bristol, Dublin, Glasgow, Leeds, Liverpool, Manchester and Newcastle, and the Sub-Centres at Sheffield and Loughborough. On each occasion he has addressed the members and was gratified to note evidence of continued activity and development and of appreciation by the members attached to the various Centres of the opportunities afforded for discussion and intercourse.

(16) WIRELESS SECTION.

The interest and activities of the Wireless Section have been well maintained. Seven meetings have been held, at which nine papers were read.

(17) INFORMAL MEETINGS.

Fourteen meetings have been held during the session and the average attendance was 59, an increase of nine over last year.

The subjects discussed have stimulated a lively interest and many have taken part in the discussions who only rarely, if ever, take part in the discussions at the Ordinary Meetings.

(18) STUDENTS' SECTIONS.

There are at present 3 841 Students on the Register of the Institution, and the eight Students' Sections, viz. at London, Birmingham, Glasgow, Leeds, Liverpool, Manchester, Newcastle and Sheffield, have carried out a very full programme of meetings, visits to works and social functions.

Addresses to the London Students' Section were given by the President and Sir James Devonshire, K.B.E., Vice-President.

In August last the Students' Sections organized a visit to France at the invitation of the Société Française des Electriciens. Lyons was chosen as the venue and, through the courtesy of Mr. J. Grosselin, Local Honorary Secretary of the Institution in France, and Mr. Dumont of the Société Française des Electriciens, a very attractive programme was arranged for the 26 Students who took part.

The programme included visits to the following places :—

A Thury direct-current system operated by the Société Générale de Force et de Lumière.
Mouche central station.
Annual International Fair, Lyons.
Silk factory of Messrs. Vital Matthieu and Sons.
Works of the Berlier Motor Company.
Beaujolais vineyard.
120 000-volt system of the Compagnie Electrique de la Loire et du Centre, at St. Etienne.
Coal mines of the Loire.
Lyons radio station.

The firms and public bodies whose works, etc., were visited have been thanked for their generous hospitality, and the Council have to thank Messrs. J. H. Reyner and G. R. A. Murray of the London Students' Section for their valuable work in organizing the Visit.

(19) FARADAY LECTURES.

With a view to increasing the interest of the general public in electrical matters, the Council instituted in 1923 the Faraday Lectures of the Institution. These Lectures, which are delivered at selected Local Centres, are open to the public by means of admission cards obtainable through members of the Institution. The first five Lectures were delivered during the Session under review by Professor G. W. O. Howe, D.Sc., at Birmingham, Edinburgh, Leeds, Manchester and Newcastle, his subject being "World-Wide Radio Telegraphy."

Making allowances for the fact that this was the first occasion on which the Lectures were delivered, the attendances on the part of the public were very satisfactory, and it is hoped that as the Lectures become better known still larger attendances will be recorded.

(20) SCHOLARSHIPS.

The following Scholarships have been awarded by the Council :—

A David Hughes Scholarship.

(Value £50 ; tenable for one year.)

H. E. W. Tumath (Municipal College of Technology, Belfast).

A Salomons Scholarship.

(Value £50 ; tenable for one year.)

E. Youel (Liverpool University).

War Thanksgiving Education and Research Fund (No. 1).

A grant of £100 for educational purposes has been made this year by the Council, under the provisions of the Trust Deed, to A. E. Morrill [City and Guilds (Engineering) College, London].

(21) CONVERSAZIONE.

The Annual Conversazione was held at the Natural History Museum, South Kensington, London, on the 26th June, 1924, when about 1 400 members and guests attended.

(22) ANNUAL DINNER.

The Annual Dinner was held at the Hotel Cecil, London, on the 12th February, 1925, the members and guests present numbering 522.

An Account will be found in the *Journal*, vol. 63, p. 490.

(23) VISIT OF OVERSEAS ELECTRICAL ENGINEERS.

There was no Summer Meeting in 1924. In place of it, since many engineers from overseas were present in England for the British Empire Exhibition, the World Power Conference and the Kelvin Centenary Celebra-

tions, the occasion was thought suitable to entertain delegates and ladies from kindred societies overseas. The Council accordingly invited the following bodies to send delegates to be the guests of the Institution :—

- American Institute of Electrical Engineers.
- Asociacion de Ingenieros de Caminos, Canales y Puertos, Madrid.
- Asociacion Nacional de Ingenieros Industriales, Madrid.
- Association Suisse des Electriciens.
- Associazione Elettrotecnica Italiana.
- Dansk Ingeniorforening, Denmark.
- Engineering Institute of Canada.
- Institution of Engineers (India).
- Institution of Engineers, Australia.
- Koninklijk Instituut van Ingenieurs, Holland.
- Norske Ingeniorforening, Norway.
- Société Belge des Electriciens.
- Société Française des Electriciens.
- South African Institute of Electrical Engineers.
- Svenska Teknologföreningen, Sweden.
- Verseniging van Directeuren van Electricteitsbedrijven in Nederland.

The visit took place from the 10th to the 15th July, 1924, and about 170 delegates and ladies participated, the Council of the Institution and past Members of Council acting as hosts. Many of the party having arrived in England some days earlier, a large number were able to accept a gracious invitation from Their Majesties to be present at a Garden Party held by the King and Queen at Buckingham Palace on the 5th July.

On the 10th July the visitors were formally received by the then President (Dr. A. Russell) in the Institution Building and entertained at a luncheon at the Hotel Cecil. A large number of members and ladies were also present at both the reception and the luncheon. In the afternoon the visitors heard the Kelvin Oration delivered at the Institution of Civil Engineers by Sir J. J. Thomson, O.M., F.R.S.

The British Empire Exhibition was visited the following day, and in the evening the delegates attended the Kelvin Centenary Banquet at the Connaught Rooms.

With the exception of Sunday, the 13th July, when parties attended the morning services at Westminster Abbey and St. Paul's Cathedral and visited the Zoological Gardens in the afternoon, the remainder of the visit was spent in excursions to Cambridge (12th July), Birmingham and Stratford-on-Avon (14th July), and Chiswick and Windsor (15th July). During these days the party inspected the Cavendish Laboratory, the Colleges and other places of interest in Cambridge, the Nechells power station of the Birmingham Corporation and the University Engineering Laboratories at Birmingham, places of interest at Stratford-on-Avon, the Chiswick overhaul works of the London General Omnibus Company, Ltd., and the State Apartments at Windsor Castle. The visit concluded with a Joint Conversazione at the Institution of Civil Engineers by invitation of the Councils of the Institutions of Civil, Mechanical and Electrical Engineers.

The Council have expressed the cordial thanks of the Institution to those whose hospitality was extended to the visitors during the period of the visit, including the Master and Fellows of Trinity College, Cambridge, the Vice Chancellor of Cambridge University, the Lord Mayor of Birmingham, the London Midland and Scottish and the London and North Eastern Railway Companies, and Lord Ashfield.

(24) Cavendish Laboratory.

As was announced at the Ordinary Meeting on the 23rd October, 1924, the Council have made a donation of 100 guineas to the Cavendish Laboratory, Cambridge, as a token of their appreciation of the immense value of the electrical researches carried out at the Laboratory by Sir Joseph Thomson, Sir Ernest Rutherford and other Cambridge physicists.

(25) Paris International Conference on Large E.H.T. Electric Supply Systems.

During the Session the Council appointed a special Committee to ensure representation of British views and interests at the above Conference, which has been arranged to take place in Paris in June 1925. The following is a list of the papers to be presented at the Conference by British authors :—

Author.	*Title of Paper.*
H. W. Clothier ..	Metal-clad Switchgear and Isolation of Faults.
F. H. Clough ..	Transmission of Electric Power over Long Distances.
A. R. Everest ..	Insulating Oils. A Review of Research Work in Great Britain.
R. W. Gregory ..	Substation Design, with particular reference to Metal-clad Switchgear.
J. L. Langton ..	Developments in Porcelain Line Insulators.
R. Borlase Matthews	Rural E.H.T. Distribution.
A. Page	The Re-organization of Electricity Supply in Great Britain as governed by the Electricity Commission.
G. V. Twiss ..	Consideration of Assumed Loadings in their relation to Safety of Overhead Lines.

The following British delegates have already been appointed by the Council, and others may be appointed later :—

Mr. W. B. Woodhouse (Chief Delegate).
Mr. A. R. Everest.
Mr. P. V. Hunter, C.B.E.
Mr. A. Page.
Mr. E. B. Wedmore.

(26) Wireless Telegraphy and Signalling Bill.

Being of opinion that some of the provisions of the above Bill, unless modified, will prove a hindrance not

only to the progress of wireless telegraphy and radio science, but also to electrical and physical research and to the progress of electrical science generally, the Council have made representations to the Postmaster-General in regard to some of the clauses. The matter is still under consideration, and the Bill has not proceeded beyond the stage of first reading.

(27) University of Brussels.

In response to an invitation from the Council and Faculty of the University of Brussels, Mr. Ll. B. Atkinson, Past-President, represented the Institution at the Ceremonies held to commemorate the 50th anniversary of the founding of the École Polytechnique (School of Technology) on the 20th, 21st and 22nd November, 1924.

(28) Norwegian Engineering Society.

Mr. M. L. Kristiansen represented the Institution at the celebration at Kristiania on the 7th, 8th and 9th December, 1924, of the 50th anniversary of the foundation of the Norwegian Engineering Society.

(29) Rensselaer Polytechnic Institute.

The Institution was represented by Mr. J. W. Lieb at the celebration of the 100th anniversary of the foundation of the Institute at Troy, New York, on the 3rd and 4th October, 1924.

(30) University of Leeds.

The Coming-of-Age of the University of Leeds and the Jubilee of its parent foundation, the Yorkshire College, were celebrated at Leeds from the 15th to the 20th December, 1924. The Institution was represented at the functions by Mr. W. B. Woodhouse (President of the Institution) and Mr. T. B. Johnson (Chairman of the North Midland Centre).

(31) Library.

During the year 295 books and pamphlets have been presented to the Reference Library by members and others, and 226 volumes have been purchased. A slight decrease in attendance is recorded, the total number for the year being 2 419, of whom 108 were non-members, as against the total of 2 526 in 1923–1924.

The Council have pleasure in recording the continued circulation of books from the Lending Library, to which 89 new volumes have been added during the year. During the year, 2 184 were issued to 872 borrowers, the corresponding numbers for the previous year being 2 232 and 897 respectively.

A new edition of the Lending Library Catalogue with a subject guide to authors is in preparation and will be issued in the course of the next few months.

(32) The Institution of Gas Engineers.

As a token of appreciation of the facilities placed at their disposal for the holding of their Annual General Meeting in June 1924, in the Institution Building, the Council of the Institution of Gas Engineers have presented to the Institution a photogravure plate for a certificate placing on record his tenure of the office to be issued to each President. The formal presentation of the plate and of the first certificate struck from it was made by the President of the Institution of Gas Engineers at the Ordinary Meeting held on the 22nd January, 1925.

(33) Gifts to the Institution.

The Council have pleasure in recording the following gifts to the Institution and in expressing their cordial thanks to the donors :—

Donor.	*Gift.*
Colonel R. K. Morcom	Bronze statuette of the late Sir Joseph Swan.
Mr. H. Moss	An original Graham Bell telephone licence.
Executors of the late Mrs. Hugh Carter	Oil painting of the late Sir Francis Ronalds, F.R.S.
Physical Society of London	Copy of photograph taken on the occasion of the Society's Jubilee Celebrations on the 21st March, 1924.
Mr. Ll. B. Atkinson ..	Set of prints illustrating the work of laying the first Atlantic cable.
Dr. J. A. Fleming ..	Portraits of himself, Clerk Maxwell and Edison.
Mr. G. W. Partridge ..	An early 10 000-volt transformer.

(34) Electrical Appointments Board.

The number of applicants for posts registered on the 31st March, 1925, was 78, against a total of 114 last year.

A classified Register of members seeking positions, containing particulars of their training and experience, is available for inspection at the Institution offices, and the Secretary of the Board will gladly put employers in touch with highly qualified electrical engineers.

The Council earnestly hope that members who are in a position to assist will not fail to make use of the Register.

(35) The Journal of the Institution.

The Volume of the *Journal* for 1924 comprised 1 006 pages, as compared with 1 204 in the previous Volume.

The net cost of printing and posting the *Journal* in 1924, after allowing for sales and the revenue received from advertisements, was £3 078, as compared with £4 159 in 1923. The net cost per page works out at £3·06, as against £3·45 for 1923, in spite of the fact that the number of copies printed increased from 11 400 in 1923 to 12 000 in 1924. The reduction in the cost of the *Journal* is mainly due to the increase in the advertisement revenue, only nine months' revenue from this source having been included in the 1923 Accounts.

(36) "Science Abstracts."

The Physics volume of *Science Abstracts* for 1924 contained 150 pages more than for 1923, and the

Electrical Engineering volume was of the same size as in the previous year. The Accounts show that the net cost of the publication to the Institution in 1924 was only £68, which the Council consider satisfactory.

(37) Wiring Regulations.

The revised edition (8th Edition) of the Wiring Rules, now published under the title of "Regulations for the Electrical Equipment of Buildings," was issued during the summer of 1924. The Committee have received from members a number of suggestions for the amendment of certain of the Regulations and there have also been discussions at Informal Meetings in London and at some of the Local Centres. The principal criticisms received are due to misunderstandings in regard to the intention of some of the Regulations, but a few questions of principle are also involved.

The Committee are considering the desirability of recommending the Council to amend the wording of a number of the Regulations with a view to removing the misunderstandings as far as possible and taking into account the points of principle which have been raised.

(38) Electricity Regulations.

The Electricity (Supply) Regulations Committee are engaged in preparing suggestions for a revision of the Electricity Commissioners' Regulations (A) for securing the safety of the Public, and (B) for ensuring a proper and sufficient supply of Electrical Energy. It is hoped that a Report thereon will be ready for submission by the Council to the Commissioners at an early date.

(39) Committee on Electricity in Agriculture.

The Report of the above Committee is nearly ready and will be presented to the Council at an early date.

(40) National Certificates and Diplomas in Electrical Engineering.

For the final examinations of the year 1924 the joint Standing Committee representing the Board of Education and the Institution approved 53 courses at schools and colleges for the award of Ordinary Certificates in Electrical Engineering, 15 for the award of Higher Certificates, 4 for the award of Ordinary Diplomas and 2 for the award of Higher Diplomas.

The final examinations were held during the summer of 1924 and the numbers of certificates and Diplomas awarded were as follows:—

282 Ordinary Certificates (including 103 distinctions).
43 Higher Certificates (including 14 distinctions).
9 Ordinary Diplomas (including 22 distinctions in individual subjects).
5 Higher Diplomas (including 3 distinctions).

(41) Benevolent Fund.

The Committee of Management of the Benevolent Fund of the Institution report that on the 31st December, 1924, the Capital Account of the Fund stood at £9 969 11s. 3d., and the accumulated income at £1 889 7s. 5d. The donations and subscriptions to the Fund in 1924 amounted to £1 152 7s. 10d.

In the course of 1924, 78 grants were made to 26 persons, amounting to a total of £1 322 16s. 6d.

(42) Annual Accounts.

Excess of Income over Expenditure.—After making provision for contingencies, as in the previous year, there is a margin to the good on the Revenue Account for 1924 of £2 925 0s. 8d. This amount, which has been carried to the credit of the General Fund, compares with £3 957 11s. 7d. in 1923. The decrease of £1 032 10s. 11d. was chiefly due to the reduction in subscriptions, which came into operation on the 1st January, 1924.

Mortgage.—

	£	s.	d.
In the Accounts for 1923 this stood at	14 801	19	4
Amount of repayments during the year	1 080	17	4
The amount now stands at	£13 721	2	0

Assets.—Taking the Tothill-street property and the investments at cost, and the Institution Building and lease, the library and furniture, etc., at the values standing in the books after writing off depreciation—

	£	s.	d.
the Assets amount to	139 485	15	5
against Liabilities	6 469	14	6
leaving a surplus of	133 016	0	11
which, in comparison with that of the year 1923, viz.	125 399	3	0
shows an improvement of	£7 616	17	11

The balance of £133 016 0s. 11d. is made up as follows:—

Assets.

	£	s.	d.	£	s.	d.
Properties—						
Institution Building and Tothill-street Property	92 289	3	11

* The above values are subject to depreciation.

We beg to report that we have audited the Balance Sheet of The Institution of Electrical Engineers, dated 31st December, 1924, and above set forth, together with the annexed Statements of Account. We have obtained all the information and explanations we have required. In our opinion the Statements are correct, and the Balance Sheet is properly drawn up so as to exhibit a true and correct view of the state of the Institution's affairs according to the best of our information and the explanations given to us and as shown by the books of the Institution.

I have audited the above Balance Sheet and Income and Expenditure Account with the Books and Vouchers and certify them to be correct, and have verified the Investments with Certificates from Bankers. The Investments, which are stated at cost, are subject to depreciation.

15th April, 1925.

JAS. ATTFIELD, F.C.A.,
Honorary Auditor.

THE BENEVOLENT FUND.

27th ANNUAL GENERAL MEETING, 7 MAY, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 5.30 p.m.

The notice convening the meeting was taken as read.

The minutes of the 26th Annual General Meeting held on the 8th May, 1924, were also taken as read and were confirmed and signed.

The Report of the Committee of Management (see below) and the Statement of Accounts for the year 1924 (see page 586) were presented and, on the motion of **The Chairman,** seconded by **Mr. P. Rosling,** were unanimously adopted.

On the motion of **Mr. Ll. B. Atkinson,** Mr. J. Attfield, F.C.A., was unanimously re-elected Hon. Auditor.

Mr. C. P. Sparks offered to make a donation to be invested to bring the invested capital which now stands at £9 969 11s. 3d. to £10 000. The offer was gratefully accepted by the Chairman.

Mr. F. B. O. Hawes advocated greater publicity of the Fund, with a view to increasing the Capital Account to meet the demands for pensions which the Fund will later be called upon to provide.

Mr. W. T. Maccall, Chairman of the North-Eastern Centre, suggested that the other Local Centres might mention the Benevolent Fund in their Annual Reports in the same way as the North-Eastern Centre.

The Chairman reported that the following Committee of Management had been appointed for 1925–26:—

The President (*ex officio*); Sir James Devonshire, K.B.E., Captain J. M. Donaldson, M.C., Sir B. Longbottom, Mr. S. W. Melsom, Mr. A. Page and Mr. P. Rosling, representing the Council; Lieut.-Col. K. Edgcumbe, Mr. W. R. Rawlings and Captain R. J. Wallis-Jones, representing the Contributors; and the Chairman of each Local Centre in Great Britain and Ireland.

The meeting then terminated.

REPORT OF THE COMMITTEE OF MANAGEMENT FOR THE YEAR 1924.

Capital.

The Capital Account stood on the 31st December, 1924, at £9 969 11s. 3d., which is invested.

Receipts.

The Income for 1924 from dividends, interest, and annual subscriptions was as follows :—

	£	s.	d.
Dividends on investments	485	0	3
Interest	3	12	7
327 annual subscriptions	293	1	6
	£781	14	4

In addition to the foregoing, the Fund benefited during the year by the following amounts, many of which are non-recurring donations

	£	s.	d.
Electrical Engineers' Ball Committee	75	0	0
Electrical Standardizing, Testing and Training Institution	50	0	0
"Gilbert Club"	40	5	11
Western Electric Co., Ltd.	40	0	0
Wembley Exhibition Carnival	38	12	4
North Midland Centre (collected)	26	17	0
C. P. Sparks, C.B.E.	26	5	0
W. T. Henley's Telegraph Works, Ltd.	25	0	0
Western Centre (collected)	21	14	11
General Electric Co., Ltd.	21	0	0
H. Marryat	21	0	0
Midland Electrical Engineers' Ball Committee	21	0	0
"Twenty-Five" Club	15	15	0
Chloride Electrical Storage Co., Ltd.	10	10	0
H. Hirst	10	10	0
Incorporated Municipal Electrical Association	10	10	0
F. R. Marsh	10	10	0
J. D. Dallas	10	0	0
and 694 non-recurring donations of under £10	361	1	2
	£809	6	4

The Fund also benefited to the extent of £50 under the will of the late Mr. A. L. Dearlove (Member).

The accumulated balance of the Income and Expenditure Account amounted on the 31st December, 1924, to £1 889 7s. 5d., of which £1 504 13s. 3d. was invested, and £225 on deposit with the Institution bankers.

Donors and Subscribers.

Lists of the names of donors and subscribers during 1924 have been published in the *Journal*.

The Committee of Management desire to acknowledge their indebtedness to the donors and subscribers, and to intimate that, apart from donations, the Committee will be grateful for annual subscriptions of any amount.

Grants.

Applications for assistance were made by or on behalf of 26 persons during 1924, and the Committee, after due consideration, made grants in all of the cases. The total amount of the grants was £1 322 16s. 6d.

Wilde Fund.

The Capital Account stood on the 31st December, 1924, at £2 949 6s. 7d., all of which is invested and brings in an annual income of £106 11s. 10d.

The balance standing to the credit of the Income Account, from which, under the Trust Deed, full Members only can benefit, on the same date was £109 5s. 10d.

A grant of £30 was made from this Fund during the year,

WAVE-FORM ANALYSIS ON RECTIFIED CIRCUITS.*

By L. B. W. JOLLEY, M.A., Member.

(*Paper received 2nd January, 1925.*)

SUMMARY.

This paper analyses the form of various waves to be expected in rectified circuits, and by the general method of treatment the analysis could be applied to a pronounced commutator ripple. A specialized form of wave-form, due to a rectifier where a sharp cut-off of the current is to be expected, is also considered.

The use of rectified alternating current is becoming daily more common, and a knowledge of the wave-form of the resulting direct current is essential for the user and designer alike. Accordingly an attempt has been made to analyse the various forms most likely to be encountered in practice; and although these curves are ideal and will be more or less distorted in actuality, yet they represent facts to a reasonable degree of accuracy, or at least give an indication as to what harmonics are likely to be present.

SINGLE-PHASE WAVE-FORM.

The first case considered is that of a single-phase wave-form as shown in Fig. 1 (*b*), resulting from the

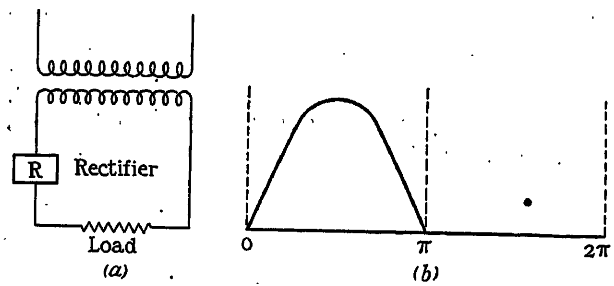

FIG. 1.

circuit indicated in Fig. 1 (*a*), where the shape of the curve is given by the equation $y = \sin\theta$.

If the function is represented by a Fourier's series

$$y = \tfrac{1}{2}a_0 + a_1\cos\theta + a_2\cos 2\theta + \ldots \infty$$
$$+ b_1\cos\theta + b_2\cos 2\theta + \ldots \infty$$

then

$$a_n = \frac{1}{\pi}\int_0^{\pi}\sin\theta\cos n\theta\,d\theta$$

and

$$b_n = \frac{1}{\pi}\int_0^{\pi}\sin\theta\sin n\theta\,d\theta$$

whence

$$a_n = \frac{1+\cos n\pi}{\pi(1-n^2)}$$

and

$$b_n = \frac{\sin n\pi}{\pi(1-n^2)}$$

Thus b_n is zero for all integral values of n except unity, where it equals $\tfrac{1}{2}$.

The wave-form is therefore

$$y = \frac{1}{\pi} + \tfrac{1}{2}\sin\theta - \frac{2\cos 2\theta}{\pi(1.3)} - \frac{2\cos 4\theta}{\pi(3.5)} - \ldots \infty \quad (1)$$

$$= \frac{1}{\pi} + \tfrac{1}{2}\sin\theta - \frac{2}{\pi}\sum_2^{\infty}\frac{\cos^2\tfrac{1}{2}n\pi\cos n\theta}{n^2-1} \quad . \quad . \quad . \quad (2)$$

BIPHASE WAVE-FORM.

From Equation (2) the biphase wave-form, which is obtained from the circuit illustrated in Fig. 2 (*a*), can be calculated and will be of the form shown in Fig. 2 (*b*).

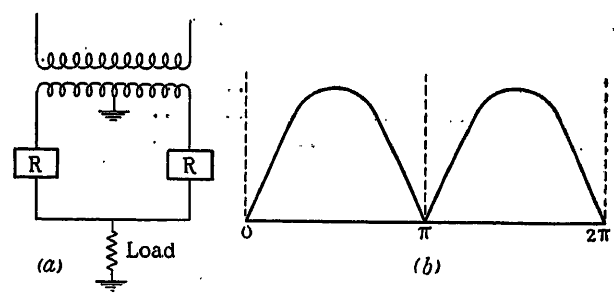

FIG. 2.

In this case let us write $\theta = \pi + \theta$ in Equation (2), whence

$$y = \frac{1}{\pi} - \tfrac{1}{2}\sin\theta - \frac{2}{\pi}\sum_2^{\infty}\frac{\cos^2\tfrac{1}{2}n\pi\cos n\theta}{n^2-1} \quad . \quad (3)$$

and by adding Equations (2) and (3)

$$y = \frac{2}{\pi}\left[1 - 2\sum_2^{\infty}\frac{\cos^2\tfrac{1}{2}n\pi\cos n\theta}{n^2-1}\right] \quad . \quad . \quad (4)$$

is obtained for the equation of a biphase wave. Thus it will be apparent that in this wave-formation the fundamental is absent and only even harmonics are present.

POLYPHASE WAVE-FORM.

It is interesting to investigate the general case of a multiphase system, and in Fig. 3 circuit connections

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

are given for a hexaphase supply, the method being of general application. The wave-form of such a supply is shown in Fig. 4, and if there are m phases there will be m complete loops in one cycle or 2π electrical degrees, the crest of the loop strictly following the sinusoidal curvature. The equation to the generating curve is in this case $y = \cos\theta$.

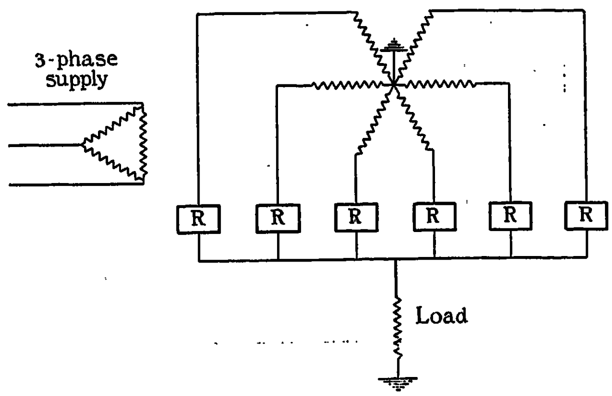

FIG. 3.

It is shown in treatises dealing with Fourier's series that the amplitudes of the nth harmonics between limits other than $\pm\pi$ can be obtained as follows :—

Assume the series to be

$$f(\theta) = \tfrac{1}{2}a_0 + a_1\cos(\pi\theta/c) + a_2\cos(2\pi\theta/c) + \ldots \infty$$
$$+ b_1\cos(\pi\theta/c) + b_2\cos(2\pi\theta/c) + \ldots \infty$$

Then $$a_n = \frac{2}{c}\int_0^c f(\theta)\cos\left(\frac{n\pi\theta}{c}\right)d\theta$$

and $$b_n = \frac{2}{c}\int_0^c f(\theta)\sin\left(\frac{n\pi\theta}{c}\right)d\theta$$

or $$a_n = \frac{1}{c}\int_{-c}^{+c} f(\theta)\cos\left(\frac{n\pi\theta}{c}\right)d\theta$$

and $$b_n = \frac{1}{c}\int_{-c}^{+c} f(\theta)\sin\left(\frac{n\pi\theta}{c}\right)d\theta$$

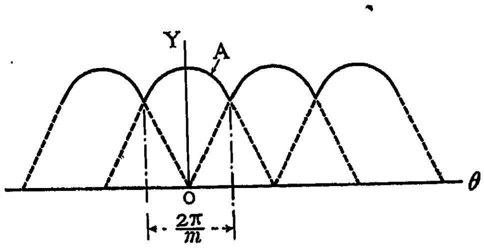

FIG. 4.

In this case $c = \pi/m$ and $n\pi\theta/c = nm\theta$, whence

$$\frac{\pi a_n}{m} = \int_{-\pi/m}^{+\pi/m}\cos\theta\cos(nm\theta)d\theta$$

and $$a_n = \frac{2m\sin(\pi/m)\cos n\pi}{\pi(1 - n^2m^2)} \quad . \quad . \quad . \quad (5)$$

Further $$\frac{\pi b_n}{m} = \int_{-\pi/m}^{+\pi/m}\cos\theta\sin(nm\theta)d\theta = 0$$

and all the sine terms are absent (this statement requires modification where $m = 1$, the single-phase wave-form considered above).

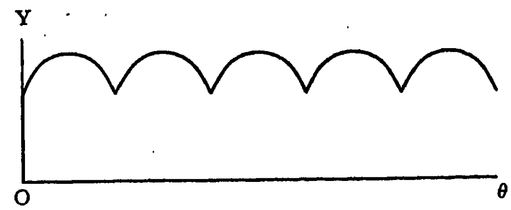

FIG. 5.

The general equation of the wave-form is therefore

$$\frac{m}{\pi}\sin\frac{\pi}{m} - \frac{2m\sin(\pi/m)\cos m\theta}{\pi(1 - m^2)}$$
$$+ \frac{2m\sin(\pi/m)\cos 2m\theta}{\pi(1 - 2^2m^2)} - \ldots \infty \quad (6)$$

$$= \frac{m}{\pi}\sin\frac{m}{\pi}\left[1 + 2\sum_{n=1}^{\infty}\frac{\cos n\pi\cos nm\theta}{1 - n^2m^2}\right] \quad . \quad (7)$$

If it is desired to reproduce the wave-form to a different set of co-ordinates, as shown in Fig. 5, it is necessary to substitute $(\theta - \pi/m)$ for θ in Equation (7), which then becomes

$$\frac{m}{\pi}\sin\frac{\pi}{m}\left[1 - \frac{2\cos m\theta}{m^2 - 1} - \frac{2\cos 2m\theta}{4m^2 - 1} - \ldots \infty\right] \quad . \quad (8)$$

$$= \frac{m}{\pi}\sin\frac{\pi}{m}\left[1 + 2\sum_{1}^{\infty}\frac{\cos nm\theta}{1 - n^2m^2}\right] \quad . \quad . \quad (9)$$

in which form it is more convenient. In future, and in the table below, this equation will be used.

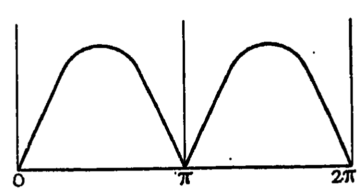

FIG. 6.

It is interesting to apply a check to this result, and to this end an infinite series is employed of the form

$$\frac{m}{\pi}\operatorname{cosec}\frac{\pi}{m} = 1 + 2\sum_{1}^{\infty}\frac{(-1)^n}{1 - n^2m^2}$$

If the midpoint of the oscillations is considered, i.e. the point represented by $\theta = \pi/m$, the amplitudes of the harmonics all have a maximum value, and hence

Equation (9) equals unity, which is the peak value of the wave.

If m is given the values 2, 3, 4, etc., to represent the number of phases or loops per cycle, the following wave-forms are obtained :—

m = 2 (*Biphase*) Fig. 6.

$$\frac{2}{\pi} - \frac{4\cos 2\theta}{\pi(1.3)} - \frac{4\cos 4\theta}{\pi(3.5)} - \ldots \infty$$

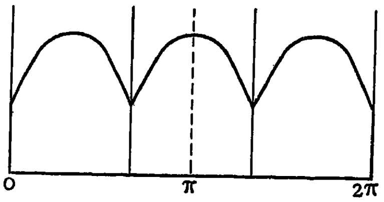

FIG. 7.

m = 3 (*Triphase*) Fig. 7.

$$\frac{3\sqrt{3}}{2\pi} - \frac{3\sqrt{3}\cos 3\theta}{\pi(2.4)} - \frac{3\sqrt{3}\cos 6\theta}{\pi(5.7)} - \ldots \infty$$

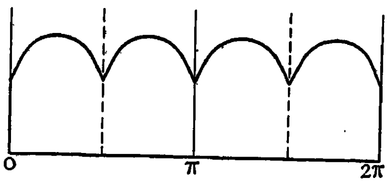

FIG. 8.

m = 4 (*Quarter Phase*) Fig. 8.

$$\frac{2\sqrt{2}}{\pi} - \frac{4\sqrt{2}\cos 4\theta}{\pi(3.5)} - \frac{4\sqrt{2}\cos 8\theta}{\pi(7.9)} - \ldots \infty$$

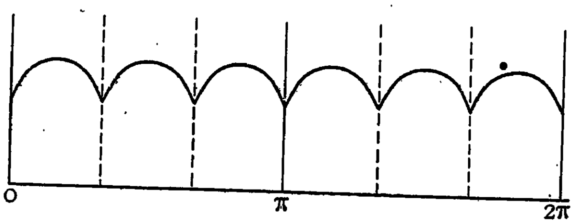

FIG. 9.

m = 6 (*Hexaphase*) Fig. 9.

$$\frac{3}{\pi} - \frac{6\cos 6\theta}{\pi(5.7)} - \frac{6\cos 12\theta}{\pi(11.13)} - \ldots \infty$$

m = 18 (*Eighteen Phase*).

$$0{\cdot}999\left[1 - \frac{2\cos 18\theta}{17.19} - \frac{2\cos 36\theta}{35.37} - \ldots \infty\right]$$

With regard to the mean square value of the wave, this will be equal to

$$\mathfrak{J}^2 = \frac{m^2}{\pi^2}\sin^2\frac{\pi}{m}\left[1 + 2\sum_1^{\infty}\frac{1}{(1-n^2m^2)^2}\right]$$

TABLE.—*Polyphase Wave-Form Data.*

Number of phases	R.M.S. value $\mathfrak{J}$	Mean value I_M	Form factor	Amplitude of nth harmonic	Maximum value ÷ R.M.S.	Maximum value ÷ mean	Minimum ordinate	Area under one loop

18	0·995	0·995	1·00	$\frac{36\sin 10^\circ}{\pi(1-324n^2)}$	1·005	1·005	0·985	0·174

To sum the series $\sum_{1}^{\infty} \frac{1}{(1-n^2m^2)^2}$ two infinite series are employed, viz.

$$\pi \cot \pi\theta = \frac{1}{\theta} + \sum_{1}^{\infty} \frac{2\theta}{\theta^2 - n^2}$$

and $$\pi^2 \operatorname{cosec}^2 \pi\theta = \frac{1}{\theta^2} + 2\sum_{1}^{\infty} \frac{\theta^2 + n^2}{(\theta^2 - n^2)^2}$$

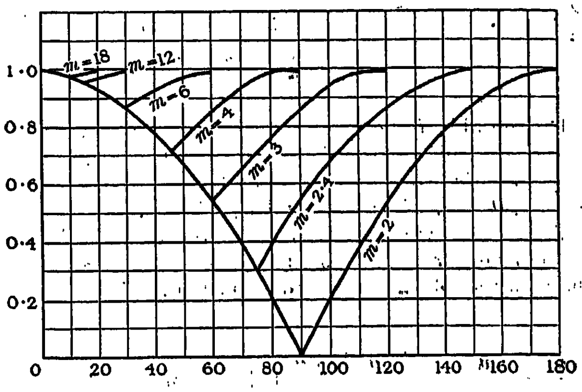

FIG. 10.

Whence, putting $\theta = 1/m$,

$$\sum_{n=1}^{\infty} \frac{1}{(1-n^2m^2)^2} = \left(\frac{\pi}{2m} \operatorname{cosec} \frac{\pi}{m}\right)^2 + \frac{\pi}{4m} \cot \frac{\pi}{m} - \frac{1}{2}$$

and therefore

$$\mathfrak{J}^2 = \frac{1}{2} + \frac{m}{4\pi} \sin \frac{2\pi}{m}$$

This result could also have been obtained directly by evaluating

$$\frac{m}{2\pi}\int_{\frac{1}{2}\pi - \pi/m}^{\frac{1}{2}\pi + \pi/m} \sin^2 \theta d\theta$$

The actual wave-forms to scale are indicated in Fig. 10, and show how the form factor is improved by increasing the number of phases.

From the above analysis, the table shown on page 590 can be prepared.

SPECIAL WAVE-FORMS.

In some forms of rectifier, such, for instance, as the vibrating reed or the neon tube, the voltage rises to a certain value before the current flows, and the current

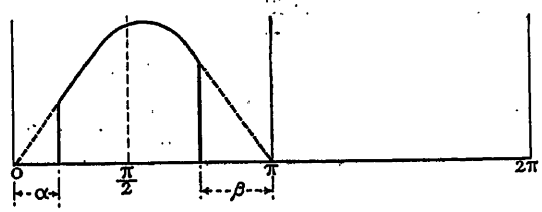

FIG. 11.

is cut off before the voltage has fallen to zero. Such an oscillation will take the form of Fig. 11, where the form of the generating curve is $y = \sin \theta$. From Fourier's series the amplitudes of the nth harmonics are

$$a_n = \frac{1}{\pi}\int_{\alpha}^{\pi-\beta} \sin \theta \cos n\theta \, d\theta$$

and $$b_n = \frac{1}{\pi}\int_{\alpha}^{\pi-\beta} \sin \theta \cos n\theta \, d\theta$$

whence

$$a_n = \frac{\cos n\pi\{\cos \beta \cos n\beta + n \sin \beta \sin n\beta\} + \cos \alpha \cos n\alpha + n \sin \alpha \sin n\alpha}{\pi(1-n^2)}$$

and $$b_n = \frac{\cos n\pi\{n \sin \beta \cos n\beta - \cos \beta \sin n\beta\} + \cos \alpha \sin n\alpha - n \sin \alpha \cos n\alpha}{\pi(1-n^2)}$$

from which $\frac{1}{2}a_0 = \frac{\cos \alpha + \cos \beta}{2\pi}$.

Similarly, by differentiating the numerator and denominator of a_n and b_n and putting $n = 1$

$$a_1 = \frac{\sin^2 \beta - \sin^2 \alpha}{2\pi}$$

and $$b_1 = \frac{\sin \alpha \cos \alpha + \sin \beta \cos \beta - \alpha - \beta + \pi}{2\pi}$$

The complete expression of the wave-form then becomes

$$y = \frac{\cos \alpha + \cos \beta}{2\pi} + \left(\frac{\sin \alpha \cos \alpha + \sin \beta \cos \beta - \alpha - \beta + \pi}{2\pi}\right) \sin \theta + \left(\frac{\sin^2 \beta - \sin^2 \alpha}{2\pi}\right) \cos \theta$$

$$- \sum_{2}^{\infty} \frac{\cos n\pi\{\cos \beta \cos n\beta + n \sin \beta \sin n\beta\} + \cos \alpha \cos n\alpha + n \sin \alpha \sin n\alpha}{\pi(n^2 - 1)} \cos n\theta$$

$$- \sum_{2}^{\infty} \frac{\cos n\pi\{n \sin \beta \cos n\beta - \cos \beta \sin n\beta\} + \cos \alpha \sin n\alpha - n \sin \alpha \cos n\alpha}{\pi(n^2 - 1)} \sin n\theta \quad . \quad (10)$$

The following series are useful in computing R.M.S. and average values :—

$$\sum_{2}^{\infty}\frac{\cos n\pi\cos n\theta}{n^2-1}=\frac{\cos 2\theta}{1.3}-\frac{\cos 3\theta}{2.4}+\ldots\infty$$
$$=\tfrac{1}{2}-\tfrac{1}{4}\cos\theta-\tfrac{1}{2}\theta\sin\theta$$

$$\sum_{2}^{\infty}\frac{\cos n\pi(n\sin n\theta)}{n^2-1}=\frac{2\sin 2\theta}{1.3}-\frac{3\sin 3\theta}{2.4}+\ldots\infty$$
$$=\tfrac{1}{2}\theta\cos\theta+\tfrac{1}{4}\sin\theta$$

$$\sum_{2}^{\infty}\frac{\cos n\theta}{n^2-1}=\frac{\cos 2\theta}{1.3}+\frac{\cos 3\theta}{2.4}+\ldots\infty$$
$$=\tfrac{1}{2}+\tfrac{1}{4}\cos\theta-\tfrac{1}{2}\pi\sin\theta+\tfrac{1}{2}\theta\sin\theta$$

$$\sum_{2}^{\infty}\frac{n\sin\theta}{n^2-1}=\frac{2\sin 2\theta}{1.3}+\frac{3\sin 3\theta}{2.4}+\ldots\infty$$
$$=\tfrac{1}{2}\pi\cos\theta-\tfrac{1}{4}\sin\theta-\tfrac{1}{2}\theta\cos\theta$$

$$\sum_{2}^{\infty}\frac{\cos\frac{1}{2}n\pi\cos n\theta}{n^2-1}=-\frac{\cos 2\theta}{1.3}+\frac{\cos 4\theta}{3.5}-\ldots\infty$$
$$=\tfrac{1}{2}-\tfrac{1}{4}\pi\cos\theta$$

$$\sum_{2}^{\infty}\frac{\cos\frac{1}{2}n\pi(n\sin\theta)}{n^2-1}=-\frac{2\sin 2\theta}{1.3}+\frac{4\sin 4\theta}{3.5}-\ldots\infty$$
$$=-\tfrac{1}{4}\pi\sin\theta$$

$$\sum_{2}^{\infty}\frac{\sin\frac{1}{2}n\pi\sin n\theta}{n^2-1}=-\frac{\sin 3\theta}{2.4}+\frac{\sin 5\theta}{4.6}-\ldots\infty$$
$$=\tfrac{1}{4}\sin\theta-\tfrac{1}{2}\theta\cos\theta$$

$$\sum_{2}^{\infty}\frac{\sin\frac{1}{2}n\pi(n\cos n\theta)}{n^2-1}=-\frac{3\cos 3\theta}{2.4}+\frac{5\cos 5\theta}{4.6}-\ldots\infty$$
$$=-\tfrac{1}{4}\cos\theta+\tfrac{1}{2}\theta\sin\theta$$

By the aid of these series it is possible to check the above generalized formulæ by putting $\theta=\frac{1}{2}\pi$, in which case the whole expression should equal unity; or by putting $\theta=0$, when it should equal zero.

The biphase wave-form as shown in Fig. 12 is obtained by replacing $\pi+\theta$ for θ in Equation (10) and adding the result so obtained to Equation (10). Thus

$$y=\frac{\cos\alpha+\cos\beta}{2\pi}-\sum_{2}^{\infty}\frac{\cos\beta\cos n\beta+n\sin\beta\sin n\beta+\cos\alpha\cos n\alpha+n\sin\alpha\sin n\alpha}{\pi(n^2-1)}(1+\cos n\pi)\cos n\theta$$
$$-\sum_{2}^{\infty}\frac{n\sin\beta\cos n\beta-\cos\beta\sin n\beta+\cos\alpha\sin n\alpha-n\sin\alpha\cos n\alpha}{\pi(n^2-1)}(1+\cos n\pi)\sin n\theta \quad . \quad . \quad . \quad . \quad (11)$$

If $\alpha=\beta$, i.e. the point of cut-off is equal to the point of cut-in, or the current wave is symmetrical, the following relationships obtain :—

Single-Phase (Fig. 11).

$$y=\frac{\cos\alpha}{\pi}+\frac{\sin 2\alpha-2\alpha+\pi}{2\pi}\sin\theta$$
$$-\sum_{2}^{\infty}\frac{\cos\alpha\cos n\alpha+n\sin\alpha\sin n\alpha}{\pi(n^2-1)}\times(1+\cos n\pi)\cos n\theta$$
$$-\sum_{2}^{\infty}\frac{n\sin\alpha\cos n\alpha-\cos\alpha\sin n\alpha}{\pi(n^2-1)}\times(\cos n\pi-1)\sin n\theta \quad . \quad (12)$$

and the fundamental cosine term disappears.

Biphase (Fig. 12).

$$y=\frac{2\cos\alpha}{\pi}-2\sum_{2}^{\infty}\frac{\cos\alpha\cos n\alpha+n\sin\alpha\sin n\alpha}{\pi(n^2-1)}\times(1+\cos n\pi)\cos n\theta \quad . \quad (13)$$

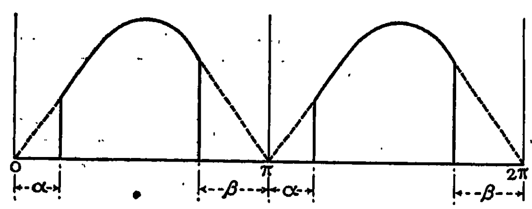

FIG. 12.

and both fundamental terms vanish as well as all of the sine terms.

SOME ARTIFICIAL LINES AND NETWORKS ASSOCIATED WITH THE UNIFORM TELEPHONE TRANSMISSION LINE.*

By the RESEARCH STAFF OF THE GENERAL ELECTRIC CO., LTD.

(Work conducted by A. C. BARTLETT.)

(*Paper first received* 21*st November*, 1924, *and in final form* 14*th January*, 1925.)

SUMMARY.

In Part 1 it is shown that the problem of constructing a network the impedance of which shall be equal to the impedance of an infinite uniform telephone line, can be solved exactly by the use of a number of sections of simple artificial lines. The artificial lines described are intended entirely for use in this way, and since their propagation constants are widely different from that of the uniform line, they cannot be used as "artificial transmission lines" to which any terminal apparatus might be added.

Some of the artificial lines can be used for attenuation correction.

In Part 2 it is shown that related networks can be obtained such that when placed in series or in parallel with the infinite uniform line, the impedance of the combination is a pure resistance.

Part 1.

It is often necessary for laboratory purposes and for use in telephonic work—especially where telephone repeaters are used—to obtain networks the input impedance/frequency characteristics of which will be

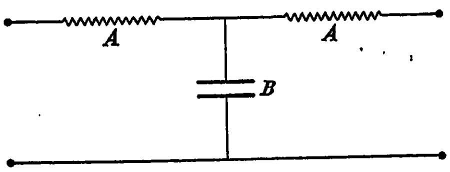

FIG. 1.

the same as those of an infinite, uniform, telephone transmission line.

A number of approximate solutions are known which make use of networks of resistances and condensers.†

It is the purpose of this paper to show that, by the use of simple artificial lines,‡ the impedance elements of which can be calculated from the constants of the line, a precise solution of this problem may be obtained.

The impedance of an infinite uniform line is $\sqrt{[(R + jpL)/(S + jpC)]}$ where R, L, C and S are the resistance, inductance, capacity and leakage per unit length.

The characteristic impedance of a **T**-section artificial line is $\sqrt{(A^2 + 2AB)}$, where A is the series member and B the shunt member. It is interesting to consider whether $(R + jpL)/(S + jpC)$ can be put in the form of $A^2 + 2AB$ with A and B both physically realizable.

Take first the simple case where $S = 0$. We have

$$\frac{R + jpL}{jpC} = \frac{L}{C}\left(1 + \frac{R}{jpL}\right)$$
$$= \left(\sqrt{\frac{L}{C}}\right)^2 + 2\left(\sqrt{\frac{L}{C}}\right)\frac{R}{2jp\sqrt{(LC)}}$$

But $\sqrt{(L/C)}$ is of the dimensions of a resistance, and $\sqrt{(LC)}/R$ is of the dimensions of a capacity.

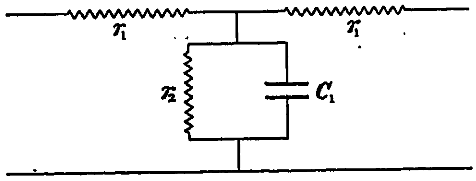

FIG. 2.

Hence the simple **T** section of Fig. 1, where A is a resistance $\sqrt{(L/C)}$, and B a capacity $2\sqrt{(LC)}/R$, has a line characteristic impedance equal to

$$\sqrt{[(R + jpL)/jpC]}.$$

The impedance of n sections of the line is

$$\sqrt{[(R + jpL)/jpC]} \tanh n\theta$$

or
$$\sqrt{[(R + jpL)/jpC]} \coth n\theta,$$

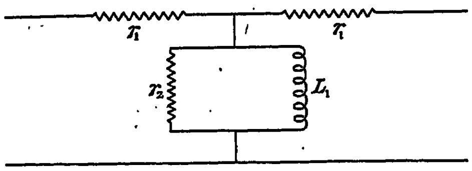

FIG. 3.

according as they are closed or open-circuited at the far end, where $\cosh \theta = 1 + A/B$. Tanh $n\theta$ and coth $n\theta$ approach the value unity at all frequencies as n is increased. Accordingly an impedance approximating as closely as desired to $\sqrt{[(R + jpL)/jpC]}$ can be obtained by using sufficient sections.

In practice for aerial telephone lines two or three sections give an approximation within 1 or 2 per cent for all frequencies above 200 cycles per second.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† HOYT: *Bell System Technical Journal*, April 1923.

‡ For general theory of artificial lines see KENNELLY: "Artificial Electric Lines" [McGraw-Hill].

Similar results hold when $S \neq 0$.

When $RC > LS$ we have the section given in Fig. 2,

where
$$r_1 = \sqrt{(L/C)}$$
$$r_2 = \tfrac{1}{2}\left(\sqrt{\frac{L}{C}}\right)\left(\frac{RC}{LS} - 1\right)$$
$$C_1 = 2C\frac{\sqrt{(LC)}}{RC - LS}$$

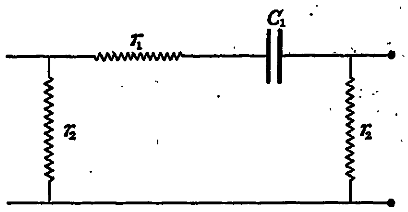

FIG. 4.

When $RC < LS_1$ we have the section given in Fig. 3,

where
$$r_1 = \sqrt{(R/S)},$$
$$r_2 = \tfrac{1}{2}\left(\sqrt{\frac{R}{S}}\right)\left(\frac{LS}{RC} - 1\right)$$
$$L_1 = \tfrac{1}{2}\left(\sqrt{\frac{1}{RS}}\right)\left(\frac{LS - RC}{S}\right)$$

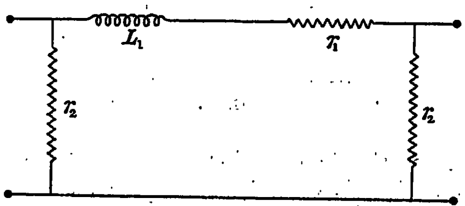

FIG. 5.

In a similar manner Π sections can be obtained. There are three cases, viz.

$$RC > LS;\ S \neq 0$$
$$RC < LS,$$
and
$$S = 0.$$

Case 1. $RC > LS$. $S \neq 0$ (see Fig. 4). We have

$$r_1 = \left(\sqrt{\frac{S}{R}}\right)\left(\frac{RL}{CR - LS}\right)$$
$$r_2 = \sqrt{(R/S)}$$
$$C_1 = \frac{CR - LS}{SR}\sqrt{\frac{S}{R}}$$

Case 2. $RC < LS$ (see Fig. 5). We have

$$r_1 = \left(\sqrt{\frac{L}{C}}\right)\left(\frac{CR}{LS - CR}\right)$$
$$r_2 = \sqrt{(L/C)}$$
$$L_1 = \frac{2\sqrt{(LC)}}{LS - CR}$$

Case 3. $S = 0$ (see Fig. 6). We have

$$r_1 = 2\sqrt{(L/C)}$$
$$L_1 = (2L/R)\sqrt{(L/C)}$$
$$r_2 = \sqrt{(L/C)}$$
$$C_1 = \frac{\sqrt{(LC)}}{R}$$

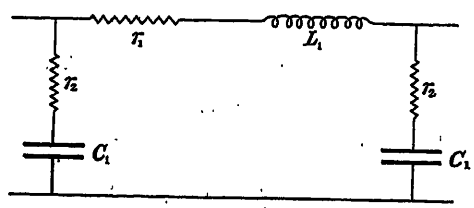

FIG. 6.

It may be noticed that the Π and **T** sections for any one case have the same propagation constant, and are thus exactly equivalent. An interesting way of deriving one from the other is to reciprocate one infinite line of **T** sections with respect to itself (i.e. with respect to

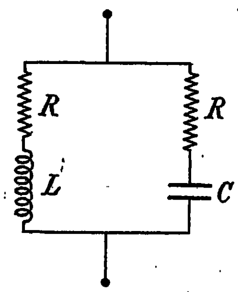

FIG. 7.

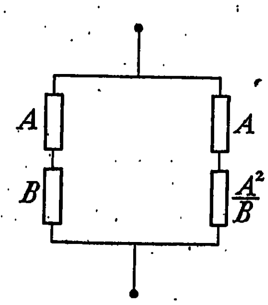

FIG. 8.

its line characteristic impedance) when the corresponding infinite line of Π sections is obtained, and vice versa.

Bridge-type artificial lines having the same impedance as uniform lines can also be obtained. Here it is necessary to express $(R + jpL)/(S + jpC)$ in the form $A \times B$. One obvious way is $x(R + jpL)[1/x(S + jpC)]$. x may be any numerical quantity and may be chosen so that the attenuation constant is a maximum within any range of frequencies that may be desired.

The attenuation constant α, which is the real part of the propagation constant, can be calculated and it will be found generally that, for any value of x, α will have a maximum at one frequency. From this it follows that by using suitable values of x, artificial lines can be obtained whose attenuation constant decreases with increasing frequency over a certain frequency range. Such a section, or number of such sections, may be inserted in a uniform line and used to compensate for the increase with frequency of the attenuation constant of the uniform line. Also, since the line characteristic impedance of the artificial line is the same as that of the uniform line, no reflection or impedance disturbance is introduced.

Other bridge types may be derived from the **T** sections

just given by using bridge arms such as xA and $(1/x)(A + 2B)$.

By terminating n sections of any of these artificial lines by $Z_0 \tanh \frac{1}{2}\theta$ the impedance $Z_0 \tanh \frac{1}{2}(2n + 1)\theta$ is obtained, and by terminating by $Z_0 \coth \frac{1}{2}\theta$ the impedance $Z_0 \coth \frac{1}{2}(2n + 1)\theta$ is obtained. Hence two series of approximations to Z_0 can be obtained of which the first five members for a **T** section are shown in Fig. 16.

Having decided on a definite number of sections, any of the equivalent networks obtainable by the methods previously given * can be substituted.

As a practical example consider the case of a 200-lb. copper air line having the following constants per mile :—

$$R = 8{\cdot}8 \text{ ohms.}$$
$$S = 10^{-6} \text{ mho.}$$
$$C = 8{\cdot}6 \times 10^{-9}\ \mu\text{F.}$$
$$L = 3{\cdot}66 \times 10^{-3}\ \text{H.}$$

cycles per second, and the results are shown in vector form in Table 1.

TABLE 1.

	$p = 2\,000$ (300 ~ approx.)	$p = 12\,000$ (2 000 ~ approx.)
Tanh θ	1·06 /5° 24′	1·0045 /3′
Tanh 2θ	1·0034 /19′	0·99913 /0·86″
Tanh 3θ	0·9996 /5″	Very nearly unity
Tanh 6θ	0·999999 /0·004″	Very nearly unity

It will be seen that a high degree of approximation is very soon attained and that two or three sections give

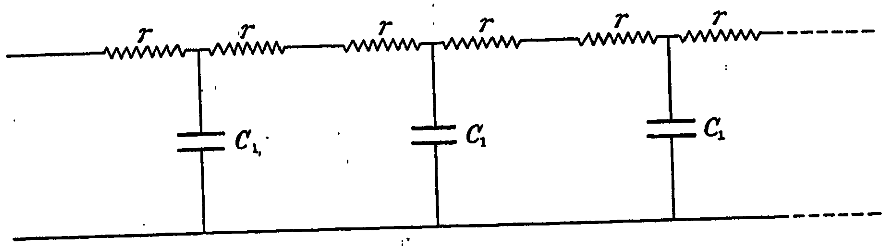

FIG. 9.

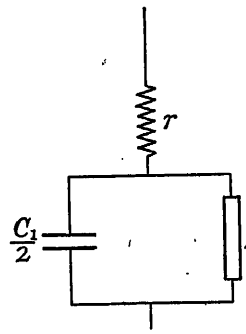

FIG. 10.

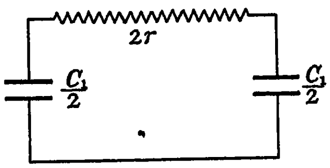

FIG. 11.

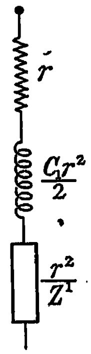

FIG. 12.

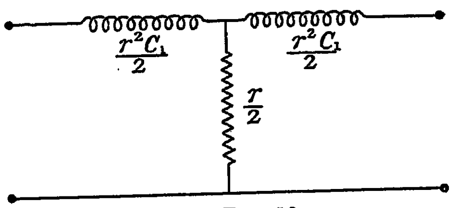

FIG. 13.

A line balance can be made using **T** sections such as that shown in Fig. 2,

where
$$r_1 = 652 \text{ ohms}$$
$$r_2 = 6\,420 \text{ ohms}$$
$$C_1 = 1{\cdot}34\ \mu\text{F}$$

If n sections are used, short-circuited at the far end, the ratio of the impedance of this network to that of the given uniform line will be $\tanh n\theta$. Tanh $n\theta$ has been calculated for this case for $n = 1$, 2, 3 and 6, and $p = 2\,000$ and $12\,000$, i.e. for about 300 and 2 000

* *Philosophical Magazine*, 1925, vol. 49, p. 728.

an accuracy much greater than is usually required in practice.

Part 2.

It is well known that the impedance of the network shown in Fig. 7 is equal to R, provided that $L = R^2C$, i.e. $jpL = R^2/(1/jpC)$, or the impedances of L and C are reciprocal to R. This at once suggests the generalization that the impedance of the circuit of Fig. 8 is identically equal to A ; the proof is obvious. If A is resistance, the reciprocals of a resistance, a capacity or an inductance with respect to A are a resistance, an inductance or a capacity respectively. Now we know that the

impedance of a uniform line (assumed to be without leakage for the sake of simplicity) can be represented by a network of the form of Fig. 9. This is of the form of Fig. 10, where Z' is the infinite Π-section artificial line having the section shown in Fig. 11.

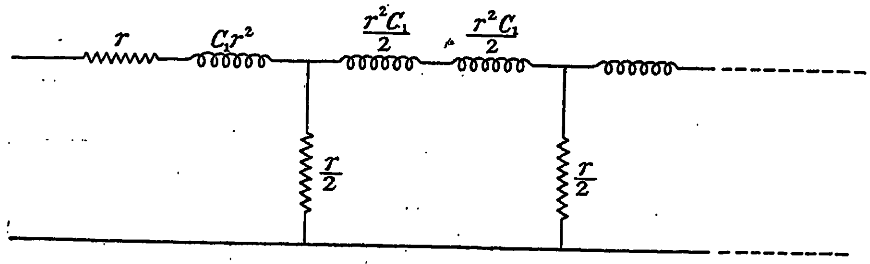

FIG. 14.

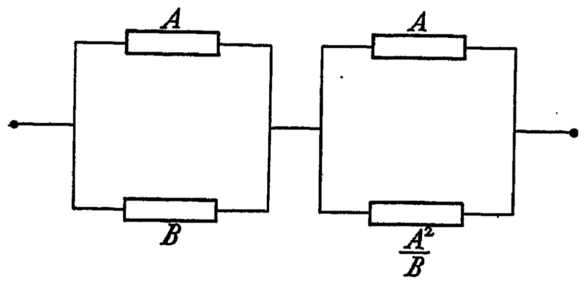

FIG. 15.

If we connect a circuit as Fig. 12 in parallel with the circuit of Fig. 10, we shall reduce the impedance of the combination to r. The impedance r^2/Z' is the reciprocal with respect to r of an infinite series of Π section (Fig. 11), and is therefore an infinite series of **T** sections of Fig. 13, having for series members inductances equal to $\frac{1}{2}r^2C_1$, and for shunt members resistances equal to $\frac{1}{2}r$. Hence by shunting the infinite line by the network of Fig. 14 the impedance is reduced to r, i.e. $\sqrt{(L/C)}$. In practice the use of quite a small number of sections of this artificial line suffices to reduce the impedance of the combination to a close approximation to a non-inductive resistance.

Results of similar form follow for the other **T** sections.

From the Π section, except for the case when $S = 0$, other shunting networks can be deduced in the same way, or, by using the result that the network of Fig. 15 is identically equal to A, networks which when placed in series with a uniform line reduce its impedance to a resistance can be obtained.

For the Π-section case where $S = 0$, by a double application of the result of Fig. 8 two networks can be obtained which together shunted across the line reduce its impedance to a resistance.

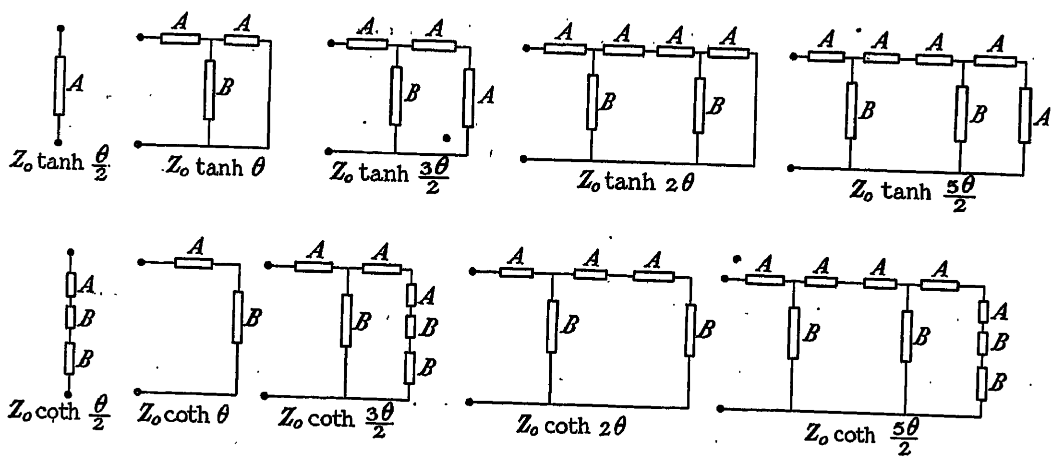

FIG. 16.

CURRENT-TRANSFORMER METHODS OF PRODUCING SMALL, KNOWN VOLTAGES AND CURRENTS AT RADIO FREQUENCIES FOR CALIBRATING PURPOSES.

By D. W. Dye, B.Sc.

[From the National Physical Laboratory.]

(*Paper first received* 31*st October*, 1924, *and in final form* 27*th April*, 1925; *read before the* Wireless Section 4*th March*, 1925.)

Summary.

A method is outlined whereby known, small radio-frequency voltages may be produced. The method consists of an arrangement of a current transformer, across the secondary of which is a suitable resistance of known value. A thermo-junction or other device serves to measure or to set the primary current. Voltages from a few microvolts to a few tenths of a volt may be conveniently produced. The nature and extent of the errors of the method are discussed, and the precautions necessary to reduce these to a negligible amount are indicated. Various uses of the method are touched upon and the limitations of the method are given.

An appendix gives a simple analytical treatment of the iron losses in the core of a current transformer at radio frequencies, in so far as these affect the ratio of the transformer. The phase displacement of the currents is, however, not discussed.

(1) Introduction.

In connection with investigations on the strength and direction of received radio signals, the strength and direction of atmospheric disturbances, measurements of the amplification of radio-frequency amplifiers and in certain classes of decrement measurement, it becomes necessary to calibrate some part of the apparatus by the help of a known, very small voltage or current applied to a particular portion of the system concerned.

A number of methods for the production of known voltages are in use by various investigators. These methods fall into two main classes:—

(1) Potential difference between the ends of a resistance. The resistance usually forms a portion of a potential divider when the voltage required is very small indeed.
(2) Electromotive force induced in the secondary coil of a mutual inductance.

These two methods are discussed at length in a paper by H. G. Möller and E. Schrader,* and a number of typical cases have been taken with a view to indicating the nature and extent of the inaccuracies which may be introduced unless certain precautions are taken.

Certain disadvantages of these two methods have not, however, been explained. With regard to class (1), when the desired voltage is very small (below 500 μV) it is necessary to use a very low resistance if the measured current through it is used as a basis of calculation. In such a case the residual inductance of the resistance may introduce large corrections. If the voltage is deduced from the ratio of a low and a high resistance in series, recourse must be had to an instrument capable of directly reading at least 1 or 2 volts, unless a very high resistance is used in series so that the total voltage may be read on an electrostatic instrument. The self-capacity of such a resistance and the mutual capacity to other parts of the apparatus will again introduce serious corrections. This method has, however, been successfully used in America * for low radio frequencies. The chief advantage of resistance methods is that, except for the corrections, the voltage produced does not depend upon frequency.

With regard to class (2), the main source of trouble is the relatively high impedance of the secondary winding of the mutual inductance. If the secondary is considered to be the source of the required electromotive force, then this source possesses a high internal impedance and hence the terminal voltage will depend upon the impedance of the circuit to which it is applied, unless this is very high. The capacity between primary and secondary windings, in such a case, may also introduce considerable changes in the effective secondary voltage. Finally, the voltage produced depends to the first order upon frequency.

The method is, however, extremely flexible, and when used with precautions, is capable of giving accurate results. Its special sphere of usefulness is at low radio frequencies.

The method described in the present paper partakes of the good qualities of both the foregoing methods and is believed to be to a large extent free from the disadvantages of either.

(2) Principle of the Method.

The essential feature of the method is the use of a current transformer whereby a known, very small current may be produced from a larger, directly measured one. The principles underlying current transformers for radio frequencies have been set out in a previous paper by A. Campbell and the present author.† This paper deals with the use of such transformers for the measurement of large currents. Reference is also made to the use of such apparatus for the measurement of very small currents; but there are serious limitations

* "On the Production of Small Alternating Voltages of Known Value," *Jahrbuch der Drahtlosen Telegraphie*, 1923, vol. 22, p. 66.

* R. Bown, G. C. Englund and H. Friis: "Radio Transmission Measurements," *Proceedings of the Institute of Radio Engineers*, 1923, vol. 11, p. 115.

† "On the Measurement of Alternating Electric Currents of High Frequency," *Proceedings of the Royal Society*, A, 1914, vol. 90, p. 621.

to the use of transformers in this direction. There are, however, no drawbacks to the use of current transformers for producing known, small currents in a secondary circuit, so long as certain conditions in the circuit are satisfied. In order to produce a known, small voltage we have only to pass the small secondary current through a moderate resistance provided with potential leads. The system is therefore as shown in Fig. 1.

Current of the value of a few mA to 100 mA is provided by a local high-frequency source. This current is measured by a heater and thermo-junction, and also passes through the primary winding (N_1) of the transformer. This winding consists of one or a few turns (N_1) of stranded wire and has an inductance which is, in general, negligibly small compared with the main inductance in the source.

The secondary winding consists of N_2 turns uniformly wound around a bundle of iron ring stampings, and thus forms a toroidal iron-cored inductance. This winding is connected to a non-inductive resistance R having a value between 1 and 50 ohms. This resistance should have separate potential leads in order that contact resistances may introduce no uncertainties, and also to eliminate or compensate residual inductance if necessary. The desired potential difference is obtained from the potential leads and is applied to the apparatus under test.

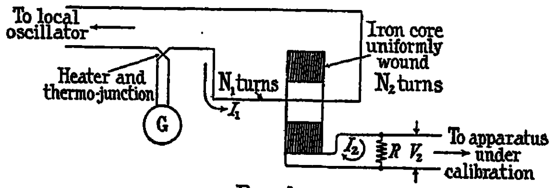

FIG. 1.

Within certain limits discussed below, the current I_2 traversing R is independent of the value of R and so a considerable range of voltage is available. The voltage V_2 is, to a close approximation, given by

$$V_2 = \frac{N_1}{N_2} I_1 R \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The current transformer is, of course, only a special form of mutual inductance, and need not take the form given above.

In more general terms of mutual and secondary self-inductances Equation (1) becomes :—

$$V_2 = \frac{M}{L_2} I_1 R \quad . \quad . \quad . \quad . \quad . \quad (2)$$

If, however, a mutual inductance of the more usual form is used it becomes necessary to measure or calculate M and L_2 in order to determine their ratio. With suitably designed windings there will be no great uncertainty of ratio if M and L_2 are measured at low frequencies.

There are, however, a number of advantages attached to the interlinking of the primary and secondary windings. We then make use of the principle that the line-integral $\int H dl$ around a conductor or bundle of conductors is constant and independent of the path followed. If, therefore, the secondary winding is of uniform cross-section and uniformly wound in such a manner as to have no appreciable leakage magnetic field when linked with the primary, the mutual inductance will be independent of the location of the two windings with respect to one another, and the ratio of secondary self-inductance to mutual inductance will be exactly equal to the ratio of secondary to primary turns and will be independent of all the dimensions.

It is only necessary in such a case to take a ring-shaped core of uniform section and uniform permeability and wind it with a uniform winding to form the secondary circuit. In some cases the core may be magnetic, but in others it is preferably non-magnetic. The primary may then consist of between 1 and 20 turns or even more. These may theoretically be wound in any manner whatever so long as they link the secondary. They are, however, better if symmetrically disposed about the secondary. When the secondary winding is effectively short-circuited the ratio of secondary to primary current will be N_1/N_2 to a high degree of accuracy, and no measurement of self-inductance or mutual inductance is necessary. This ratio will also be almost independent of frequency.

Two examples are given below to indicate the range of voltages conveniently available.

Very small voltage.

$I_1 = 2 \times 10^{-3}$ ampere
$N_1 = 1$ turn
$N_2 = 200$ turns
$R = 0{\cdot}1$ ohm (not recommended at high frequencies)
$E_2 = 1 \times 10^{-6}$ volt

Moderate voltage.

$I_1 = 100 \times 10^{-3}$ ampere
$N_1 = 10$ turns
$N_2 = 100$ turns
$R = 50$ ohms
$E_2 = 0{\cdot}5$ volt.

(3) CONDITIONS GOVERNING THE ACCURACY OF THE METHOD.

There are two sets of conditions governing the accuracy of the method :—

(*a*) Those inherent in the method itself.
(*b*) Those depending upon the nature of the circuit to which it is applied.

Dealing with (*a*) first, the equations connecting primary and secondary currents in an air-core current transformer are as follows :—

(i) *For damped or modulated wave-form.*—

$$\frac{I_2}{I_1} \doteq \frac{M}{L_2}\left[1 - \frac{R_2\{R_2 - (\delta_1/\pi)L_2\omega\}}{2L_2^2\omega^2}\right] \quad . \quad . \quad (3)$$

(ii) *For sine-wave form.*—

$$\frac{I_2}{I_1} \doteq \frac{M}{L_2}\left(1 - \frac{R_2^2}{2L_2^2\omega^2}\right) \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where δ_1 = logarithmic decrement per whole period,
L_2 = total self-inductance of the secondary circuit,
M = mutual inductance between primary and secondary,
R_2 = total effective resistance of secondary circuit.

Considering only the sine-wave case, it is seen that the only term involving frequency is the correction term $\frac{1}{2}\{R_2/(L_2\omega)\}^2$. If it is desired to keep this correction term not greater than 0·5 per cent, the value of $R_2/(L_2\omega)$ must be not greater than 0·1. For various reasons an upper limit of R_2 should be about 50 ohms. In an extreme case in which ω is only 10^5 it will be necessary to make L_2 as great as 5 mH. To achieve such a value even with an iron core would require a considerable number of turns on the secondary winding. If, at the same time, we wished to produce a considerable voltage it would be necessary to provide a considerable number of primary turns—about 20. At such a low frequency, however, there will be no objection to this, since a very large inductance in the generator oscillatory circuit will be inevitable.

For the case of damped waves, an inspection of Equation (3) shows that for all ordinary values of δ_1 the term $(\delta_1/\pi)L_2\omega$ will be not greater than R_2 unless R_2 is very small, in which case the whole correction will still be small. We may write $L_2\omega = qR_2$; Equation (3) then becomes

$$\frac{I_2}{I_1} \doteq \frac{M}{L_2}\left\{1 - \frac{1}{2q}\left(\frac{1}{q} - \frac{\delta_1}{2\pi}\right)\right\} \quad . \quad . \quad (5)$$

As an example, if $q = 10$ then $\delta_1/(2\pi)$ would need to be equal to 0·2 before the correction term became + 0·5 per cent on account of δ_1. In such a case δ_1 would need to be 1·26.

Sine-wave modulated waves may be considered to be of the form

$$i = I_0(1 + r \sin ft) \cos \omega t$$

This may be considered to be equivalent to three independent sine-wave sources having the values

$$I_0 \cos \omega t + \tfrac{1}{2}I_0 r \sin (\omega + f)t + \tfrac{1}{2}I_0 r \sin (\omega - f)t$$

The R.M.S. current will then take the form

$$I_{R.M.S.} = \frac{1}{\sqrt{2}}I_0\sqrt{(1 + r^2)}$$

In practice the three frequencies are not very different from one another, so that the mean correction term in (4) will be almost identical with that for a single sine-wave case. The worst case would be that of a completely modulated wave with the carrier wave suppressed. In such a case the correction term would be increased in the ratio of $1 : (1 + f^2/\omega^2)$. The value of f is never likely to be greater than 1/20th of ω. In this case the increase in the correction term is entirely negligible.

In the case of an iron-cored transformer the hysteresis and eddy-current losses in the iron introduce a correction term which is proportional to R_2 and not to R_2^2. This question is dealt with more fully in the Appendix.

The additional term which will be inside the bracket of Equation (4) takes the form

$$- R_2\frac{m_2^2 S}{L_2^2(N^2\omega^2 + S^2)}$$

where the iron losses are represented by a tertiary circuit having constants of resistance and inductance equal to S and N respectively and coupled with the secondary circuit by mutual inductance m_2. The correction term due to the iron losses may be very conveniently written

$$\frac{\pi}{4}\delta i\frac{R_2}{L_2\omega}$$

where δi represents the logarithmic decrement * of the magnetic core. This term tends to become more important than the second term of Equation (4) if the flux density in the iron is not kept very low. Since δi may approach unity in an extreme case it is very desirable to keep $R_2/(L_2\omega)$ as small as convenient. In general a value of 0·05 should be considered as a working limit for the method when using an iron-cored transformer.

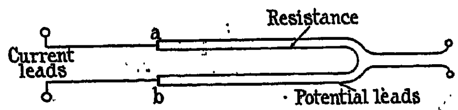

FIG. 2.

When the method is in use it is easy to see if the correction terms are small. There are two ways of doing this :—

(a) To vary the ratio of transformation and then alter R to bring the nominal voltage to the same value. There should be no alteration in the voltage as indicated on the amplifier or other device under calibration.

(b) A resistance of 10 ohms or so may be added in the secondary circuit in series with the standard resistance across which the desired voltage is produced. There should be no change in I_2 and hence no change in the voltage across R. Both these methods have been tried and no appreciable change in voltage across R could be detected in a case in which this calibrating method was used in connection with measurements on signal strength. In general, the surest way of ascertaining that the value of R chosen is not too large is to add a resistance equal to $\frac{1}{2}R$; the total correction will then become about twice what it was before. Hence the change noted can be used to correct the original observation if found great enough.

There are two other quantities associated with the method which may introduce errors in the value of the electromotive force at the potential points of R. These are, residual inductance l in the resistance, and capacity between the points "a, b" of Fig. 2. Such

* The logarithmic decrement of the magnetic core may be defined as the ratio $\Delta R/(2\pi\Delta L)$, where ΔR and ΔL are the increases in effective resistance and effective inductance respectively of an inductive coil, due to the presence of the magnetic core. The ratio is independent of the shape or size of the core.

capacity will include the self-capacity of the secondary winding and of the leads connecting R to it.

For the capacity effect we may consider R to be replaced by a condenser and a resistance in parallel. The equivalent series impedance of such a combination is given by

$$R_0 = \frac{R}{1 + R^2C^2\omega^2} \doteqdot R(1 - R^2C^2\omega^2)$$

and
$$L_0\omega = - R^2C\omega$$

We may consider the total ingoing current I_2 as being entirely unaltered by the addition of C. We have, therefore,

$$\begin{aligned} E_2 &= I_2\sqrt{\{R^2(1 - R^2C^2\omega^2)^2 + (R^2C)^2\omega^2\}} \\ &\doteqdot I_2\sqrt{\{R^2(1 - R^2C^2\omega^2)\}} \\ &\doteqdot I_2R(1 - \tfrac{1}{2}R^2C^2\omega^2) \end{aligned}$$

If we take an extreme case, we may have $R = 50$ ohms, $C = 200\,\mu\mu$F, $\omega = 10^7$. The correction then becomes equal to 0·5 per cent.

The second source of error resides in the inductance of the resistance. Instead of $E_2 = RI_2$ we shall have

$$E_2 = RI_2\sqrt{\left(1 + \frac{l^2\omega^2}{R^2}\right)}$$

where l is the residual inductance of the resistance.

If the correction term is small, this may be written

$$E_2 = RI_2\left(1 + \frac{l^2\omega^2}{2R^2}\right)$$

Taking an extreme case, and assuming that the correction term must not exceed 0·5 per cent, we have $l\omega = R/10$.

If $R = 0\cdot1$ ohm and $\omega = 10^7$,

$$l = 1 \times 10^{-9} \text{ henry, i.e. 1 cm only.}$$

If the resistance is a four-terminal one, the effective inductance will include mutual inductance between the current and potential leads. Use can be made of this property to compensate the true residual inductance so as to cause the effective residual inductance to be strictly zero, as first shown by Campbell.*

There are, however, considerable uncertainties attaching to the measurement of residual inductance of low resistances to such an accuracy as 0·001 μH. It is considered undesirable, therefore, to use resistances smaller than 1 ohm at high radio frequencies. Even with this value, care should be taken in the construction and mounting of the resistance and its leads. These should be arranged in a manner which will bring about a compensation in the potential leads if accuracy is required at high radio frequencies. If the resistance consists of a loop of wire only 1 cm or so long doubled closely on itself, its inductance will be only of the order 0·01 μH, a value of importance only at frequencies above 10^6 per second. A suitable form of resistance is shown in Fig. 2.

It will be convenient to discuss the effects of the circuit to which the transformer is connected, when describing some of the applications and the convenient arrangement of the circuits.

(4) Arrangement of the Apparatus.

A suggested outlay of a valve generator apparatus suitable for the method is given in Fig. 3. The oscillatory circuit consists of toroidal inductance L_1 and screened adjustable capacity C_1; this circuit is outlined with heavy lines and shows a two-turn primary winding on the current transformer. A thermo-junction and a galvanometer G serve to measure the primary current. The parts of the circuit at a high alternating potential above that of the point marked B are enclosed in a metal-lined box which is connected to the circuit at B. A large condenser C_2 across the anode battery serves to keep its impedance practically zero. The only external lead requiring a screen is that going to the insulated, fixed set of plates of the variable condenser. If this scheme is carried out there is practically no potential difference between any two points in the external circuit or the oscillator, except at the place where it is required.

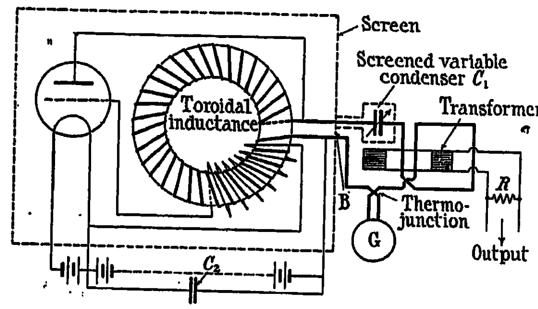

Fig. 3.

It is not essential to use a toroidal form of inductance in every case, but where highly sensitive apparatus is being calibrated the superiority of this form from the point of view of screening will be evident. In such a case it is really only necessary to provide electrostatic screening against capacity coupling between the oscillator and the apparatus being calibrated. Some measurements made on toroidal coils showed that their effective self-capacity was only about 50 per cent greater than those of the single-layer cylindrical type of the same overall diameter.

When toroidal coils are used in a one-valve oscillator it is essential to use a separately wound grid inducing coil. This coil should not be completely overwound on the main oscillator coil but may extend from $\frac{1}{4}$ to $\frac{1}{3}$ the distance round the ring, commencing at the point connected to B.

In oscillator circuits used in this manner for calibrating purposes it is desirable to keep the capacity C_1 as large as possible. A capacity of 0·002 μF is not too large in most cases.

Typical transformer.—A transformer constructed at the National Physical Laboratory for general laboratory use consists of a secondary winding of 100 turns uniformly wound around the core. There are three primary windings of 1, 5 and 10 turns respectively. The turns of

* "Compensation of Residual Inductance in Four-terminal Resistances," *Electrician*, 1908, vol. 61, p. 1000.

the secondary winding are located in position by small notches spaced around the four circular edges of a ring-shaped ebonite box in two halves. This box contains the iron stampings forming the core. These latter are of thin stalloy and have a cross-sectional area of about 2 cm^2. In some cases where relatively large voltages are required at low radio frequencies it is desirable to use a larger cross-section of iron than 2 cm^2. A larger resistance may then be used without increasing the flux in the iron to a value at which the iron correction term becomes serious.

(5) Applications of the Method.

The method of applying the voltage to other apparatus will, of course, vary considerably according to the conditions which must be maintained in the apparatus, and to its impedance. The factors to be considered are :—

(1) The effect, on the applied voltage, of the circuit to which it is applied.

(2) The effect, on the circuit, of the application or introduction to it of the resistance across which the applied voltage is produced.

(i) *Calibration of an amplifier.*—When the amplifier is of a type possessing the very high input impedance of the grid-filament circuit of the first valve, the attachments of this to the terminals of the resistance will not alter the calibrating voltage. The main precautions to be taken then consist in so arranging the disposition and connections of the parts that no electromotive forces, other than that directly applied, may operate on the amplifier system. In a case where the grid filament is directly connected to the resistance, any capacity coupling to this valve will be of negligible consequence, but when the grid and filament are separated by a small condenser of comparatively high impedance the leads and other parts of the grid circuit may receive an alternating potential which is not negligibly small, as the result of capacity coupling to portions of the generator system. On this account it is desirable to connect the transformer primary at the high-tension battery end of the toroidal inductance and not at the inductance end joined to the anode of the generator valve. In the latter case the capacity coupling between the primary and secondary of the transformer, together with the capacity of the amplifier valve to earth, constitute a circuit in which a parasitic current will flow. As a result an additional E.M.F. will be applied to the grid-filament circuit of the valve of the amplifier.

Some measurements made on transformers gave values for the mutual capacity varying between the limits of 1·5 $\mu\mu$F and about 10 $\mu\mu$F, depending upon the number of primary turns.

The most rigorous test to apply, to ensure that these parasitic E.M.F.'s are not of importance, is to reduce the applied voltage to zero by making R zero. There should now be no difference in the amplifier measuring circuit when the calibrating oscillator is switched off and on. In general when a very sensitive amplifier is under calibration it is impossible to realize this condition perfectly, unless complete electromagnetic screening is adopted as well as inserting the primary of the transformer on the anode battery side of the oscillator inductance.

(ii) *Calibration of a receiving system.*—When it is desired to introduce a known E.M.F. into an oscillatory circuit of low resistance, two effects will occur. The applied voltage will be reduced, owing to the shunting effect of the circuit on the resistance. Also, the voltage amplification of the receiving circuit will be reduced, owing to the increase of its effective resistance consequent upon the addition of the resistance R.

If the oscillatory circuit has an effective resistance S, then when in resonance it will reduce the voltage across the terminals of R in the ratio $S/(R+S)$. Also, by reason of the increase in effective resistance of the oscillatory circuit from S to $(S+R)$, the voltage amplification of the circuit will be reduced in the ratio $S/(R+S)$. The nominal voltage applied must therefore be multiplied by the factor $S^2/(S+R)^2$ in order to render it equivalent to an unaffected voltage operating on the unaffected resistance of the receiving circuit. Since, in general, the effective resistance of a receiving system will not be greater than 20 or 30 ohms and may be as low as 1 or 2 ohms, the correction terms may become very serious, and would entail an accurate knowledge of S. It is suggested, therefore, that this method of applying a voltage to a receiving system must be used with great caution and with full knowledge of the conditions of the receiving system.

(iii) *The provision of a very small current or voltage in an inductive coil—such as a Bellini-Tosi inducing coil.*—In such a case the conditions are quite different, since the transformer is not effectively short-circuited. In this use of the method it will be essential to use an air-core transformer in order that the secondary inductance may be invariable with frequency and current.

The formulæ for current ratio will be as in Equations (3) and (4), but instead of L_2 we shall have (L_2+L_3), where L_3 is the self-inductance of the coil through which the desired current is passing. The secondary winding of the transformer should again be toroidal in form and may be wound conveniently on a frame made up of two ebonite rings separated by three ebonite pillars. If the ratio of secondary to primary turns is N_2/N_1, then the secondary current in the external coil will be given by

$$\frac{I_3}{I_1}=\frac{N_1}{N_2}\cdot\frac{L_2}{L_2+L_3}\left\{1-\frac{R_t^2}{2(L_2+L_3)^2\omega^2}\right\} \quad . \quad (6)$$

in which R_t is the total effective resistance of the secondary circuit.

When L_3 is not small compared with L_2 it may become necessary to take account of the self-capacities of the secondary winding and of the external winding; the capacity of the connecting leads will also need to be included. For the purpose of making this correction we may consider these capacities to be represented by a single concentrated capacity shunted across the secondary winding. Calling this capacity C it will be found that the ratio of current in the external coil to that in the primary is given by

$$\frac{I_3}{I_1}=\frac{N_1}{N_2}\cdot\frac{L_2}{L_2+L_3}\left\{1-\frac{R_t^2}{2(L_2+L_3)^2\omega^2}+\frac{L_2L_3C\omega^2}{L_2+L_3}\right\} \quad (7)$$

It will be seen that the corrections are of opposite signs. Since, however, the first term varies inversely as ω^2, whilst the second one varies directly as that quantity, a compensation cannot be obtained over any useful range of frequency.

It is desirable, in general, to keep L_2 fairly large compared with L_3. In this case L_2 and L_3 do not need to be known with very high accuracy. If, however, $L_3C\omega^2$ is as great as $0{\cdot}1$ it would be better to keep L_2 about the same value as L_3 in order to reduce the value of the second correction term.

Except at very low radio frequencies the first correction term will not be large, since we are not adding resistance intentionally in the secondary circuit.

For recommendation and permission to publish the method, the author's thanks are due to the Committee of the Radio Research Board on Standards and the Propagation of Waves established under the Department of Scientific and Industrial Research, under whose auspices the work was done. He is also indebted to Mr. Hollingworth, of the Wireless Division of the National Physical Laboratory, where the method has been adopted, for confirmatory information regarding some of the points referred to in the paper.

APPENDIX.

IRON-CORED CURRENT TRANSFORMER.

Consider iron losses as equivalent to a closed tertiary circuit N_1S carrying an instantaneous current i_3' (see Fig. 4).

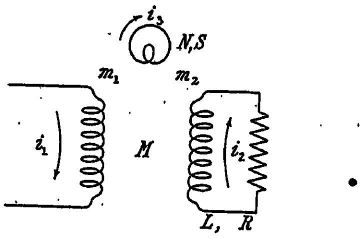

FIG. 4.

We have

$$i_2(R + La) + e_2 = 0 \quad . \quad . \quad . \quad . \quad (8)$$

$$i_3(S + Na) + e_3 = 0 \quad . \quad . \quad . \quad . \quad (8a)$$

$$e_2 = i_1Ma + i_3m_2a \quad . \quad . \quad . \quad . \quad (9)$$

$$e_3 = i_1m_1a + i_2m_2a \quad . \quad . \quad . \quad . \quad (9a)$$

where

$$a = j\omega$$

from which

$$i_3 = -\frac{i_1m_1a + i_2m_2a}{S + Na}$$

and

$$i_2(R + La) + i_1Ma - \frac{m_2a}{S + Na}(i_1m_1a + i_2m_2a) = 0$$

$$i_2\left\{(R + La) + \frac{m_2^2\omega^2}{S + Na}\right\} = -i_1\left\{Ma + \frac{m_1m_2\omega^2}{S + Na}\right\}$$

whence

$$\frac{I_2^2}{I_1^2} = \frac{(MN - m_1m_2)^2\omega^4 + M^2S^2\omega^2}{\{(LN - m_2^2)\omega^2 - RS\}^2 + (LS + RN)^2\omega^2} \quad . \quad (10)$$

$$= \frac{M^2\omega^2\left(N\omega - \dfrac{m_1m_2\omega}{M}\right)^2 + M^2\omega^2S^2}{L^2\omega^2\left(N\omega - \dfrac{m_2^2\omega}{L} - \dfrac{RS}{L\omega}\right)^2 + L^2\omega^2\left(S + \dfrac{RN}{L}\right)^2} \quad (11)$$

If we assume m_1m_2 to be small compared with MN, we shall find that

$$\frac{I_2^2}{I_1^2} = \frac{M^2}{L^2}\left[1 - \frac{R^2}{L^2\omega^2} + \frac{2m_2^2\omega^2}{N^2\omega^2 + S^2}\left(\frac{N}{L} - \frac{Nm_1}{Mm_2} - \frac{RS}{L^2\omega^2}\right)\right] \quad (12)$$

The only important term due to the tertiary circuit is the term $RS/(L^2\omega^2)$, since $(Nm_1)/(Mm_2) \doteq N/L$. We therefore have :—

$$\frac{I_2^2}{I_1^2} \doteq \frac{M^2}{L^2}\left[1 - \frac{R^2}{L^2\omega^2} - \frac{2m_2^2RS}{L^2(N^2\omega^2 + S^2)}\right] \quad . \quad (13)$$

The relative importance of the second correction term will depend upon the nature and extent of the iron losses. There is a lack of information regarding the losses in iron sheets at very small alternating inductions of radio frequency. In a typical case of a well designed transformer the effective R.M.S. magnetizing force will be of the order of 1×10^{-4} to 5×10^{-4}. At such weak magnetizations the hysteresis losses become small compared with the eddy-current losses, since the former vary as a power of B which is considerably greater than 2. The second correction term in Equation (13) cannot be used in its present form owing to the uncertainties attaching to the values of m_2, S and N, and to the fact that these quantities will vary with $B_{max.}$ and frequency. It is therefore desirable to introduce some more fundamental term to express the effects of the losses in the iron core. For this purpose it is very convenient to think of the core as possessing a logarithmic decrement δi given as the ratio $\Delta R/(2n\Delta L)$, where ΔR and ΔL are the increments of resistance and inductance respectively conferred upon any circuit in virtue of the iron core.

Consider the single winding of N_2 turns of the transformer on a circular core of magnetic material of effective permeability μ and of cross-section and length s and l respectively.

We shall have

$$L = \frac{1{\cdot}257 \times N_2^2 \times \mu \times s \times 10^{-8}}{l} \text{ henry}$$

Let a current I_e be flowing in the winding, of such value as to produce the value of H actually existing in the current-transformer core in normal use. We shall have

$$H = \frac{4\pi N_2I_e}{10l} \quad . \quad . \quad . \quad . \quad . \quad (14)$$

The circuit will have a resistance component r representing the iron losses. This resistance will be such that $rI_e^2 = W =$ iron losses. We have also $r/(2Ln) = \delta i$.

Reverting for a moment to the transformer case, we have, at the secondary terminals, a voltage E_2 given by

$$E_2 = RI_2$$

The value of H necessary to produce this value of E_2 will be given by

$$E_2 = 2\pi N_2 H\mu sn \times 10^{-8} \quad . \quad . \quad . \quad (15)$$

where n = frequency.

We can equate the two values of H in (14) and (15) thus:—

$$\frac{4\pi N_2 I_s}{10l} = \frac{E_2 \times 10^8}{2\pi N_2 \mu sn}$$

whence

$$I_s = \frac{RI_2 \times 10^9 \times l}{8\pi^2 \times N_2^2 \mu sn}$$

Now the iron losses are given by rI_s^2. We have

$$r = \delta i \times 2Ln$$

$$= \delta i \times \frac{2n \times 1 \cdot 257 N_2^2 \mu s \times 10^{-8}}{l}$$

The losses become

$$Wi = \frac{\delta i R^2 I_2^2 l \times 10^9}{8\pi^3 \times N_2^2 \mu sn} = \frac{\delta i R^2 I_2^2}{2\pi^2 nL}$$

The secondary losses are equal to RI_2^2.

The ratio of the losses, σ, is given by

$$\sigma = \frac{Wi}{RI_2^2} = \frac{\delta i}{\pi} \times \frac{R}{L\omega} \quad . \quad . \quad . \quad (16)$$

$$= \frac{I_3^2 S}{I_2^2 R} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (17)$$

in the equivalent of Fig. 4.

From Equations (6) to (9) we shall find that

$$\frac{I_3^2}{I_2^2} = \frac{m_1^2 R^2 + (m_1 L - m_2 M)^2 \omega^2}{M^2 S^2 + (MN - m_1 m_2)^2 \omega^2} \quad . \quad . \quad (18)$$

Since the primary and secondary windings are similarly situated with respect to the fictitious tertiary winding representing the iron losses, we may assume that $m_1/M = m_2/L$. We shall also have $m_1 m_2$ small compared with MN, so that

$$\frac{I_3^2}{I_2^2} = \frac{m_1^2 R^2}{M^2(S^2 + N^2\omega^2)} = \frac{m_2^2 R^2}{L^2(S^2 + N^2\omega^2)} \quad . \quad (19)$$

If we substitute σ from (16) into (18) we get

$$\sigma = m_2^2 RS/[L^2(S^2 + N^2\omega^2)]$$

so that 2σ is equal to the second correction term of Equation (13). But σ by (16) is equal to $\delta iR/(\pi L\omega)$.

We see, therefore, that, in terms of the fundamental properties of the iron, Equation (13) may be written

$$\frac{I_2}{I_1} \doteq \frac{M}{L}\left[1 - \frac{R^2}{2L^2\omega^2} - \frac{\delta i}{\pi} \cdot \frac{R}{L\omega}\right] \quad . \quad . \quad (20)$$

The quantity δi may vary over very wide limits according to the quality and thickness of the iron and according also to the frequency and the value of $H_{max.}$ to which it is exposed. With thin stalloy (0·02 mm thickness) and at a frequency of 10^5 cycles per second, δi has values varying between 0·01 and 0·1 for a range of $H_{max.}$ from a very small value up to $H = 0 \cdot 002$. On the other hand, with thicker iron and at higher frequencies δi may be as high as 1·5.

DISCUSSION BEFORE THE WIRELESS SECTION, 4 MARCH, 1925.

Mr. F. E. J. Ockenden: The author does not refer to the probable accuracy of his method, i.e. the accuracy which one could hope to attain by the use of cores of convenient dimensions and windings and the usual values of M. I have recently been experimenting with a current transformer of turn ratio 1/1 with 30 primary ampere-turns, using a differential thermo-couple to detect any difference between the primary and secondary currents. A typical result is as follows: Primary current, 1 ampere; primary turns, 30; secondary turns, 30; frequency, 1×10^6; secondary watts, 0·5; difference between primary and secondary currents, 1·5 per cent. In the second example given by the author the number of primary ampere-turns is 1·0 and the secondary watts = 0·005. Assuming that the error per cent falls as the square of the flux and therefore as the square of the secondary load, but varies inversely as the primary ampere-turns, the error would be $1 \cdot 5 \times (30/10) \times (0 \cdot 005/0 \cdot 5)^2 = 0 \cdot 0045$ per cent, or about 5 parts in 100 000. This appears to be exceedingly good. I do not know if it is the sort of accuracy which the author himself would expect. It occurs to me, however, to wonder whether, when the secondary load is exceedingly small, the core loss of the transformer is really the deciding factor. It is very difficult to wind an iron-core transformer with two windings so perfectly linked that the leakage flux is really nil, and at frequencies of between 10^5 and 10^6 a very small leakage

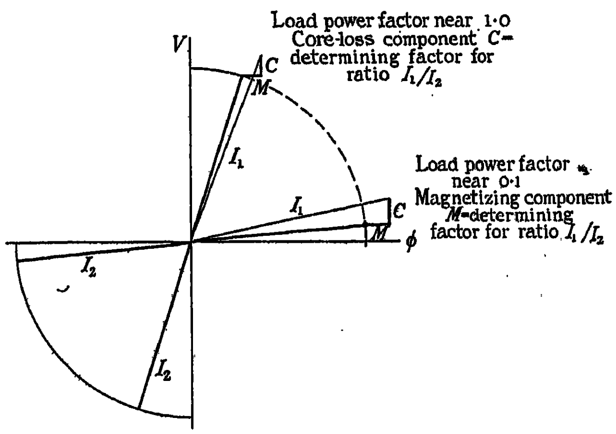

FIG. A.

flux will add to the secondary load a large inductance, which will reduce its apparent power factor to a figure far below unity. In the example mentioned before,

the power factor appeared to be only 0·40, i.e. cos ϕ = about 65°, and as the non-inductive component is reduced to lower and lower values the angle will approach nearer and nearer to 90°. The primary current will, of course, follow this very closely and the internal power factor of the transformer will remain very high, but, as the power factor of the load decreases, it will move more nearly into phase with the magnetizing component of the primary current and nearly in quadrature with the core-loss component. The latter will then have practically no effect on the transformer ratio, whereas the former or magnetizing component must be added vectorially to the primary current, or in the case of a 1/1 ratio may be deducted from the secondary current (see Fig. A). In reference to Fig. 3, the author mentions the necessity of carefully screening the oscillator circuit from the apparatus being calibrated, and states that this is very difficult to do perfectly. If it is difficult in the case of a small valve oscillator, it may be imagined that it is almost impossible however, when such a method is used for the purpose of signal-strength measurements, for here the secondary forms part of the antenna system and it is always the E.M.F. induced into the antenna system which is required to be simulated. We are thus not concerned with other than induced E.M.F.'s. In connection with signal-strength measurements, it is often necessary to go below the limiting value of 1 μV quoted by the author; for instance, in practical measurements I often go as low as 0·2 μV, and I should like to ask the author what arrangement of N_2 and R he would recommend for this purpose. The method I use is shown in Fig. C. Here M is a calibrated variable mutual inductance having a maximum value of the order of 1 μH, the primary being fed from a screened oscillator. The secondary, which has an inductance, L, of about 20 μH, is shunted by a non-inductive resistance, R, of 100 ohms, of which 1 ohm is tapped off and included in a frame-antenna circuit. The voltage, E, across the 1 ohm is given as a function of I_1, the current in the primary of

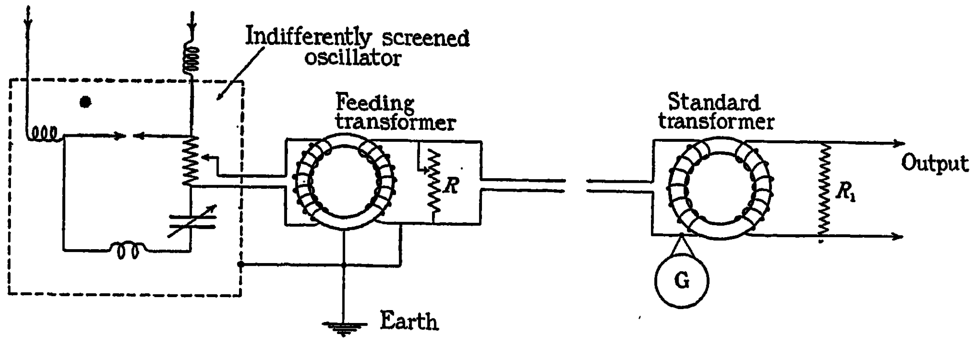

FIG. B.

in the case of a 2 kW Poulsen arc such as I have been using. I have tried screening the test apparatus only, but, apart from burying it, this seems almost as difficult. I have, however, successfully solved the problem by the use of a second iron-cored transformer. Thus, referring to Fig. 3, imagine the transformer shown to be merely a feeder transformer of indifferent accuracy. The core and secondary winding of this transformer may be earthed and the leads marked "output" may be carried away for a considerable distance and then be used to feed the primary of a second transformer, used as a standard, the thermo-couple being inserted in the primary of this second transformer. By using the resistance marked R as a variable shunt across the feeding transformer secondary, the current in the standard, and therefore the potential across R_1, may be adjusted to a nicety. At the same time the whole of the standard gear and the amplifier under test may be placed remote from the generator and exceedingly free from the parasitic potentials which the author mentions as being difficult to eliminate (see Fig. B).

Mr. F. E. Nancarrow: In the introduction to the paper the author states, in referring to the second method of producing small E.M.F.'s, that a disadvantage of the method arises from the high impedance of the secondary winding. No such disadvantage exists, the mutual inductance, and M, the value of the mutual inductance, by the following:—

$$E = \frac{RI_2}{100} = \frac{R}{100}\cdot\omega MI_1(R^2+\omega^2L^2)^{-\frac{1}{2}}$$
$$= \frac{R}{100}\cdot\frac{\omega MI_1}{R}\left\{1-\frac{1}{2}\left(\frac{\omega L}{R}\right)^2+\dots\right\}$$
$$\doteq \omega MI_1\left\{1-\frac{1}{2}\left(\frac{\omega L}{R}\right)^2+\dots\right\}$$

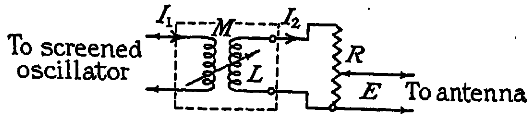

FIG. C.

Hence, provided that R is sufficiently large compared with ωL, the voltage across the tap is always proportional to I_1 and M. In a practical case where n = 60 000 p.p.s., i.e. $\omega = \frac{1}{3}\times 10^6$ (approx.) we have $\omega L = 20/3$ ohms and $\omega L/R = 1/15$, or $(\omega L/R)^2 = 1/225$, i.e. this term would involve a correction of less than $\frac{1}{2}$ per cent, which is negligible in practical measurements of signal strength. For the measurement of I_1 I actually use a valve voltmeter, which gives the voltage

across a condenser in the circuit including the primary of the mutual inductance, and from which I_1 is derived in the usual way. The author's method is of course fundamental, inasmuch as it only relies on the single measurement of current. I have found that a valve voltmeter, especially after much use, requires frequent recalibration, and I should be glad if the author could give any information as to the constancy to be expected from thermo-couples suitable for the measurement of currents of the order of 1 mA and less. On page 601 in connection with the calibration of a receiving system the author states: "If the oscillatory circuit has an effective resistance S, then when in resonance it will reduce the voltage across the terminals of R in the ratio $S/(R+S)$." This is very true and has of course to be taken into account in the application of the method I have described above. The author goes on to say: "Also, by reason of the increase in the effective resistance of the oscillatory circuit from S to $(S+R)$, the voltage amplification of the circuit will be reduced in the ratio $S/(R+S)$." In some methods of measuring signal strength, the resistance R is continuously kept in circuit, so that I do not think the second correction would apply.

Mr. J. Hollingworth (*communicated*): Since the introduction by the author of this method of producing accurate radio-frequency E.M.F.'s, we have made considerable use of it in the Wireless Section of the National Physical Laboratory and have found it of very great value. From the point of view of the practical user it possesses two very great advantages. The first is that, provided proper attention has been paid to the fundamental points in the design, all subsequent calibration is not at radio frequency but consists merely of ordinary Wheatstone-bridge resistance measurements. Consequently the apparatus can be modified and recalibrated in circumstances where there are no facilities for accurate high-frequency measurements. The second is the large range available from a single transformer, especially if not more than 2 or 3 per cent accuracy is required. The effective range of a variable mutual inductance is not usually large, at any rate on the more open portion of the scale, whereas with this system it is possible to retain the same accuracy over a very large range of intensity. In my present signal-measuring apparatus the primary contains two windings with 60 and 30 turns, the latter also being tapped so that altogether 90, 60, 30, 10 or 5 primary turns are available. The secondary is connected across a fixed resistance of 20 ohms divided into 2-ohm and 0·2-ohm sections. With this it has been possible to deal, with the same order of calibration accuracy, with signal intensities ranging from 10 to 17 000 microvolts per metre. As regards the absolute accuracy of the method, a direct check is almost impossible, owing to the difficulty of measuring the small secondary current to an accuracy comparable with that claimed by the system. It can of course be done by increasing both primary and secondary currents until the latter reaches a value which can be dealt with by a thermo-junction of suitable resistance, but in this case the iron-loss factor may become serious. Personally, at any rate for frequencies below about 2×10^5, I prefer to rely on the tests suggested by the author on page 599 and to accept the theoretical values as long as these are satisfied. I have also had the apparatus working at a frequency of 3×10^6, but have not had sufficient experience in this case to give a definite opinion of its working under practical conditions.

Dr. N. W. McLachlan (*communicated*): There is an error in Equation (12) which can be found readily by simplifying (11), when it will be discovered that $(Nm_1)/(Mm_2)$ should read $m_2^2/(2L^2)$. The correct expression for (12) is therefore

$$\frac{I_2^2}{I_1^2} = \frac{M^2}{L^2}\left\{1 - \frac{R^2}{\omega^2 L^2} + \frac{2m_2^2\omega^2}{S^2 + N^2\omega^2}\left(\frac{N}{L} - \frac{m_2^2}{2L^2} - \frac{RS}{\omega^2 L^2}\right)\right\}$$

To reproduce the author's version of Equation (13) it is essential that $N/L - m_2^2/(2L^2) = 0$. Now $m_2^2 = k_2^2 LN$, where k_2 is the coefficient of coupling between the fictitious tertiary circuit and the secondary winding. Making use of this condition we find that $(N/L)(1 - \frac{1}{2}k_2^2) = 0$, or $k_2^2 = 2$, which is only possible if we violate the law of conservation of energy. Since Equation (20) is derived by the aid of (12) and (13) it is clearly erroneous also. Then the derivation of (16) is accomplished by a confusion between mean, root-mean-square, and maximum values. The right-hand side of Equation (16) should read $(di/\pi)(R/\omega L)$, i.e. $\pi/4$ should be replaced by $1/\pi$.* Reverting now to the physical aspect of the problem, the use of a fictitious tertiary circuit may be of assistance mathematically—provided of course that the analysis is free from errors—but I do not think that it is so fundamental as a method based on a loss in the primary circuit. In a transformer having equal numbers of primary and secondary turns, the primary current would exceed the secondary by a small percentage owing to the magnetization loss in the iron necessitated by the ohmic resistance of the secondary. Assuming steady conditions and neglecting radiation, there would be no magnetization of the core if the secondary resistance were zero, and the error would vanish. Moreover, it appears reasonable to base the analytical work on the extra primary current. This is the customary practice pursued by engineers, and it seems to have stood the test of time. Following this procedure, I published a theory of iron-cored high-frequency current transformers more than eight years ago.† When the secondary load is purely resistive the error is—neglecting a term of the second order—given by $R \cos\theta/(\omega L)$ where $\cos\theta$ is the power factor of the primary winding due to the iron alone. In the same publication I discussed the question of loss and low flux density which obtains in these transformers, and from actual data and experiments showed that at low frequencies the error was many times that on high frequencies, since $\mu_a f$ increases with the frequency. Although the influence of capacity in the secondary circuit was omitted, an analysis was made at the time. Since capacity effects are negligible unless the wavelength is very short, publication was thought unnecessary. For example, at 600 m ($f = 5 \times 10^5$ p.p.s.) with

* Corrected for the *Journal*.
† N. W. McLachlan: "Theory of Iron-Cored High-Frequency Transformers," *Electrician*, 1916, vol. 78, p. 382.

a primary of 8 turns and a secondary of 150 on a core of 10-mil stalloy sheets 3 cm^2 cross-section and 10 cm mean diameter, a 0·003 μF condenser across the secondary caused an error of the order of 1 per cent. In dealing with decrement due to the iron, the author refers this to the secondary circuit. The only loss in this circuit is the I^2R of the copper winding, since the secondary magnetization is annulled by that due to the primary balancing current. It seems that the author's mode of viewing the matter is physically incorrect, in spite of its apparent mathematical orthodoxy. Errors due to large resistance and inductance in the secondary circuit have been examined experimentally and analytically in another paper.* My experience with current transformers has been confined chiefly to the measurement of fairly large currents, although some years ago I used them to obtain small voltages across an inductionless resistance in the secondary for purposes of measurement. As this occurred prior to the popular advent of valve amplifiers, the voltages were larger than those quoted by the author. I have recently, however, reverted to the method in measuring amplification. In the construction of current transformers there are several interesting practical points, some of which were cited in a recent article.† When a transformer has to cover a wide range of wave-lengths, it is imperative to design the primary and secondary windings to avoid excessive heating at short wave-lengths. A transformer may be quite cool at 1 500 m, whereas at 600 m it may heat up considerably due to I^2R loss in the secondary arising from increased resistance (the usual frequency effect), and to the proximity of the primary—especially if the turns are close to one another—causing additional eddy-current losses. If this happens, the primary and secondary turns must be decreased to allow a greater copper section on the primary and a less dense field due to the primary, the turns of which should be well away from the secondary. Stranded wire is useful in reducing heating due to this proximity effect. Then there is the problem of relatively small transformation ratio where a wide range has to be covered. For small error on long waves the secondary must have a reasonable number of turns, but in thus accommodating the secondary we should with a small ratio and a large primary current have to use small wire to thread the primary round the core the requisite number of times. This would increase the resistance of the primary circuit and probably cause local heating and reduced aerial current, and these are conditions to be avoided. Such a case can be met by using thin iron of reasonably large apparent permeability, so that the inductance of the secondary can be sufficiently high without having to use too many turns. Thus the factor $R \cos \theta$ in the error term $R \cos \theta/(\omega L)$ would be reduced considerably, since the copper section of the secondary could be augmented. The condition for minimum R/L with given iron and copper sections is that the core shall be circular. An approximation can be obtained by using stampings of different diameters, i.e. stepping the core. In practice, however, a square section will probably meet the requirements. In this country little or no attention has been paid to the commercial production of thin, pure iron or iron alloys of high resistivity. This is possibly due to the lack of interest evinced in iron-cored radio apparatus here, and also to a misconception of the properties of iron at radio frequencies. The thinnest material procurable is 0·25-mm (10 mil) stalloy, whereas in Sweden 2-mil stalloy can be obtained, and in America 1·5-mil pure iron. There are two points about very thin iron which are apt to be overlooked, viz. (1) the space factor, and (2) the cost of manufacture. There is a practical limit to the thinness of insulation between sheets, and this governs the space factor. Thick iron sheets give a small value of inductance at radio frequencies, whereas extremely thin iron means a goodly proportion of insulation, thereby yielding a like result. Thus there must be a happy medium or optimum thickness of metal for any given frequency. This result can be shown quite concisely by mathematical analysis if an elliptical hysteresis loop and a constant permeability throughout the thickness of the plate be assumed. In practice, of course, these conditions are violated. As regards cost, it is clear that, thin iron being more expensive and more difficult to handle, the transformer will be more expensive.

Mr. D. W. Dye (*in reply*): The points raised by Mr. Nancarrow are of great interest and I am glad of the opportunity to amplify and modify the statements made in the paper on account of the special and difficult conditions under which Mr. Nancarrow works. The successful measurement of signal strength when voltages

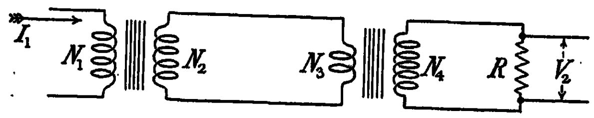

Fig. D.

so exceedingly small as 0·2 μV are involved is a triumph even to a rough degree of accuracy; without a considerable amount of serious experimenting I should not care to suggest any other methods than those Mr. Nancarrow has, doubtless after much painful experience, found to give consistent results. Whilst realizing that it is much easier to make suggestions than to carry them out, it occurs to me that a further extension of my method to the case in which still smaller voltages than those I have mentioned are required would be to use two transformers in cascade. That is, instead of connecting the resistance R of Fig. 3 directly to the transformer secondary, let us interpose another transformer as in Fig. D. If N_3 and N_4 are the primary and secondary respectively of the second transformer, then the equation for V_2 will be

$$V_2 \doteq \frac{N_1 N_3}{N_2 N_4} I_1 R$$

One can then easily step down a further hundredfold by making N_3/N_4 equal to, say, 1/100.

Mr. Nancarrow refers to the measurement of currents as small as 1 mA or less. It is precisely to avoid the necessity of using such small currents that the present

method has been evolved. I do not think that currents less than between 3 and 5 mA can be satisfactorily measured with portable apparatus by means of thermal heaters and vacuum junctions. Even for currents of this order it is necessary to use vacuum thermo-junction heaters of a type similar to those made by the Cambridge Instrument Co. These are chosen so that they may be calibrated with reversed direct current. In a good specimen the galvanometer deflections are not very different on reversal of the current through the heater. The calibration may then very conveniently be made in terms of a Weston miniature-type milliammeter in series with the heater. Such a calibrating arrangement would form a part of the set-up. The correction terms given for the case in which the resistance R is in a frame aerial or other receiving system include the effect produced on the system by the insertion of R in series in it. If this resistance forms a permanent part of the circuit and is included in the term S, then, of course, the correction term will need to be modified. If S is the total resistance including R, then instead of R in any of the equations given we shall write $R\,(1 - R/S)$ and no correction will be necessary on account of change of amplification of the receiving system.

Mr. Ockenden has raised the question of the accuracy of the method described in the paper. I should, I think, assess the overall accuracy at not better than 1 per cent, but I hesitate to commit myself to a definite figure. As far as the transformer itself is concerned, I think that an accuracy of knowledge of the small current to 1 per cent should be attained, if adequate shielding is provided to prevent parasitic currents from flowing through the resistance by reason of capacity. I think that the core loss is of importance, even at the very small inductions at which the iron is worked. The permeability tends to a constant value, and the power factor of the iron may also tend to a constant value since the eddy currents are more and more predominant over the hysteresis losses as the flux density is reduced. The method of using an intermediate current transformer for the purpose of eliminating the parasitic currents appears to be very good. As a result of Mr. Ockenden's remarks I suggested the use of an intermediate transformer as a suitable means of obtaining still smaller voltages such as have been used by Mr. Nancarrow. The scheme outlined in Fig. B has much to recommend it, but for voltages of less than 1 μV it would be necessary to insert the current-measuring device in the primary of the first transformer, which would also need to be of a design capable of giving a constant ratio.

With reference to the apparent error between Equations (11) and (12) to which Dr. McLachlan has referred, I am afraid that the way in which I have arranged these equations is misleading. The results obtained depend upon the place in the development of the equations at which the approximations are made. Intermediate stages were left out between Equations (11) and (12) and it is evident that an apparent inconsistency can be demonstrated, whereas in reality both Equations (12) and (13) are correct. I have set out here my reasoning in a slightly different manner from that which I originally used. Taking, first, Equation (11), we have

$$\frac{I_2^2}{I_1^2} = \frac{M^2\omega^2(N\omega - m_1 m_2\omega/M)^2 + M^2\omega^2 S^2}{L^2\omega^2\left(N\omega - \dfrac{m_2^2\omega}{L} - \dfrac{RS}{L\omega}\right)^2 + L^2\omega^2\left(S + \dfrac{RN}{L}\right)^2} \qquad (a)$$

For the case considered, and from the point of view of corrections which are not very large, we may assume that the coefficient of coupling between the NS circuit and the primary is equal to that between the NS circuit and the secondary. The coefficient of coupling between the primary and secondary may also be considered to be unity. Introducing suffixes to discriminate, for the moment, between the primary and secondary we shall have

$$L_1 L_2 = M^2\,; \quad L_1 N = k^2 m_1^2\,; \quad \text{and} \quad L_2 N = k^2 m_2^2$$

From these we derive that

$$m_1 = m_2 M \quad \text{and} \quad m_1 m_2/M = m_2^2/L$$

Equation (a) above may therefore be written

$$\frac{I_2^2}{I_1^2}\cdot\frac{L^2}{M^2} = \frac{(N\omega - m_2^2\omega/L)^2 + S^2}{\left(N\omega - \dfrac{m_2^2\omega}{L} - \dfrac{RS}{L\omega}\right)^2 + \left(S + \dfrac{RN}{L}\right)^2} \qquad (b)$$

Let $N\omega - m_2^2\omega/L = X$. The right-hand side of (b) becomes

$$\frac{X^2 + S^2}{X^2 - 2X\dfrac{RS}{L\omega} + \dfrac{R^2S^2}{L^2\omega^2} + S^2 + 2RS\dfrac{N}{L} + \dfrac{R^2N^2}{L^2}}\,. \qquad (c)$$

which reduces to

$$\frac{1}{1 + \dfrac{R^2}{L^2\omega^2}\left(\dfrac{S^2 + N^2\omega^2}{S^2 + X^2}\right) + \dfrac{2RS}{L\omega}\left(\dfrac{N\omega - X}{S^2 + X^2}\right)}\,. \qquad (d)$$

Now $N\omega - X = m_2^2\omega/L$; also, for the case under consideration, the coefficient of coupling between the tertiary circuit and the secondary circuit may be considered to be small. As far as corrections are concerned, therefore, we may consider $S^2 + X^2$ as equal to $S^2 + N^2\omega^2$. This gives for (d) the expression

$$\frac{1}{1 + \dfrac{R^2}{L^2\omega^2} + \dfrac{2RSm_2^2}{L^2(S^2 + N^2\omega^2)}}$$

or

$$\frac{I_2^2}{I_1^2} \doteq \frac{M^2}{L^2}\left[1 - \frac{R^2}{L^2\omega^2} - \frac{2m_2^2RS}{L^2(S^2 + N^2\omega^2)}\right]$$

exactly as given in the paper in Equation (13).

The deductions regarding the conservation of energy are of course without meaning, when obtained by consideration of the small differences arising between methods of approximation. The final equation, (20), is therefore not in error in respect of the equations discussed above. With regard to the constant $1/\pi$ in the last term of Equation (20), I regret to find that I made an error in deducing this and that in the advance copies of the paper it was incorrectly given

as $\pi/4$. I am indebted to Dr. McLachlan for pointing this out. The error was really in Equation (15). All the quantities were intended to be root-mean-square values, and the constant (4 in the advance copies) in that equation should therefore have been 2π. Since the square of E_2 enters into the development of the quantity given in the advance copies as $\pi\delta i/4$ in Equation (20), this latter should therefore be multiplied by $4/\pi^2$, giving the quantity $\delta i/\pi$ as stated by Dr. McLachlan. This error, whilst regrettable, was only in a constant and does not in any way invalidate the theory.

I am afraid that I must agree to differ from Dr. McLachlan as to the standpoint from which the losses are viewed. I consider that the representation of the magnetic losses by means of an equivalent tertiary circuit is more fundamental than consideration of them as an increased primary resistance or current. The iron losses do definitely occur in a distributed manner throughout a conductor which is undoubtedly a tertiary circuit, though of a distributed kind. In the theory presented, this circuit is considered to be concentrated and the losses are attributed to it. The losses must, of course, be discussed in relation to the secondary circuit. Apropos of this, however, it would, if otherwise desirable, be just as consistent to consider the effect of the losses from the standpoint of a reduced secondary current as from the more usual standpoint of an increased primary current. My object in introducing this theory of the current transformer was to avoid the necessity of reference to vector diagrams. I am, of course, on controversial ground, but, in common with many others whose opinion I have consulted, I think that, except for quite simple cases, the analytical methods are far more powerful than vectorial ones and enable us to follow in a clear manner the effect of each quantity involved upon the whole. What is needed is, I think, a careful investigation of the change of ratio of transformers when under their normal working conditions in which the flux is extraordinarily small. In my own experiments I have found that the power factor of the iron continually diminishes as the flux density is reduced, and does not show a very definite trend to a constant value at vanishingly small values of B. These experiments are very difficult and I feel that we are working in the dark, especially when dealing with very thin materials such as the 1-mil stalloy to which I have referred.

DISCUSSION ON

"THE PULLING INTO STEP OF A SYNCHRONOUS INDUCTION MOTOR." *

Mr. L. H. A. Carr (*communicated*): The author criticizes the equation of motion of the rotor of a synchronous induction motor †

$$- \rho T_m + T_m \sin \theta + \rho \frac{T_m}{p\omega} \cdot \frac{d\theta}{dt} + \frac{\mathrm{I}}{p} \cdot \frac{d^2\theta}{dt^2} = 0$$

on the grounds that it does not take into account any of the following facts :—

(1) Armature resistance and reactance;
(2) Low-frequency alternating currents in the exciting winding at speeds other than synchronism;
(3) Armature reaction.

To appreciate fully the meaning of the above equation it is necessary to go back to first principles. Any winding when connected to an alternating source of supply will allow to flow in it just sufficient current to produce a flux which, in turn, produces an E.M.F. in the winding of just the right amount to balance the supply E.M.F. (except for the necessary difference to cause that current to overcome the resistance drop). Let the armature winding of a synchronous induction motor be considered and, for simplicity, let the armature resistance and leakage reactance be neglected, so that the internal E.M.F. equals the line E.M.F. at all times. Then at all times the flux will be just sufficient to produce a back E.M.F. equal and opposite to the line E.M.F. When run synchronously, with field excited, the armature will draw from the line only the current corresponding to the difference (either positive or negative) between the M.M.F. produced by the field and the M.M.F. required to produce the necessary flux. If load is put on the machine, within its limits, the current drawn from the line will also include a component in phase with the E.M.F., thus supplying the necessary power. The whole armature current, however, exerts a magnetizing (or demagnetizing) effect, and the current must take up such a phase angle that while the in-phase component yields the necessary power, the vector sum of the field ampere-turns and the armature ampere-turns (the latter being the "armature reaction") gives the required constant value of M.M.F. corresponding to full flux. This is illustrated in Fig. A, where OA represents the flux-producing ampere-turns (F.P.A.T.) and OB the field ampere-turns (F.A.T.).

AB must necessarily represent to scale the armature reaction (A.R.). The circle BCD is the locus of the point B, while θ gives the angle of lag of the centre of the exciting winding behind the centre of the magnetic flux. This diagram can be coupled to a diagram representing the conditions in the electrical circuit, shown in Fig. B. Here PE, parallel to OA, represents the induced E.M.F., the line E.M.F. being PE′ equal and opposite to PE.‡ The relation between the current I in Fig. B and the armature reaction in Fig. A can be determined by reference to Fig. C, which, for simplicity, is drawn for a generator at unity power factor, so that the same arrow-heads and tails represent both E and I. Commencing with the wave of flux (and flux-producing ampere-turns), the induced E.M.F. and currents can be drawn, the arrow, E and I, in line with the centre of the flux wave representing the position on the armature where the induced E.M.F. and also the current reach their maximum. The curve A.R. then represents the magnetic effect of the current I, while F.A.T. represents the total ampere-turns that have to be supplied to the field. It is seen from the diagram that I leads the armature reaction by 90°, and it is so drawn in Fig. B. Referring again to Fig. A, it is seen that the line OG = AB cos ϕ. Since AB is proportional to I, OG is

* Paper by Mr. H. Cotton (see page 211).

Fig. A.

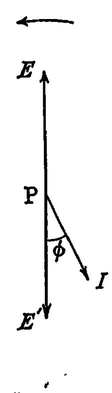

Fig. B.

proportional to $I \cos \phi$, that is to say, OG is proportional to power and, since the machine is synchronous, to torque also. But OG = OB sin θ. That is to say, the torque is proportional to sin θ. In other words the term $T_m \sin \theta$ in the fundamental equation not only allows for armature reaction, but its very existence in that form depends on the fact of armature reaction.

It also follows from Fig. A that the maximum synchronous torque occurs when B has moved to the point C. Here the armature reaction of the in-phase component of current = OC. That is to say, the in-phase component of current equals the armature current that flows on short-circuit with that particular excitation. This fact enables the maximum power and hence T_m to be easily calculated.

If the machine does not move exactly at synchronous speed, slip-frequency currents are induced in the exciting

‡ In this and the succeeding vector diagrams, the convention is adopted that "the sum of the voltages in a circuit is zero"; consequently an impedance drop is represented by $-I(r + jx)$, while an E.M.F. representing a motoring action or absorption of electrical power is in the contrary sense to $I \cos \theta$.

winding. To balance these (so that the flux and consequently the E.M.F. remain the same) equal and opposite currents will be drawn from the line by the armature. The currents produce the "induction motor torque" and the term

$$\rho \frac{T_m}{p\omega} \cdot \frac{d\theta}{dt}$$

represents their action. Consequently the fundamental equation covers this condition also, so that two of the immaterial whether the short-circuit excitation is assumed to be entirely absorbed by armature reaction, or partly by armature reaction and partly by the production of volts lost in impedance, if the test short-circuit curve is used as a basis to calculate T_m. Since reactance causes θ to be smaller for a given torque, the curve of torque against lag of rotor is displaced in a forward direction with reference to a sine wave. This is illustrated in Fig. E, where the sine wave 254 sin θ is compared with the wave-form obtained with a motor

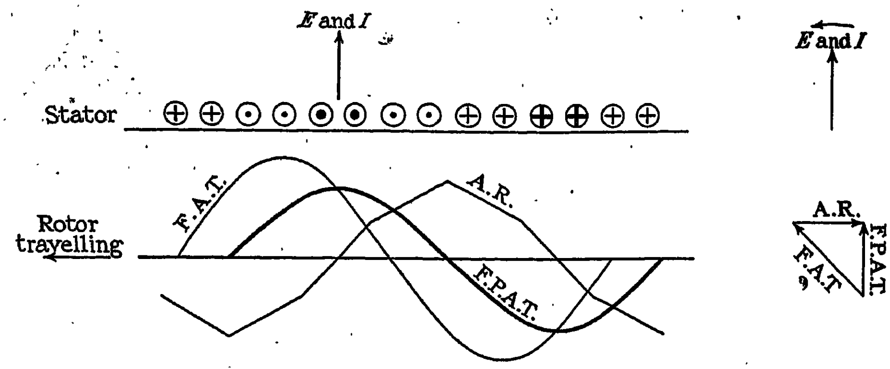

FIG. C.

author's criticisms are unfounded and his "corrections" based on these criticisms are not only unnecessary but are actually wrong.

With reference to armature resistance and leakage reactance, it is admitted that these are not included in the equation. Fig. D is drawn to show the effect of these quantities, and combines both E.M.F. and ampere-turn diagrams, the scales being so chosen that the same

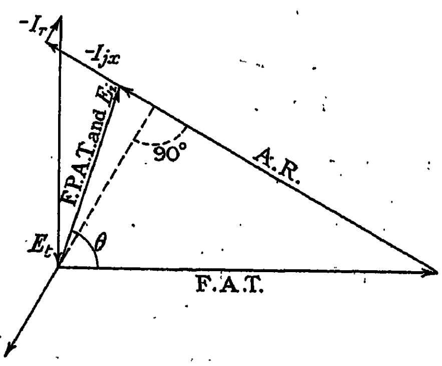

FIG. D.

length of line represents both the internal E.M.F. and the flux-producing ampere-turns on which it is dependent. It is seen that the principal effect of r is to reduce the useful length of E_t, the terminal E.M.F., so that the maximum torque is reduced in the same proportion. The presence of r also slightly modifies the angle θ for any given load. The only effect of x is to reduce the angle θ corresponding to any given torque. The maximum value of $I \cos \phi$ is, as before, the short-circuit value of I for the given excitation, and it is having so much leakage reactance that the maximum torque occurs at $\theta = 77°$, the resistance being neglected. It is seen that, as the machine slips away from $\theta = 0$, the torque is actually greater than in the sinusoidal case, and consequently the motor will synchronize against more torque, rather than less, and consequently

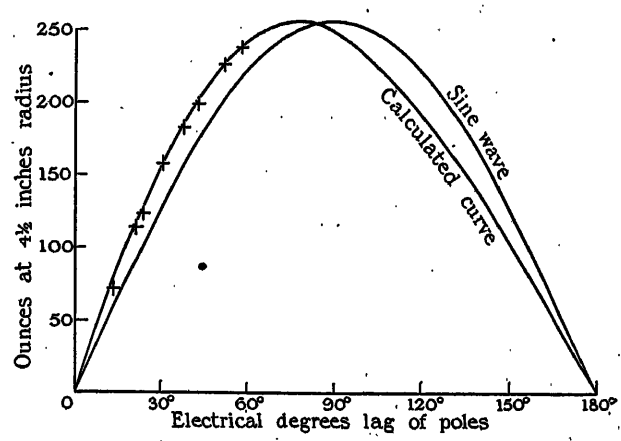

FIG. E.

the error due to reactance tends to cancel out the error due to resistance, and may even overcome it.

Applying the above reasoning to the motor used in the author's experiments, since 10 amperes excitation gives 3 amperes short-circuit current, T_m corresponds to an electrical power of

$$\sqrt{3} \times 245 \times 3 = 1\,270 \text{ watts.}$$

This is equivalent to 1·70 h.p., which corresponds to a torque of 5·95 lb.-ft. or 254 oz. at $4\frac{1}{2}$ in. radius, which

almost exactly agrees with the 258 oz. determined experimentally by the author (see page 215). An attempt was made to reproduce Fig. 4 in the paper by calculation, using the author's value for x the leakage reactance per phase, but the resulting curve was found to rise much more sharply than the test curve. The value of x was therefore examined critically, and consideration shows that the author's value of 40·5 ohms per phase is far too high. The machine is stated to be a 2-h.p. 245-volt three-phase induction motor. If the efficiency is, say, 84 per cent and the power factor 0·82, the full-load current is 5·1 amperes. Yet a reactance of 40·5 ohms per leg, as given by the author, would only allow a maximum current of $245/(\sqrt{3} \times 40{\cdot}5)$ or $3\frac{1}{2}$ amperes to flow on short-circuit as an induction motor, apart entirely from any extra reactance due to the rotor. It would therefore appear that the construction shown in Fig. 5 has broken down for some reason, possibly high rotor-tooth saturation. The points plotted in Fig. 4 (page 214) appear to indicate that θ at pull-out is of the order of 77°, and the author's experimentally determined points are plotted in Fig. E above to show the coincidence with the calculated curve. Even this curve, however, corresponds to a leakage reactance of 9·5 ohms, which is high for a motor of the size in question. To assist in settling this point, it would be of value if the author could give the calculated armature-reaction figure for the machine.

The direct current necessary to balance the polyphase current depends in a cylindrical rotor on whether the direct current splits up in the three phases in the ratio 1, $\frac{1}{2}$, $\frac{1}{2}$, or in the ratio 1, 1, 0. In the former case the exciting amperes to compensate for armature reaction

$$= \frac{2{\cdot}828 \times \text{A.C. amperes} \times \text{Conductors per pole per phase}}{\text{Rotor conductors per pole in series}}$$

In the latter case the constant is 0·866 × 2·828. In either case the number of rotor conductors per pole in series is twice the conductors per pole per phase for a three-phase rotor. Subtracting the resultant figure from the corresponding short-circuit test excitation, the difference would give the excitation corresponding to the internal voltage Ix, from which x could be calculated. Owing to the difference between the two quantities considered being relatively small, the method is, unfortunately, not very exact.

On page 222 the author suggests that the true criterion of synchronizing power should be the minimum exciter capacity and not the slip. In an equation containing several interdependent quantities (which can, nevertheless, be varied within limits by the designer) any one may be chosen as a criterion if desired, but as the full-load excitation is determined by the (synchronous) overload capacity of the machine, it seems wrong to use a variation of this as the criterion of synchronizing power. Although when the machine is built and installed slip is dependent on load, in the design stage that is not so, and, if necessary, the slip can be decreased by increasing the quantity of copper in the exciting winding without seriously affecting the other quantities in the equation. Further, a margin in slip must be allowed for the increase in slip due to the resistance of the leads to the starter and switchgear. The criterion of maximum slip for the required load then appears to be the most suitable practical basis. Again, since it is found in practice that machines are frequently started up by unskilled operators, it is necessary, as a commercial proposition, to ensure that the machines shall always synchronize immediately, that is to say, that they must be capable of synchronizing on the first swing, even if the excitation is switched on at the worst possible position. Consequently this worst position of switching must be used in determining the capacity of the machine to meet the specified requirements.

On pages 223 and 224 the author discusses the agreement between his practical results and his theoretical investigations. Unfortunately these results cannot be compared with the true theoretical equations, since the author's data are conflicting; for example, on page 214 it is stated that $\mathbf{I} = 4{\cdot}32$, while on page 223 $\mathbf{I}$ is said to be 0·135, the same units being apparently used in the two cases. It must be considered, therefore, in view of the foregoing considerations, that the author has failed to prove either theoretically or practically his conclusion (page 224) that "the conditions of operation of a synchronized induction motor during the process of pulling into synchronism are much more severe than they are generally taken to be."

Mr. H. Cotton (*in reply*): I am very glad that Mr. Carr has contributed to the discussion on my paper, because even when the discussion is mainly critical, as in the present case, it adds to the value and interest of the original paper. The most important part of Mr. Carr's criticism is his denial that the armature reaction produces a double-frequency component in the torque created by the motor. To support this he assumes the simplest possible case "so that the internal E.M.F. equals the line E.M.F. at all times." Now the internal E.M.F. (referred to as the back E.M.F. in my paper) is, for a given motor, a function of the speed and the flux per pole, including armature reaction. The speed of a synchronous motor is constant; and, even when it is slipping, the variation in speed is not considerable, so that in the present investigation the back E.M.F. can be assumed to depend on the total flux per pole, and on this only. Hence if the excitation is varied, or if the flux per pole changes because of variations in magnitude of the armature reaction, the back E.M.F. will vary, and the supposition that it is always equal to the line E.M.F. is impossible. Consider now the vector diagram of the motor and assume for simplicity that the armature has zero resistance and that there are no losses, so that the output is equal to the intake. Then since the speed is constant the motor torque is proportional to the intake. In Fig. F, the length OA represents the line E.M.F. per phase, and AB the back E.M.F. per phase. Then OB is the resultant E.M.F., and since we are assuming zero armature resistance the current will lag 90° behind OB, being represented in phase by the direction of OI, and in magnitude by the length of OB. Now OB makes an angle ϕ with the axis OY equal to the external phase angle, and therefore OB represents, with respect to OY, the current in

magnitude and phase. Now torque per phase $\propto$ intake per phase $\propto EI \cos \phi \propto I \cos \phi \propto$ AM, where AM is the projection of AB on to the vertical OZ. The angle θ in the dynamical equation of motion is the angle included between OA and AB; and, as θ varies, the vector AB must rotate about the point A. But the torque of the motor is given by the projection of this vector on to the vertical AZ, and therefore if the torque is to be a pure sinusoidal function of θ, as stated by Mr. Carr, the locus of B must be a circle and therefore the length AB must remain constant. If this is to be the case, then either the armature reaction must be zero, which is absurd, or it must be of constant magnitude and independent of either the magnitude or phase of the current, which is equally absurd. Since the armature reaction varies in magnitude, the increment or decrement of the induced voltage due to it must be variable, and therefore the locus of B is not a circle. Therefore the torque, when expressed as a function of θ, is not a pure sinusoidal function, the departure from this

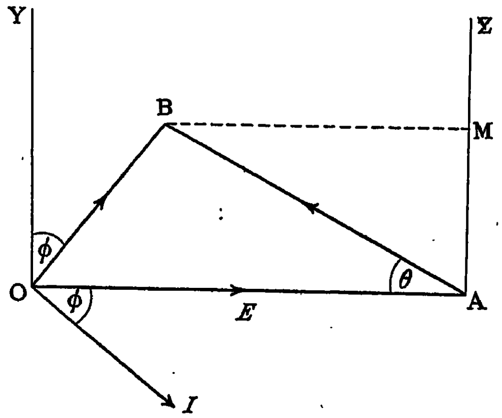

FIG. F.

form being proved in the original paper to be represented by the addition of a sin 2θ term. The solution is not presented as being complete from the point of view of taking all factors into account; it deals only with the most important cause of the departure from the pure sinusoidal form, namely, the direct component of the armature reaction.

I now come to the numerical data derived from the test carried out on the 2-h.p. induction motor. Mr. Carr states that it would be of value if I could give the calculated armature-reaction figure for the machine. It would, but unfortunately I have no design data of any kind for it, otherwise it goes without saying that I should have made a predetermination of the operation of the machine from these data. It is quite possible that the value of 40·5 ohms for the leakage reactance per phase is on the high side. The experimental determination of this quantity can be satisfactorily carried out on a large machine, but it is quite another matter on such a small one, especially when an abnormally large armature reaction has to be allowed for. It was necessary, however, to take the experimentally determined value, since there was no other method of arriving at the figure. The results given in the tables and the analysis indicated by Fig. 5 were the result of carefully made experiments and therefore had to be taken. It is to be expected that, with this type of motor, tests made under abnormal conditions, e.g. open circuit and short-circuit, and operation on wattless current, should give a result somewhat different from the figure for operation under normal conditions. This is stated quite frankly on page 217 of the original paper: it would have been remarkable if there had been a close agreement between the calculated and observed behaviour in such a case. This does not, however, alter the general form of the torque curve as given in Fig. 7. The resultant curve does rise more steeply than a pure sine wave, but whereas the difference between the full-line and dotted curves is only small between $\theta = 0$ and $\theta = 180$, it is very considerable between $\theta = 180°$ and $\theta = 360°$. Therefore, if the motor succeeds in pulling into step before the first unstable position is reached, the effect of armature reaction will be very small, but if it passes this position the large negative torque will produce an increase in slip velocity much greater than would be the case if armature reaction were non-existent. Hence the conditions for pulling into step are more severe than generally supposed when the motor does not pull in between zero and the first unstable position. Surely it was unnecessary to make this qualification in the original paper, because the curves of Fig. 13, which were determined to illustrate this point, were all drawn for a complete revolution of slip. With regard to the unit for the moment of inertia **I**, the experimental determination gave 4·32 lb.-ft. units. When using a dynamical equation of motion it is necessary to use the quantity **I**/g, which is of course 4·32/32, or 0·135, this latter value being used in the equation on page 223.

The final criticism deals with the method of calculating the exciter capacity necessary to enable the motor to pull into step under certain definitely specified conditions. Mr. Carr's objection to the equation developed is obviously the result of his preference for his own method of calculation, as developed in his second paper (*Journal I.E.E.*, 1924, vol. 61, p. 695), which method I criticized on pages 223 and 224 of my paper. The conditions in my method of calculation are that the direct-current excitation is switched on at the angular position $\theta = 0$, and that the slip velocity just comes to zero at the position of unstable equilibrium. This method gives the minimum exciter capacity which will enable the motor to pull into step under the most favourable conditions. It is therefore a definite piece of information. It is perfectly true that the motor may be left to the tender mercies of unskilled attendants, and also that the exciter has another function to perform after the motor has pulled into step, namely, to supply the necessary excitation to give the required pull-out torque and the requisite power factor on stated load. Surely, however, it is very unscientific to try to introduce disturbing factors of this kind into a calculation which has no reference to them. As the title of the paper suggests, the whole of the investigation deals with the phenomena of pulling into step, and not with anything that may take place afterwards. It is quite true that some increase of the exciter capacity as calculated by my method would have to be made,

even for the motor to synchronize in the first swing when operated by unskilled attendants, but the calculation has to be made before the factor of safety can be applied. Now consider Mr. Carr's method of making the calculation. He states in his criticism that the motor must synchronize in the first swing, that is, it must not go past the position of unstable equilibrium. Hence, after excitation, the velocity must decrease from the ordinary induction motor slip at $\theta = 0°$ to zero at the unstable position. Instead, however, of taking the proper value of the slip, he uses a value which is derived from a purely mathematical conception of the problem, which may have no existence in practice at all. It gives, in fact, the worst possible conditions that can exist from the point of view of synchronizing, so that his method and mine give the two extremes between which the exciter capacity must lie, this capacity referring only to the pulling into step of the motor and not to its subsequent operation at synchronous speed. In conclusion, therefore, it will be seen that with the exception of the figure for the leakage reactance, an error in which was unavoidable under the circumstances, Mr. Carr's somewhat extensive criticism is not justified.

INSTITUTION NOTES.

Council's Nominations for Election to the Council.

The following have been nominated by the Council for the vacancies which will occur in the offices of President, Vice-Presidents, Honorary Treasurer, and Ordinary Members of Council on the 30th September, 1925 :—

President. *(One Vacancy.)*

R. A. Chattock.

Vice-Presidents. *(Two Vacancies.)*

Lieut.-Col. K. Edgcumbe, R.E. (T.A.).
Prof. W. M. Thornton, O.B.E., D.Sc.

Honorary Treasurer. *(One Vacancy.)*

P. D. Tuckett.

Ordinary Members of Council.

Members. *(Four Vacancies.)*

Prof. C. L. Fortescue, O.B.E., M.A.
H. Marryat.
R. W. Paul.
S. J. Watson.

Associate Members. *(Three Vacancies.)*

R. Grierson.
Major E. O. Henrici, R.E.
J. W. T. Walsh, M.A., M.Sc.

Associate. *(One Vacancy.)*

E. Leete.

Premiums.

The Council have awarded the following Premiums for papers :—

The Institution Premium (*value* £25).

H. W. Clothier. "Design of Electrical Plant, Control Gear and Connections for Protection against Shock, Fire and Faults."

The Ayrton Premium (*value* £10).

Major E. I. David. "Electricity in Mines."

The Fahie Premium (*value* £10).

Col. T. F. Purves, O.B.E. "The Post Office and Automatic Telephones."

The John Hopkinson Premium (*value* £10).

G. Rogers. "Automatic and Semi-Automatic Mercury-Vapour Rectifier Substations."

The Kelvin Premium (*value* £10).

K. G. Maxwell and A. Monkhouse. "Recent Improvements in the Insulation of Electrical Machinery."

The Paris Premium (*value* £10).

D. Murray. "Speeding up the Telegraphs: A Forecast of the New Telegraphy."

A Premium (*value* £10).

J. D. Cockcroft, R. T. Coe, J. A. Tyacke and Prof. Miles Walker, D.Sc. "An Electric Harmonic Analyser."

A Premium (*value* £5).

S. Holmes. "A Vector Treatment of Long Transmission Lines."

Wireless Section Premiums.

The Duddell Premium (*value* £20).

Major A. G. Lee, M.C., B.Sc., and A. J. Gill, B.Sc. "The Leafield Coupled Arc."

A Premium (value £20).

Capt. H. J. ROUND, M.C., T. L. ECKERSLEY, K. TREMELLEN, and F. C. LUNNON.	"Report on Measurements made on Signal Strength at Great Distances during 1922 and 1923 by an Expedition sent to Australia."

A Premium (value £10).

Prof. E. MALLETT, M.Sc., and A. D. BLUMLEIN, B.Sc.	"A New Method of High-Frequency Resistance Measurement."

A Premium (value £5).

L. C. POCOCK, B.Sc.	"Faithful Reproduction in Radio-Telephony."

The Premiums for papers read before the Students' Sections will be announced later.

Associate Membership Examination Results, April, 1925.

Passed.

Akehurst, A. G. (Southsea).
Bamber, L. J. (Horwich).
Beynon, J. H. (Swansea).
Birtwistle, F. (Bromborough).
Blaquiere, H. A. (Leeds).
Carson, W. N. (Sunderland).
Carter, A. (London).
Cash, H. H. (Bradford).

Overington, L. E. (Ilkley).
Pegg, R. N. (London).
Pizzey, J. H. (Portsmouth).
Prockter, C. E. (Norwich).
Robson, O. L. (London).
Rowbottom, J. R. (Blackpool).
Taylor, H. L. (Rugby).
Turner, V. R. (London).
Verano, E. A. A. (Southsea).
Wales, W. A. (London).
Whitehurst, J. T. (London).
Wicks, P. (Enfield).
Wilson, P. M. (Edinburgh).

Passed Part I only.

Fletcher, C. B. H. (Llanishen).
Hazel, H. (London).
Staygle, E. G. (Worthing).

Passed Part II only.

Aldis, R. F. (Windsor).
Davidson, H. S. (Wolverhampton).
Hoskin, F. (Plymouth).
Shepherd, J. H. (Rawtenstall).
Watkin, H. (Nottingham).
Watson, E. P. (London).

The results relating to candidates who sat for the Examination abroad will be published later.

International Conference on Large Electric Supply Systems.

The Proceedings of the Second Conference, held in 1923, have now been published The volume is entirely in French and comprises 1 200 pages and 400 illustrations. It contains the 50 papers presented at the Conference and full reports of the discussions. The papers cover the practice of 20 different countries in regard to the generation and distribution of electrical energy, and especially porcelain insulators, towers for overhead lines, operation of large transmission lines, outdoor substations, oil circuit-breakers, manufacture and use of high-tension cables, interconnection of networks, earthing the neutral, protection against surges, etc.

Copies can be obtained from the Secretary of the Conference, 25, Boulevard Malesherbes, Paris, at the price of frs. 120 per copy.

The Third Conference is being held at Paris from the 16th to the 25th of this month (June).

International Commission on Illumination.

The Report for the year 1924 of the National Illumination Committee of Great Britain states that the following decisions were agreed upon at the meeting of the above Commission held at Geneva in July 1924 (see *Journal I.E.E.*, 1925, vol. 63, page 66) :—

(1) The International Commission recommended for international adoption as the primary standard of light the brightness of a black body operated under conditions subject to accurate specification, and further recommended that the National Laboratories be asked to take steps—

(*a*) To formulate standard specifications for the construction and operation of the black body as a primary standard of light;

(*b*) To fix upon a definite figure for the brightness as a function of the temperature, of such body expressed in international candles per square centimetre.

(2) A Sub-committee was appointed to draw up a vocabulary dealing with Illumination.

(3) The Commission provisionally recommended certain values for the visibility factor.

(4) The Sub-committee on heterochromatic photometry was asked to include in its work the study of the properties of absorbent screens.

(5) A Sub-committee was appointed for the study of colorimetry.

(6) The following definitions were adopted :—

(*a*) The *Transmission factor* of a body is the ratio of the flux transmitted by the body to the flux incident upon it.

(*b*) The *Absorption factor* of a body is the ratio of the flux absorbed by the body to the flux incident upon it.

(*c*) The *Reflection factor* of a body is the ratio of the flux reflected by the body to the flux incident upon it.

The flux reflected according to the laws of specular reflection is called specularly reflected flux, and the

corresponding reflection factor is called the factor of specular reflection. The flux diffused, i.e. that sent out in directions other than that of specular reflection, gives the diffuse reflection factor. The total reflection factor is obtained by considering the whole of the flux reflected by the body.

(*d*) The *Total flux* of a source is the flux emitted by that source in all directions.

(*e*) The *Upper hemispherical flux* of a source is the flux emitted by that source above the horizontal plane passing through its centre.

(*f*) The *Lower hemispherical flux* of a source is the flux emitted by that source below the horizontal plane passing through its centre.

(*g*) The *Mean spherical intensity* of a source is the average value of the intensity of that source in all directions in space.

(*h*) The *Mean upper hemispherical intensity* of a source is the average value of the intensity of that source in all directions above the horizontal plane passing through its centre.

(*i*) The *Mean lower hemispherical intensity* of a source is the average value of the intensity of that source in all directions below the horizontal plane passing through its centre.

(*j*) The *Mean horizontal intensity* of a source is the average value of the intensity of that source in all directions in the horizontal plane passing through its centre.

(*k*) The *Reduction factor of the mean spherical intensity* of a source is the ratio of the mean spherical intensity to the mean horizontal intensity.

(*l*) The *Efficiency of a source* is the ratio of the total luminous flux emitted to the total power consumed. In the case of an electric lamp it is expressed in lumens per watt. In the case of a source depending upon combustion it may be expressed in lumens per thermal unit per unit of time.

(*m*) The *Visibility factor* for monochromatic radiation is the ratio of the luminous flux to the corresponding energy flux.

The relative visibility factor of a monochromatic radiation is the ratio of the visibility factor of that radiation to the maximum value of the visibility factor.

(*n*) *Brightness*. The brightness in a given direction of a surface emitting light is the quotient of the luminous intensity measured in that direction by the area of this surface projected on a plane perpendicular to the direction considered. The unit of brightness is the candle per unit area of surface.

NOTE.—The above definitions are translated from the official French text. The official English translation will be published later.

(7) The following symbols were adopted :—

Luminous Flux	F	Transmission Ratios	τ
Candle Power	I	Absorption Ratios	α
Illumination	E	Reflection Ratios	ρ
Brightness	B	Visibility Factor	K

(8) It was decided that at the next session a meeting should be devoted to papers and discussion on the art of illumination and the furtherance of good lighting.

(9) It was decided that questions relating to street lighting should be considered at the next session and the National Committees were asked to study the subject and to transmit their communications to the Central Office at the earliest date possible.

(10) The report submitted by the Chairman of the Advisory Committee on the lighting of factories and school buildings was recommended as a basis for regulations or recommendations on the lighting of factories and school buildings.

(11) The National Committees were asked to study the question of glare from motor-car headlights and to send their communications to the Central Office in ample time for the next session.

The following committees have been appointed by the International Commission, the representatives of Great Britain thereon being shown in brackets :—

Heterochromatic Photometry and Colour Screens—(Dr. E. H. Rayner).

Definitions and Symbols—(Mr. J. W. T. Walsh).

Lighting of Factories and Schools—(Mr. L. Gaster).

Motor-car Headlights—(Lt.-Col. K. Edgcumbe).

Colorimetry—(Mr. T. Smith).

It was decided to reduce the annual contribution payable by each country in view of the probable increase in the number of constituent countries. Great Britain will now pay about £77 per annum instead of £113 10s.

A Sectional Committee on Illumination has been formed by the British Engineering Standards Association. The British National Committee forms the nucleus of this Committee, which also includes 12 representatives of Government Departments, manufacturers' Associations and technical Institutions. Five Sub-committees dealing respectively with Photometers, Nomenclature and Symbols, Illumination Glassware, Fittings and Street Lighting have been set up and have held a number of meetings.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 April–25 May, 1925 :—

THE POST OFFICE AND AUTOMATIC TELEPHONES.

By Colonel T. F. PURVES, O.B.E., Member.

(*Paper first received* 13*th October*, 1924, *and in final form* 4*th February*, 1925; *read before* THE INSTITUTION 5*th March*, *before the* NORTH-WESTERN CENTRE 17*th March*, *before the* NORTH-EASTERN CENTRE 23*rd March*, *and before the* SOUTH MIDLAND CENTRE 1*st April*, 1925.)

SUMMARY OF CONTENTS.

(1) *Introductory.*—The paper attempts to describe points of general interest rather than detail. Absence of automatic aids to manipulation in early telephone switchboards; increasing introduction of such aids as manual systems developed; early automatic systems; the fundamental "Strowger" step-by-step system, and power-driven systems.

(2) *Post Office experience and practice.*—Systems already in use; results obtained; methods of comparing costs; advantageous field of manual and automatic systems.

(3) *The semi-automatic system.*—Claims and objections.

(4) *Layout of telephone areas.*—Economic studies; differences between manual and automatic layout of exchange positions and external lines; subscribers' lines, junction plant, sites and buildings; synthesis of costs.

(5) *Internal plant and wiring.*—Calculation and layout of exchanges; traffic data; grades of service; availability of switches; grading of switching outlets in accordance with theory of probabilities; "artificial traffic," "trunk-hunting" facilities and methods of increasing them.

(6) *Services reserved for manual operating.*—Trunk calls, extra-fee calls, coin-box and call-office traffic; automatic dialling to and from distant exchanges.

(7) *The problem of very large areas.*—Transition difficulties of schemes involving a rigid plan of subscribers' numbers.

(8) *The "panel" system of the American Bell Companies.*—Solution of numbering-scheme difficulties by exchange-code translation; brief description of "panel" system.

(9) *The choice of a system for London.*—Strong attraction of the "panel" system; ultimate adoption of the Automatic Electric Co.'s "director" system; anticipated development in London; agreements for supply of apparatus; standardization of Post Office "step-by-step" automatic system.

(10) *The "director system."*—General description of the system; methods of translation; intercommunication between manual and automatic exchanges during transition period; "key sender" and "call indicator" equipment; the London "mechanical tandem" exchange; various classes of service provided; tone signals; alarms and guarding devices; private branch exchange lines.

(11) *The subscriber's automatic telephone set.*—Standardization of signalling impulses and calling dials; circuit arrangements to avoid high-voltage surges, tinkling of bells, and impulse clicks in receiver.

(12) *Tariffs for automatic systems.*—"Message rate" versus "flat rate"; "time and distance" tariff.

(13) *Progress of automatic exchange construction.*—New exchanges required in London and the provinces; training of staff; output capacity of factories.

(1) INTRODUCTORY.

In the art and practice of telephony the development of means whereby one talking circuit can be connected, at will, with any other has always presented a leading problem, second only to those involved in the actual transmission of speech.

Although its study has been accompanied by a large amount of invention, it is essentially a problem in pure engineering. The object accomplished is one which, in itself, is simple, and the immense amount of effort and ingenuity which has been expended upon it by many hundreds of engineers has been directed wholly to securing its accomplishment at minimum cost in money and time.

The various systems of switching classed as "automatic" perform no new function in telephony; rather do they represent the culmination of a continuous process, in which electrical and mechanical devices have been increasingly utilized, in order to reduce the amount of human effort required to place a telephone subscriber in communication with the correspondent with whom he desires to speak. In this economy of effort the subscriber has shared, and in modern "manual" switching systems the only manipulative act required of him is that he should lift the telephone receiver from its rest before speaking, and replace it when he has finished.

The adoption of the automatic system represents a reversal of this policy of economy of operation, so far as the subscriber is concerned, since it throws upon him the whole of the manipulation required to effect the ordinary local calls which generally constitute the bulk of his transactions, and for that reason the introduction of automatic exchanges in any telephone area is generally a matter of considerable public interest.

The desire of the general public for information is catered for by the daily Press, and, at the other extreme, the professional telephone engineer has at his disposal a great mass of technical literature in many forms, in the multitudinous details of which the electrical engineer who is interested in only a general way may be pardoned for sometimes complaining that he "cannot see the

wood for the trees." I shall therefore endeavour to give a general description of the function of automatic switching apparatus in telephony, with a few main details of the most recent innovations incorporated in the system which is now being installed in new exchanges in London.

The fact that the inception of automatic telephony dates from a time only about three years later than that of the telephone itself, is often overlooked. The electrical telephone was invented—or at least *effectively* invented—in 1876 by Dr. Graham Bell, a native of Edinburgh domiciled in the United States, who was present at a Meeting of the Wireless Section held in the Institution Lecture Theatre in 1921, only about a year before his death.

Although the first telephones were used only for point-to-point communication on private wires, Dr. Bell from the earliest days visualized the use of his invention for general communication among members of the public. In a letter written from Kensington and addressed to the capitalists of the "Electric Telephone Co.," he expressed himself as follows :—

"It is conceivable that cables of telephone wires could be laid underground, or suspended overhead, communicating by branch wires with private dwellings, country houses, shops, factories, etc., etc.; uniting them through the main cable with a central office where the wires could be connected as desired, establishing direct communication between any two places in the city. Such a plan as this, though impracticable at the present moment, will, I firmly believe, be the outcome of the introduction of the telephone to the public. Not only so, but I believe that, in the future, wires will unite the head offices in different cities, and a man in one part of the country may communicate by word of mouth with another in a distant part. Believing, as I do, that such a scheme will be the ultimate result of introducing the telephone to the public, I will impress upon you all the advisability of keeping this end in view."

It has been given to few pioneers in a matter of such magnitude to see their early visions so fully realized. The telephone has indeed provided a notable illustration of the rapid application of scientific discoveries to commercial life and to the home requirements of the people, and this applies with equal force to its most modern developments, such as inductively loaded land and sea cables and thermionic valve repeaters, and coupled wire and wireless transmission, which have so greatly increased the stability and range of communication. In this connection it is noteworthy that the fundamental elements of telephony have undergone only slight modification. The receiver of to-day is almost identical with that of 30 years ago, and the standard transmitter is still the box of carbon granules invented about the same time, while these, in turn, differ only in minor characteristics from the receiver first devised by Dr. Bell and the original carbon transmitter introduced a few years later.

The first exchange switchboard was brought into use at Newhaven, Conn., in 1878 and was equipped with switching apparatus of the "rheostat switch" type, now so well known to wireless amateurs. The limiting possibilities of such apparatus were soon reached and the necessity for the design and manufacture of entirely new types of equipment became evident.

"Plug and cord" exchanges quickly followed. An early switchboard of that type is shown in Fig. 1.* Every operation of signalling and connecting had to be performed by hand. The subscriber had to switch in a generator to call the exchange and had to connect and disconnect his speaking battery by means of another switch. The operator had to restore the shutters of the drop indicators by hand; to connect his speaking set by a plug to the calling line; to plug his generator to the called line and turn the handle; to transfer his speaking set to that line; and, after obtaining a reply, to connect the two lines together by a separate pair of plugs and cord. From time to time he had to reconnect his speaking set and listen, in order to ascertain before severing the connection whether the conversation had been completed.

As the numbers of lines and the amount of traffic increased it was found possible to facilitate the work of the operator by the introduction of such devices as connecting jacks, with auxiliary contact springs for signalling, self-restoring indicators for calling and clearing purposes, and fixed pairs of cords and plugs equipped with pulleys and with ringing and speaking keys which automatically effected all the circuit changes required to send calling signals and to enable the operator to speak and listen on any line. Automatic switching receiver-hooks were also added to the subscribers' telephones.

The increasing size of switchboards made it necessary to employ several operators in one exchange, and the difficulties so introduced were solved by the invention of the multiple switchboard. The British Patent for this was taken out in 1879 by Mr. Scribner, until a few years ago chief engineer of the Western Electric Co. in America, by whom the multiple switchboard was introduced and developed. This notable invention enormously increased the number of lines which could be handled in a single exchange. It enabled the lines to be apportioned in suitable groups to an indefinite number of operators, each of whom answered the calls arising in his particular group and was enabled to complete the connection to any required line in the exchange by means of a compact panel of connecting jacks in which the whole of the lines appeared. Such panels were provided within reach of all operators and every line was multipled to a jack in the same numbered position on every panel of the entire suite. This necessitated the provision of many additional operating aids and refinements, including the simple electrical "engaged" signal which has ever since been a feature of large manual exchanges.

The introduction of the "common battery" system represents another important advance. The first such exchange was opened in Louisville, Kentucky, in 1897; the first in England was opened at Bristol in 1900. The essential feature of the common-battery system is the elimination of batteries from the subscriber's telephone set by the supply of talking current from a large central battery located at the exchange; but the system as launched by the engineers of the American

* Not reproduced in the *Journal*.

Bell Association included a great many new developments of a subsidiary character, among which may be mentioned the use of small electric glow lamps in place of mechanical indicators.

It introduced, for the first time, the use of electrical power to the telephone system, and the current requirements of a large exchange began to be measured in hundreds of amperes instead of in milliamperes. Many types of relays and other electro-mechanical devices were designed and introduced in combinations which greatly extended the automatic signalling and connecting features of exchange working.

Since then the telephone engineers of all the leading nations have participated in the further development of the common-battery system, both as applied to subscribers' lines and to the junction circuits which are required in great numbers in large multi-exchange areas.

The object throughout has been to reduce the cost of giving a rapid and reliable service, by simplifying in every possible way the operations of the telephonist in handling calls. Such savings affect the engineering and other costs as well as the service operating costs. If we assume that the introduction of a certain amount of automatic aid to the operator results in halving the amount of time taken to deal with a call, not only is the effect to double the average number of lines which an operator can handle, and so reduce the number of operators by half, but the costly multiple switchboard suites will also be reduced to half the previous length, the necessary dimensions of switch-rooms and operating-staff accommodation rooms will likewise be halved and a large economy effected in the cost of sites and buildings.

The amount of assistance given to the operators in all modern manual exchanges, by the introduction of automatic devices, is very great. In the case of some of the small telephone companies in the United States, where the whole service is given from a single exchange at a "flat rate" charge, it has been possible to combine these devices in such a way that the normal manipulative action of the operator is reduced to the mere insertion and withdrawal of a single plug for each communication effected. The call is indicated by the glowing of a lamp adjacent to a particular plug. When the operator lifts the plug, her speaking set is automatically connected to the line and the number of the called party is ascertained. The insertion of the plug in the jack of the wanted line automatically disconnects the operator's speaking set and connects a periodic ringing machine to the line. When the called subscriber lifts his receiver to reply he actuates a trip magnet which disconnects the ringing machine and places the two parties in communication. The replacement of the receivers at the end of the conversation sends a clearing signal, on observing which the operator withdraws the connecting plug. With so simple a manipulative system the number of calls which an operator can normally deal with in an hour is naturally very high.

Side by side with the foregoing development of so-called "manual" systems many inventors and engineers have been devoting their attention to the devising of purely automatic systems in which the intervention of an operator in connection with ordinary local calls is entirely dispensed with.

Probably the first recorded proposal for an automatic system is that of Connolly,' which is covered by the joint patent of Messrs. M. D. and T. A. Connolly and T. J. McTighe, United States Patent 22458, dated 9th December, 1879. This system bears a remarkable resemblance to the Wheatstone "ABC" dial telegraph, and although the Patent refers to a system of 100 lines the drawings associated with it only illustrate one of 25 lines. The face of the dial was marked with letters, each of which represented one subscriber on the system.

The first really important development of automatic telephony is represented by the inventions of Mr. Strowger, whose name was destined to become universally known as its pioneer. Strowger's first patent is dated 10th March, 1891, United States Patent No. 447918. This early system required five wires between

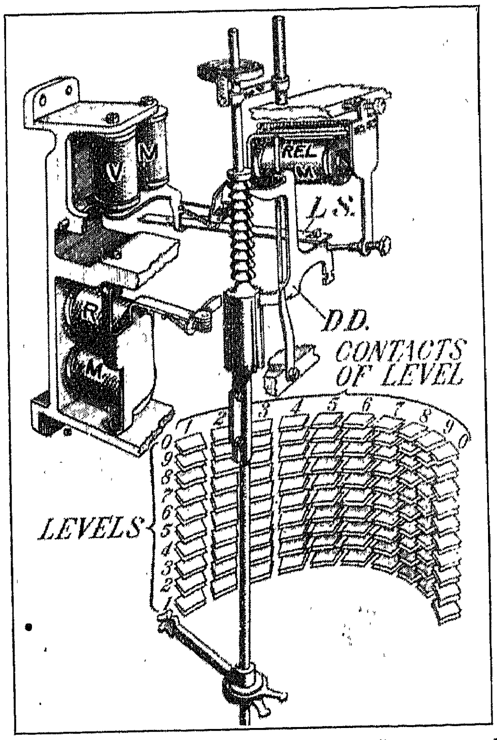

FIG. 2.—Diagram illustrating working of Strowger selector.

each subscriber's station and the exchange. Subsequent improvements enabled the number of wires to be reduced to two, which brought the system into line with standard telephone engineering practice and led to its fairly extensive adoption among the smaller telephone companies in America and elsewhere.

The Strowger system is the basis of what is known as "step by step" automatic telephony, and at the present day there are more automatic telephones served by exchanges of that type than by any other. Its fundamental idea is the simple one of straight decimal selection, digit by digit, in a forward direction. Fig. 2 gives a diagrammatic view of the well-known Strowger selector switch. It consists essentially of a set of insulated contact brushes, or wipers, with means for bringing them into connection with any one of 100 sets

of contacts, 10 of which are placed side by side, in the arc of a circle, on each of 10 levels. The brushes are carried on a vertical spindle to which step-by-step vertical movement and rotation can be imparted by means of electromagnets actuated by the trains of signalling impulses produced by the calling dial of the subscriber's telephone. The brushes rest normally slightly below, and to the left-hand side of, the banks of contacts, being held in that position by gravity and by means of a spiral spring, shown at the top of the figure, which acts upon the spindle. Impulses in the vertical magnet (VM) step up the brushes to a position

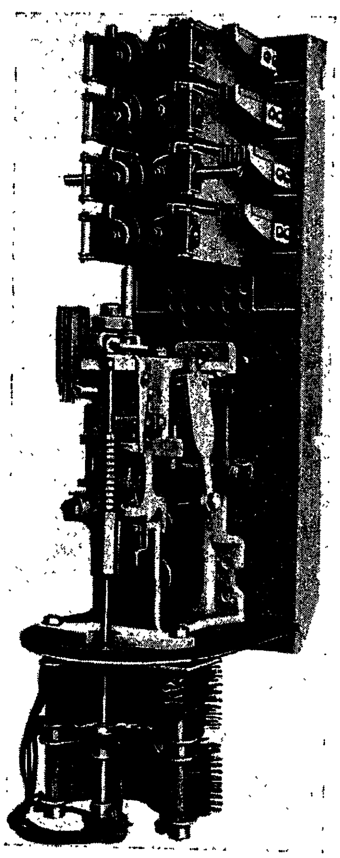

FIG. 3.—Strowger selector.

opposite any required level by means of a pawl which engages with a vertical ratchet on the spindle. A subsequent train of impulses in the rotary magnet (RM) will cause the brushes to enter the bank of contacts on that level and will rotate them into connection with any desired set of contacts, representing the line of the called subscriber, by means of a pawl and horizontal ratchet. So long as the connection is required the vertical and horizontal ratchets of the spindle are engaged by a double detent (DD) which locks it in position. When the calling subscriber restores his receiver on the completion of conversation, a release magnet (Rel.M) is actuated and disengages the double detent; the spiral spring then restores the brushes to a position horizontally clear of the contacts bank, and the spindle and wipers drop by gravity to the normal position of rest.

The foregoing description applies to the operation of the final selector switch of 100 lines, which completes the connection to the called subscriber and is governed by the impulses representing the tens and units digits.

In order to effect the selections represented by the hundreds, thousands, and other digits, a switch of the same general design is employed, but the digit impulses are utilized to govern only the vertical selection of a level of 10 contacts, all of which are connected to further selector switches instead of to the actual subscribers' lines. In this case the function of the rotary magnet and of the horizontal movement of the brushes within the bank of contacts, is known as "trunk hunting"; the brushes are driven rapidly forward by local impulses until they find, and come to rest upon, a set of contacts connected with an *idle* selector in the next rank of switches, which will receive, and deal with, the next train of digit impulses sent in by the calling subscriber. The bank contacts of all ranks of switches are multipled together in groups, in a manner analogous to the multipling of subscribers' and junction lines at a manual exchange.

Fig. 3 gives a view of a final selector switch of present-day pattern, without its protective cover. It will be seen that in addition to the double brush and bank contacts carrying the talking-circuit connections, a separate brush and set of bank contacts—known as the "private bank"—is also provided. The latter carry a third conductor used for preventing the making of connections with engaged lines or switches, a function similar to that of the third or "sleeve" conductor used in the plugs and cords of manual exchanges. The eight relays shown at the top of the figure control the circuit re-arrangements associated with each step of the operation of the selecting mechanism, and perform other necessary duties which, *inter alia*, enable the switch :—

- To ascertain whether the wanted line is disengaged, and, if not,
- To transmit a "busy" signal to the calling subscriber;
- To provide against interruption by other calls for the same line;
- To disconnect the called line from its call-receiving equipment;
- To ring the wanted subscriber;
- To disconnect the ringer, join the circuit through, and operate the caller's meter when the called subscriber has replied;
- To supply talking current;
- To release the connections when conversation has finished.

In early Strowger exchanges it was necessary to provide a selector switch for every subscriber's line, the line being connected to the brushes and finding its outlets via the banks of multipled contacts. This practice involved the use of a very large number of these comparatively expensive pieces of mechanism, each of which was utilized, on the average, for only a very short time daily. Great economic advantage therefore resulted from the invention in 1907 by Mr.

Alexander Keith, one of the engineers of the Automatic Electric Co. of Chicago, of a simple form of line switch, which took the place of the selector on the subscriber's line, and connected the line to an idle selector in a common group before the operation of dialling impulses began. The use of the Keith line switch thus enabled the number of selector switches in an exchange to be very much reduced and to be proportioned in accordance with the total traffic to be carried, without regard to the number of subscribers' lines connected. The Keith switch has recently been superseded by a simple form of rotary line switch which serves the same purpose.

Although the Strowger step-by-step system, with many variants, has reached a high state of development in many lands, it is very far from holding the field alone. Its basic principle of straightforward decimal selection of circuits in comparatively small groups, although simple both in theory and in practice, undoubtedly tends to multiplicity of switches. The fact that all the motions of its parts are energized by the attraction of the armatures of electromagnets has also appeared to some highly competent authorities to be a weakness.

The development of forms of automatic exchanges in which the motive power of all the main elements is derived directly from a power motor has therefore received much attention and has attracted the efforts of many exceedingly able inventors and engineers. The earliest achievements in that direction are marked by the names of E. A. Faller, the Lorimer brothers, and F. R. McBerty. Faller was responsible for United States Patent 686892 of the 19th November, 1901, which provides for the use of "well-designed mechanism performing a definite cycle of operations and driven by some source of power." He also provided at the subscriber's telephone a calling device which enabled the required number to be visibly set up before any impulses were transmitted over the line.

Both these features were adopted in the Lorimer system, which had its origin in Canada and was installed in two public exchanges—Brantford and Peterborough—in Ontario. It was one of the first systems to be tried by the British Post Office and was installed in 1914 at the Hereford exchange, where it is still giving good service. Although the manufacture of this system for new installations has apparently now been abandoned, it contributed important ideas to the general subject.

The principle of power-driven machine-switching has been further developed by the Western Electric Co., in association with the American Bell telephone organization, in two forms known as the "rotary system" and the "panel system." These two systems differ widely from each other in mechanical design, but are electrically analogous. The rotary system, devised by Mr. McBerty, was installed experimentally in the company's New York factory in 1910, but the subsequent development and ultimate adoption by the Bell organization of the panel system, to which fuller reference will be made later, led to the abandonment of manufacture of the rotary system in the United States, where it has not been installed in any public exchange. Its manufacture was transferred to the Western Electric Co.'s factory in Antwerp, and it has been adopted with success in many European and other cities. The system, which is in operation in the Post Office exchanges at Darlington and Dudley, is undoubtedly an excellent one.

(2) Post Office Experience and Practice.

For more than 15 years the Post Office has studied the development of automatic exchanges very closely. In the early stages it adopted the policy of giving an actual working trial to such systems as promised to be capable of providing good and reliable public service.

The exchanges which it has, so far, installed are as follows:—

Exchange	*System*	*Opened*
Headquarters Official	Automatic Electric Co. (step-by step)	1912
Epsom	,, ,,	1912
Hereford	Canadian Machine Telephone Co. (Lorimer)	1914
Darlington	Western Electric Co. (rotary)	1914
Accrington	Automatic Telephone Mfg. Co. (step-by-step)	1915
Newport (Mon.)	,, ,,	1915
Chepstow	,, ,,	1915
Portsmouth	,, ,,	1916
Paisley	,, ,,	1916
Dudley	Western Electric Co. (rotary)	1916
Blackburn	Automatic Telephone Mfg. Co. (step-by-step)	1916
Leeds	,, ,,	1918
Grimsby	Siemens Bros. (step-by-step)	1918
Stockport	,, ,,	1919
Ramsey	Siemens Bros. (village)	1921
Hurley	,, ,,	1921
Fleetwood	Relay Automatic Co.	1922
Southampton	Siemens Bros. (step-by-step)	1923
Swansea	,, ,,	1924
Sketty	,, ,,	1924
Dundee	Peel Conner: North Electric Co. (step-by-step)	1924
Broughty Ferry	,, ,,	1924
Marton	Automatic Telephone Mfg. Co. (village)	1924
York	Auto. Tel. Mfg. Co. (step-by-step)	1924
Hadleigh	P.O. (Rural Auto. System)	1924
Blockley	,, ,,	1924

In some of these cases installation was seriously delayed by the war. The behaviour and the running expenses of all the exchanges mentioned have been critically watched and it may be mentioned that in no case has there been reason to regret the selection of any of the systems for installation. All have given, and continue to give, good service at reasonable maintenance cost.

It was also proved that the automatic method of working was generally acceptable to the British public and that the linking up of the automatic plant with the manually operated switchboards, required at all exchanges for toll junction and trunk traffic, could be effected satisfactorily.

The first exchanges of each type were installed, for the sake of experience, at places where new switchboards were needed, and it was quite recognized that some of them would operate under conditions which would not enable the automatic system to produce its best economic results in comparison with the cost of manual service. This arose mainly from the need for associating with each automatic exchange an unduly large proportion of manual switchboards for the purpose of dealing with external traffic. Much of this traffic fell within the unit-fee area and would, in a fully equipped area system, have been disposed of by automatic means. The total expenses were, in some cases, found to be somewhat higher than those which would have resulted from the use of manual exchanges, but they provided data by means of which financial comparisons could be made between the economic results to be anticipated in multi-office unit-fee areas fully equipped with the automatic or with the manual system. Such comparisons are made on the basis of inclusive annual costs, taking into account interest on capital, depreciation, maintenance and operating, with a calculated proportion of commercial and overhead charges. Many typical areas were studied in this way and the results were generally favourable to the full equipment of the area with automatic plant. In the Sheffield and Newcastle areas, for example, savings of over £14 000 a year and of nearly £7 000 a year respectively were indicated. After the various factors entering into these calculations had been investigated, it was found that the policy of providing automatic or manual equipment could in many cases be determined, without detailed calculation, by the application of the following general principles :—

(1) In an area where the anticipated development on all exchanges in a period of 20 years does not exceed 1 000 subscribers' lines, manual equipment is to be provided.
(2) In all other cases automatic equipment is to be installed, provided that the following traffic conditions obtain :—
    (*a*) The "calling rate" to average not less than 1·2 calls per subscriber in the busy hour of the day.
    (*b*) The proportion of local traffic to be not less than 70 per cent.
    (*c*) The number of manual operators' positions required, in association with the automatic exchange, not to exceed 55 per cent of the number of positions required for a manual system.

The fulfilment of conditions (*a*), (*b*) and (*c*) provides a safe case for the adoption of the automatic system. Cases which fail to satisfy these conditions are treated as border-line cases and are subjected to detailed calculation. The result of the investigation of these doubtful cases has, so far, shown that in more than 80 per cent of them the automatic system represents an economy.

Appendix 1 shows the results of the calculations made up to a 10-years period in three such border-line cases : Keighley, Maidstone and Macclesfield. Experience has shown that there are few areas, where the 10-years' development will reach or exceed 2 000 subscribers' lines, in which the automatic system will not show a comparative saving, and, as a result, it has just been decided that it is safe to install the automatic system, without detailed financial comparison with manual, if the following conditions will be satisfied within that period :—

(1) The average subscriber's calling rate to be not less than 5 calls per day.
(2) The number of local calls switched automatically to be not less than 4 000 per day.
(3) The proportion of originated calls requiring to be handled manually to be not more than 40 per cent.

On the other hand, if the number of local calls which might be switched automatically will not exceed 3 000 per day within the 10 years' period, manual equipment will be installed without question.

The introduction of the automatic system does not necessarily involve any appreciable modification of the private branch exchange switchboards working in the area. A great many private automatic exchanges have nevertheless been installed by the Post Office to meet the wishes of its subscribers. Some of these exchanges provide for over 500 lines. The majority of them are of the Relay Automatic Telephone Co.'s type.

(3) The Semi-automatic System.

Many telephone authorities, while constrained by the force of facts to admit that automatic selecting and switching mechanisms had been shown to be capable of furnishing reliable and economical service, yet hesitated to entrust the means of operating them to the general body of subscribers. It was argued that personal communication with an operator was necessary in order to reassure the public and to ensure proper use of the plant. To meet this frame of mind several systems known as "semi-automatic" have been introduced. These utilize the complete mechanical switching equipment of a full automatic exchange, in addition to a suite of manual switchboards, the operators at which receive all calls through the medium of an automatic "traffic distributor," ascertain the required connections verbally, and manipulate impulsing keyboards which steer the connection through the automatic selecting switches to the desired line. The subscriber is provided with an ordinary common-battery telephone set, and his procedure may be identical with that of a manual exchange system.

In effect, the semi-automatic system carries to its extreme the principle of reducing the work of the operator to a minimum, and its economic justification, as compared with manual systems, mainly depends upon the very high traffic load which it enables an operator to carry without strain. In addition, the cost of training operators is somewhat reduced and the setting up and severance of connections are effected more rapidly.

Its claims to superiority over the full automatic system are mainly based upon the simplicity of the subscribers' apparatus and procedure, the personal supervision of each call by an operator, the generation

of signalling impulses by easily maintained mechanism at the exchange, and restriction of the transmission of these impulses to circuits which are either within the exchange or are carried to other exchanges over junction circuits which are likely to be in more perfect condition than the subscribers' lines. All these claims are valid, so far as they go. It is also true that, from a service standpoint, it is much easier to introduce semi-automatic than full automatic in substitution for the manual system, especially in a multi-office area. There is no need to make wholesale changes in the subscribers' numbers or in the names of exchanges, or to worry subscribers by troublesome alterations in directories and working instructions, as the various exchanges in the area are successively converted to the automatic system. So great and so real did these difficulties appear that many convinced advocates of the full automatic system recommended the adoption of semi-automatic as an interim system during the long period of years that must elapse in an extensive telephone area before all its exchanges are transformed, notwithstanding the large wastage of distinctively semi-automatic equipment which must necessarily take place when full automatic working is finally introduced in the area as a whole.

A few years ago the Post Office was seriously considering the installation of one or more semi-automatic exchanges, mainly with a view to gaining experience which would be useful in connection with the treatment of very large areas such as London, and endeavours were being made, in association with contracting companies, to develop a system embodying the following prescribed features :—

(1) Standard manual-exchange operating supervision for all classes of calls.
(2) Control and release of all connections to be vested in the operator.
(3) Manual registration of successful calls.
(4) Even distribution of calls to operators in a regular indicated sequence; no waiting traffic to be hidden.
(5) Automatic team work and traffic concentration facilities to be provided.
(6) Facilities to be provided for holding switching plant for observation when faulty connections are established.
(7) Facilities to be provided for transferring special calls to separate positions for completion.
(8) Automatic selection of outgoing junction circuits for non-fee junction calls.

The quantity and complexity of equipment required to furnish the service and traffic facilities stipulated are, on a semi-automatic basis, considerably greater than are necessary for the full automatic system, and both the capital and the annual costs are higher. After careful study and valuation of all the pros and cons, the Post Office Engineering Department has reached the conclusion that, in general, when a change from manual working is justified, the full automatic system presents a greater balance of advantage than the semi-automatic.

As regards the interim use of the latter to overcome the special difficulties of introducing full automatic in large multi-office areas, recent inventions have, as described later, indicated a way out of these difficulties which permits of direct conversion, exchange by exchange, without any need for utilizing the semi-automatic system as a stepping-stone.

(4) Layout of Exchange Positions and External Lines.

The determination of the most economical number and location of exchanges to serve a telephone area involves an exhaustive study of all the costs of providing and maintaining external and internal plant and buildings, and also the cost of operating the plant. This is necessarily prefaced by development studies of all parts of the area, and general traffic estimates, extending many years ahead. Comparison of the costs of alternative schemes is made on the basis of annual charges, capital cost being converted into interest and depreciation and added to the direct annual costs of maintenance and operation.

The main items of cost to be considered in designing the layout are represented by :—Subscribers' lines, junction circuits, exchange buildings, equipment and power plant, "A" (answering) operators, "B" (junction) operators.

An increase in the number of exchanges reduces the area to be served by each of them, and consequently reduces the cost of subscribers' lines, both by shortening their average length and by enabling standard transmission efficiency to be attained by the use of a lighter gauge of copper wire. On the other hand, it increases the requirements for junction circuits, buildings and power plant. The optimum number of exchanges is represented by the layout which reduces the summation of all these costs to a minimum.

The number of exchanges required for the most economical service of an area on the automatic system differs materially from that required for the service of the same area on the manual system.

The main reason for this is the fact that junction circuits can be provided much more freely in an automatic system, since they do not carry with them the heavy operating costs which accompany their use in a manual system. In the automatic case only the plant costs of the junction system come into the calculation, and fuller advantage can therefore be taken of the economies represented by shortening the subscribers' lines. As a consequence, the adoption of automatic service in any large area generally involves an increase in the number of exchanges and a reduction in their average capacity.

The foregoing does not apply to portions of an area in which the telephonic density is such that exchanges of 10 000 lines' capacity are justified under either system. This number of lines happens to represent the practical limiting capacity of both manual and automatic exchange units, the limit in the manual case being the maximum number of connecting points which an operator is physically able to reach, and in the automatic case the decimal limit of the number of lines ever required at one point. The theoretical locations of exchanges in a dense city area are therefore the same for both systems.

In either case two or more 10 000-line units are housed in the same building if convenience so dictates.

The economies in line plant that can be realized in a properly laid-out automatic system, as compared with a good layout on a manual basis, are considerable. Calculations made about three years ago in connection with the layout of the London area showed that the costs of the line plant for the automatic system, at or about the year 1945, would be nearly 30 per cent below those of a manual system.

In the matter of exchange buildings the automatic system also enjoys a certain advantage. Accommodation for operators is not required at many of the smaller exchanges, while at larger centres, where provision is made for inquiries and certain classes of traffic to be dealt with by operators, the amount of such accommodation required is comparatively small. The plant serving a given number of lines can therefore be housed in smaller and cheaper buildings. This advantage is partly discounted by the fact that the average number of lines per exchange is less in the automatic system, and more buildings are required than would be the case in a manual layout. In general, the cost per line of small buildings is greater than that of larger buildings, but it is found that the automatic system introduces an overall economy of about 13 per cent in the cost of exchange sites and buildings. The total economy in external line plant, sites and buildings, which may be credited to the automatic system is about 23 per cent as compared with the manual system.

Reduction in the size of exchanges below a critical figure of about 3 000 lines also increases to a certain extent the cost per line of power plant and of automatic switching equipment for handling a given amount of traffic. These factors therefore tend, so far as they go, to keep up the size of exchanges of smaller capacity than 3 000 lines. In this respect automatic conditions differ markedly from those of the manual system, in which the high cost of the multiple equipment and its cabling causes the cost of exchanges, per line, to increase very rapidly with their size; this increase is, of course, much more than counterbalanced by the economies in junction working which attend the gathering up of the lines into large exchange groups.

The methods of calculation adopted in determining the layout of automatic exchange areas can be referred to only briefly.

The telephone system in this country is laid out in local fee areas covering all territory within a radius of 5 miles of a main exchange, with the exception of some of the largest towns which have a greater radius, up to 10 miles in the case of London. It is usual to consider the layout for one of these areas as a whole, but in making a detailed study the area has, of course, to be divided up into small portions, each covering the maximum territory that might be served from one exchange. The costs of serving this portion from one, two or more exchanges are then calculated, and the most economical arrangement ascertained.

In order to calculate quickly the economical layout of various telephone areas it is first necessary to prepare graphs showing the cost variation of each of the following items for different sizes of exchange :—

(a) Subscribers' lines.
(b) Junctions to carry traffic which would be created by increasing the number of exchanges serving each portion of the area, as explained above (these will be referred to later as "local junctions").
(c) Junctions to other exchanges, in so far as they vary with the size of exchange.
(d) Building and power plant.

Other costs, such as that of subscribers' instruments, are independent of the size of exchange and therefore do not enter into the calculation.

In applying these factors to the problem of determining the most economical size of exchange in areas of various densities, they are all expressed in the form

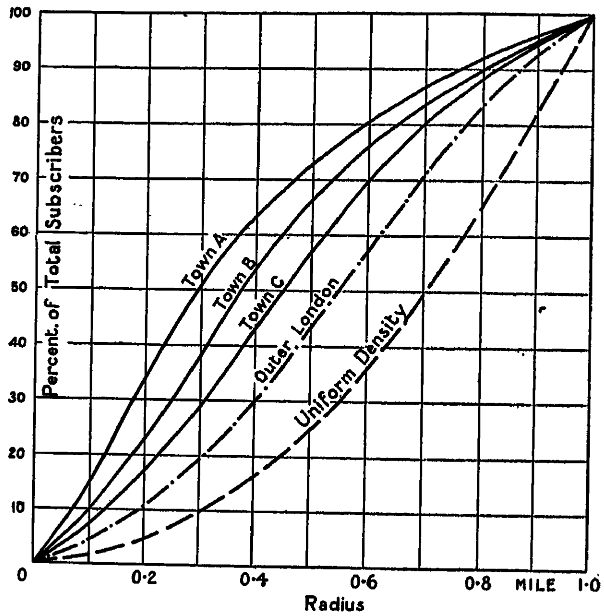

FIG. 4.—Number of subscribers within various radii, shown as percentage of subscribers within 1 mile radius.

of annual cost per subscriber's line and plotted against the size of exchange.

The calculation of the cost of the subscribers' line plant is somewhat complicated, but certain approximations can be made which simplify the work considerably. To determine the basic costs involves numerous calculations of the capital costs of various cable routes comprising different types of cable and different numbers of ducts laid under all classes of roads, with additions for overcoming difficulties depending on the particular locality being considered. From these and investigations into the lives of the various components of the plant, the interest and depreciation charges are derived. An allowance for maintenance is then added, giving the total annual cost per mile of each type of circuit. Fig. 4 shows the distribution of subscribers in a few typical cases, expressed as percentages of the total within a 1-mile radius of the exchange. The curve for "uniform density," which is of course the simple geometrical curve representing increase of area, gives

the largest percentage of subscribers in the outer portions of the area and represents one extreme condition. The nearest approach in practice to uniform distribution is found in the central districts of large cities. The curve for the districts of outer London, which is also shown, approaches more closely to the curves for smaller cities. The other curves represent towns in which the density diminishes, in various degrees, from the centre outwards. The curve most nearly representative of the area being studied is taken.

From this graph, curves are prepared showing the average length of subscribers' lines within any maximum radius, due allowance being made for the difference between route mileage and radial mileage. Owing to the fact that the cable routes have to follow the lines of streets, the route distance is much in excess of the radial, and generally the ratio is highest for the lines nearest to the exchange. From an analysis of a large number of exchange areas an average ratio of

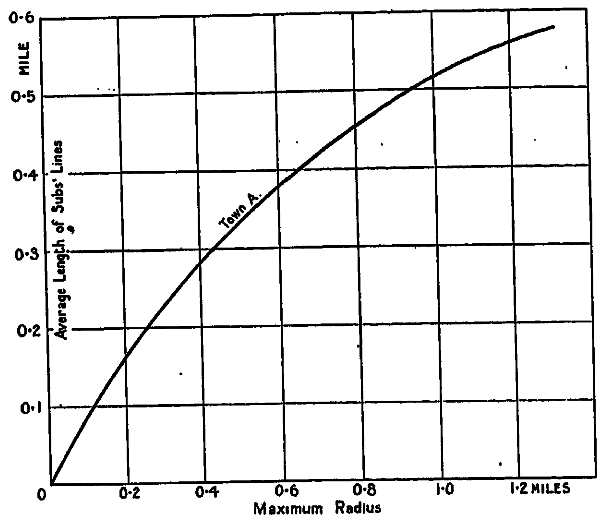

FIG. 5.—Average lengths of subscribers' lines within various radii.

route to radial measurement at various distances from the exchange has been arrived at and is used for working purposes.

Fig. 5 shows as an example the curve for an area similar to town A of the previous figure. From such curves and the cable cost per mile, the average cost per subscriber's line is ascertained.

The number of junctions required depends upon the traffic, which can be estimated from records of the traffic under existing conditions, and upon the number and methods of connecting the outlets from selector switches used in the switching system adopted. In estimating the cost of these junctions due allowance must be made for the various gauges of conductor necessary to give the required transmission efficiency, and for loading where this proves more economical than the provision of heavy conductors; the limits of resistance imposed by switching and signalling requirements have also to be taken into account. Detailed capital costs have been estimated for each of the types of cable necessary, and the annual costs per mile of circuit have been arrived at as described previously. In this manner a curve showing cost of junctions against size of exchanges for any particular area can be prepared.

Fig. 6 shows combined building and power plant costs based on statistics of a large number of existing exchange buildings. It has been necessary to ascertain

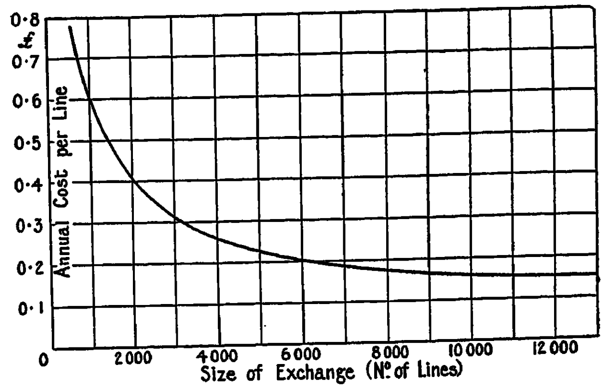

FIG. 6.—Annual cost of automatic exchange buildings.

capital costs of sites and of buildings specially designed for automatic exchanges, with all incidental accommodation. On this the interest and depreciation are calculated, and the charges for maintenance, cleaning, heating, etc., are added.

The annual charges for the power plant are arrived at in a similar way. For automatic exchanges over

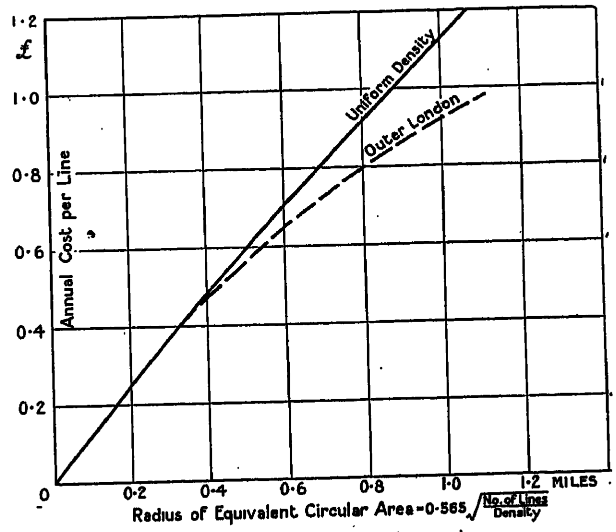

FIG. 7.—Annual cost of lines in various areas.

about 3 000 lines the cost of power plant, maintenance, etc., is practically the same per line; but as the size of exchange decreases, this cost increases, as already mentioned. Hence the 3 000-line exchange is taken as a datum point and only the excess cost for exchanges of smaller capacity is brought into the graph. The curve shows that the accommodation cost for exchanges of 1 000 lines is about 12s. per line per annum, reducing to below 4s. per line in the case of the largest exchanges.

The first step preparatory to dealing with the layout of an exchange area is to have a detailed development study made of the whole area to ascertain the number of subscribers likely to be obtained in the future, and their distribution. The Post Office practice is to have

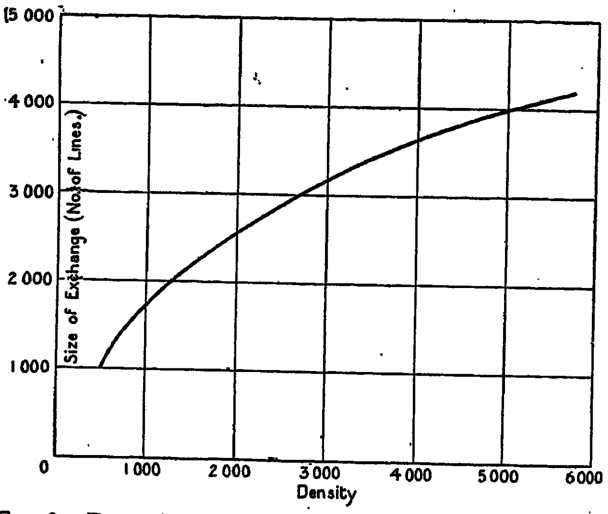

FIG. 8.—Economical sizes of exchanges for various densities.

these forecasts plotted on plans to show the number of subscribers anticipated in each small portion of the area, say in sixteenths of a square mile, at 5, 10, 15 and 20 years ahead. In the case of an ordinary provincial town an inspection of this plan shows that there is always a fairly definite business centre where the telephonic density is high, falling off rapidly towards the suburbs. This condition calls for a large exchange

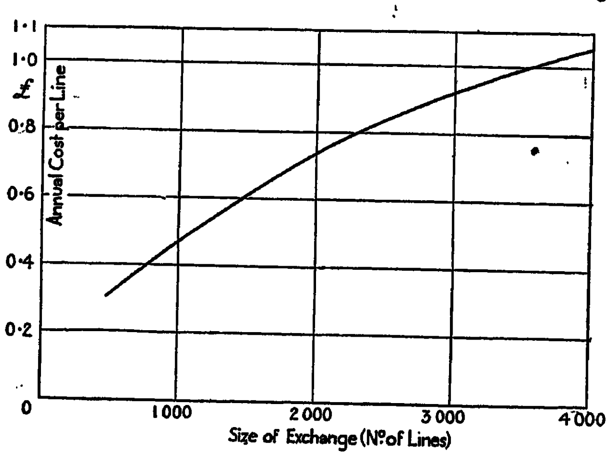

FIG. 9.—Subscribers' line costs for density = 1 500.

in the centre, the best position for which is generally more or less obvious, and this may be surrounded by one or more rings of small exchanges. The most economical position of the central and adjacent exchanges is then determined by inspection and a comparison of the costs of two or three alternatives.

Although the process is necessarily laborious, involving a large mass of calculations, an engineer experienced in this class of work can, within a reasonable time with the aid of these curves, work out the most economical layout for all but the largest towns.

In dealing with the larger towns, however, especially London, such a method would be unwieldy, and therefore the problem has to be attacked in a more indirect manner. It is assumed that the density, or number of subscribers per square mile, will be fairly uniform over the small portions of the area to be studied in separate

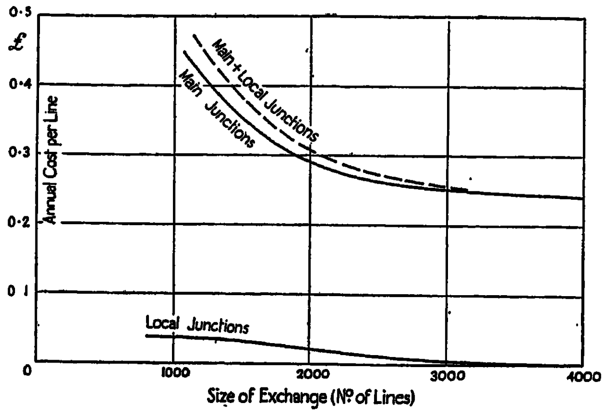

FIG. 10.—Junction costs for density = 1 500.

detail, which in the central part of the area is reasonably accurate. In order to relate the average length of a subscriber's line, and therefore the cost, to density and size of exchange, the graph shown in Fig. 7 has been prepared, based on Fig. 4 and the average cable costs.

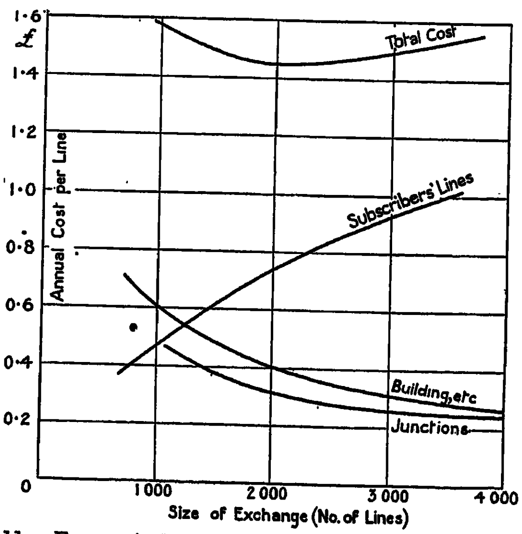

FIG. 11.—Economical sizes of exchanges for density = 1 500.

It will be noticed that the base of the graph is the radius of an equivalent circular area, not the size of exchange as in other graphs. This is found convenient for purposes of calculation because it combines the two independent variables, size of exchange and density. Numerically, the density is the number of subscribers per square mile.

In practice, of course, the exchange area is never

circular but, provided it is not very irregular and the exchange is properly placed at the telephone centre (that point which makes the total mileage of wire a minimum), the assumption introduces no serious error.

By means of this curve and the curves for junction and building costs already referred to, the economical size of exchange to serve an area of uniform density is arrived at, and a further curve (Fig. 8) can then be prepared giving the economical size of exchange for each density. Having this curve and the map showing the densities, the areas and location of the exchanges can then be set out, corrections being made for non-uniformity of density and other special conditions.

The application of the method may be illustrated by taking a typical area having a density of 1 500 subscribers per square mile. Fig. 9 shows the costs of subscribers' lines varying with the size of exchange, obtained from the curves already prepared. Fig. 10 shows similarly the cost of junction lines. The curve of total costs, Fig. 11, shows that for a density of 1 500 the economical size of exchange is about 2 000 lines.

It will no doubt be appreciated that this process represents only the first step in a case where an automatic system has to be grafted into an existing manual system. Allowance must be made for such factors as the layout of existing plant and the necessity for replacing each portion of the manual system only when it is economical to do so. This involves many considerations which it is unnecessary to detail here, but which all add to the complication of the problem confronting the engineer responsible for the layout of an exchange area and the economical introduction of the automatic system.

(5) Calculation and Layout of Internal Plant and Wiring.

After the position and capacity of a required automatic exchange have been settled, and a particular system has been chosen for adoption, there still remain many intricate problems to be studied and solved before the details of exchange design and specification can be matured. Subscribers' lines have only a small amount of apparatus allotted to the individual service of each. The great bulk of the exchange switching equipment consists of apparatus provided for the common use of all subscribers; its quantity depends upon the volume of traffic to be carried, and not upon the number of lines. There are many alternative ways in which the enormous number of selectable outlets involved may be grouped, and very careful calculation and planning are needed in order to arrive at the best economic layout and to ensure that the amount of switching plant at all points in the system shall be adequate to the requirements of the traffic without wasteful over-provision anywhere. It is necessary to prepare data of anticipated traffic for all classes of calls, and the average probable duration of the calls, known as the "holding time," has also to be determined. The amount of switching plant which will be simultaneously held in occupation during the busiest hour of the day depends on the product of "busy hour calls" and "holding time." This is expressed in what is known as "traffic units"—a term now standardized by the British Engineering Standards Association—in which holding time is reckoned in hours. Thus if each subscriber in a group of 100 makes, on the average, two calls during the busy hour, with an average duration of 3 minutes, the traffic originated will be $(100 \times 2 \times 3)/60 = 10$ traffic units. In other words, a traffic unit represents the equivalent of one hour's occupation of a switching channel. In most cases the switches engaged in providing a connection are engaged during its whole duration, and the calculated holding time for those switches includes the time to set up and to clear the connection, in addition to the period of conversation. Several recent systems involve the use of auxiliary sets of switches which are temporarily employed as steering switches to control the setting up of a through connection, and are then released. The holding time in the case of these switches averages only a few seconds, and a small number of sets can therefore handle a great many calls.

Another essential factor entering into the determination of the best economic layout is that known as "grade of service." Telephone traffic varies widely at different times of the day, and even the traffic of the "busy hour" shows considerable fluctuation from minute to minute. The provision of telephone plant in general is subject to the unfortunate economic condition that, so far as the bulk of it is concerned, its periods of idleness must greatly exceed its periods of employment. An endeavour to furnish an automatic exchange with switching facilities sufficient to ensure that exchange channels will be available for all calls at the peak of the busy-hour load in the busy season, would involve hopelessly uneconomic provision of expensive mechanism and would increase the cost of the service out of all proportion to the increase in its quality.

It is therefore necessary to fix a limit for the number of calls which may fail to get through on account of insufficiency of switching plant. This number must be so small that, to the subscriber, it is inappreciable. The proportion of calls that may be allowed to fail in this way in the busy hour represents the "grade of service" or "standard of service," and the Post Office has standardized a proportion of lost calls of 1 in 500 for each switching, with the proviso that if the traffic should increase temporarily by 10 per cent the grade of service shall not fall below 1 in 100. There are also certain modifications to cover special circumstances. Experience and observation have shown that the actual availability of switches, in groups carrying a given amount of traffic per hour, is closely in accord with the results obtained from a mathematical calculation of the probabilities, and, as is well known, the theory of probabilities is used, as far as it can usefully be applied, in the determination of the numbers of switches required.

For example, if a group of subscribers originating a given amount of traffic can be given access to a group of selectors, in such a way that each subscriber can reach any of the selectors, the application of the theory in order to determine the resulting standard of service is trustworthy and comparatively simple.

Most of the problems encountered in large areas are, however, too complicated to be readily solved by theoretical means. In the case quoted above each

subscriber will, in practice, obtain access to the first rank of selectors by means of a pre-selector or line switch having a limited number of outlets, say, 24. The number of first selectors required in the exchange may, however, be 1 000 or more, and the problem will be to arrange the inter-trunking of line switches and selectors in such a way that, while each line can only reach 24 selectors, the traffic of the exchange will be carried, at the specified standard of service, by a minimum total number of selectors. According to early automatic trunking practice the selectors would have been divided into independent groups of 24 and each group would have been multipled to as many line first selectors. The grading has 16 groups, each group comprising 75 subscribers with access to 24 outlets. There is thus a total of 384 outlets to be graded down to 128 selectors, and the way in which this may be done is shown in the figure.

It will be seen that each group of 75 lines has individual access to 4 selectors via exchange trunks, that it shares 4 further selectors with one other group, 3 with 3 other groups, and 7 with 7 other groups, while the remaining 6 selectors are at the common service of all the 16 groups, into which the 1 200 subscribers have been divided.

Each 75 lines has therefore access, complete or partial,

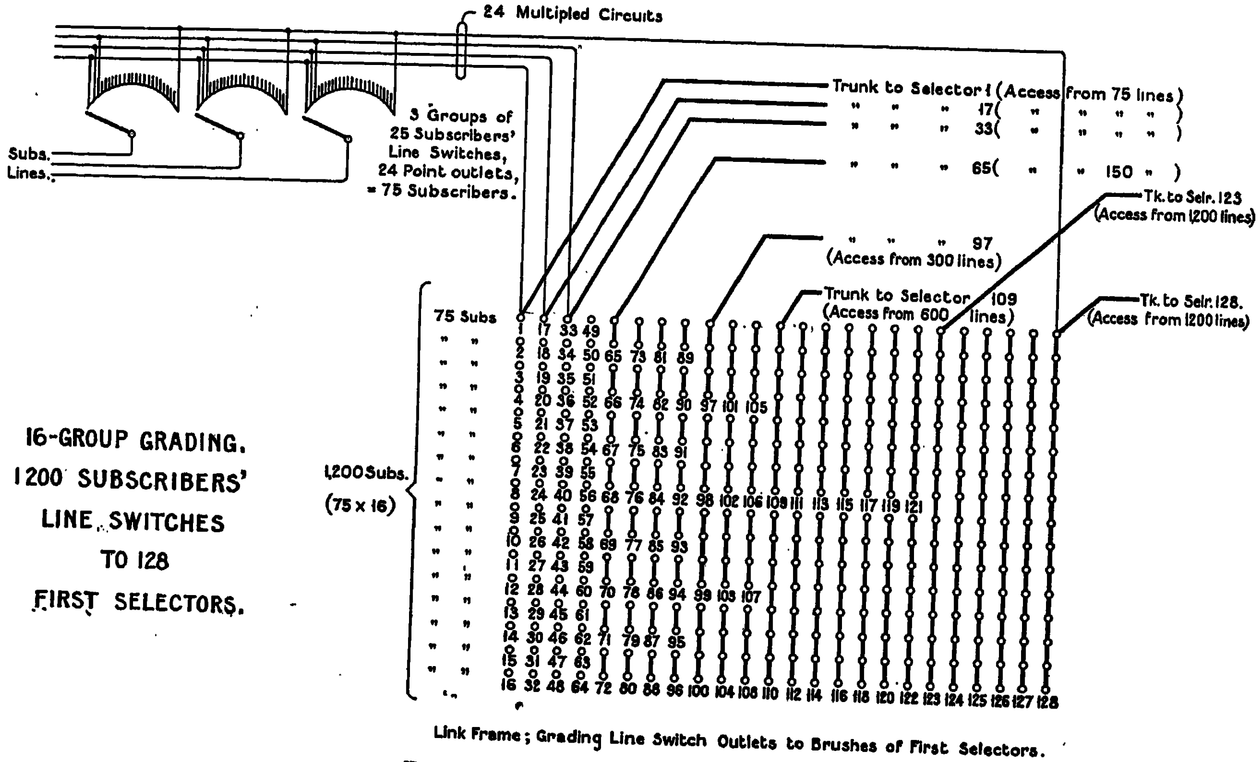

FIG. 12.—Diagram of group grading.

switches as it would suffice to serve during the busy hour. It has been found, however, that the average availability of selectors may be much increased by dealing with them in much larger groups, and by "grading" the multipled connections on the line switches in such a way that the 24 selectors to which each of them has access will be distributed throughout the larger group.

Fig. 12 illustrates the principle of grading applied to a group of 1 200 subscribers who require 128 first selectors to carry their originated traffic. Each subscriber is connected to a line switch having 24 outlets, and the outlets of 25 line switches are multipled together and terminated on a connecting rack. Any multiple of 25 subscribers may therefore be given access to one or more "individual" selectors, i.e. selectors to which that multiple, and no other, has access. In the figure, 1 200 subscribers' line switches are connected to 128 to 24 selector trunks, although its aggregate access necessarily remains equivalent to 8 trunks as below:—

Complete access to	4 trunks	= 4
Half access to	4 trunks	= 2
One-fourth access to	3 trunks	= 0·75
One-eighth access to	7 trunks	= 0·875
One-sixteenth access to	6 trunks	= 0·375
Mixed access to	24; aggregate access to	8

It should be mentioned that, as the selector trunks which represent the first choice of the line switches are naturally kept more fully occupied than those later in the series, and as the selectors themselves are arranged in groups of 10 having a common multiple, it is necessary to calculate the probable traffic in each and to connect them to the grading tags in such an order that each group of 10 will carry the same amount of traffic.

Apart from any method of grading, the best arrangement of the plant—in this ratio of 1 200 subscribers to 128 selectors, which is equal to 8 selectors for 75 lines—would have been obtained by combining the 24 outlets of 225 subscribers' line switches in a common multiple with access to 24 selector trunks. Assuming normal busy-hour traffic, this would have provided a standard of service of 1 lost call in 100.

Grading in 16 groups, as shown, raises the standard of service to 1 in 500 without involving the use of any additional plant. In the absence of grading, this standard could only have been attained by reducing the number of subscribers' lines served by 24 trunks and selectors from 225 to about 190—equal to an increase of 15 per cent in the required number of trunks and selectors. The economy effected by grading is therefore an important one.

Another, and older, method of increasing the traffic capacity of first selectors is to provide access to them via an intermediate set of secondary line switches or "preselectors." Many descriptions of this method have appeared in automatic literature, and it is not necessary to describe it here. There is good reason for believing, however, that, considering switching plant as a whole, the grading scheme effects substantially the same economy as the use of secondary line switches, while it has the great advantage of avoiding the circuit complications and the increased fault liability that the latter entails.

Problems similar to those mentioned arise in connection with the operation of hunting for disengaged trunking circuits between one rank of selectors and another. In this case the economic importance of securing optimum trunking arrangements is greatly increased by the fact that the next rank of selectors may be located in another exchange and the circuits may have to traverse some miles of street cables.

The increased traffic efficiency attending the selection of circuits in large groups has led to the design of selector switches which are capable of searching, or hunting, through much larger banks of trunking circuit contacts than the banks of 10 which are usually associated with the "step-by-step" automatic system. The rotary system of the Western Electric Co. searches over a bank of 22 circuits, while the panel system of the same company is arranged to search a maximum of 90 circuits and could probably, if desired, be arranged to search nearly 500 circuits. The switches of Messrs. Ericsson's machine-driven automatic system could also, if necessary, be arranged to find a disengaged circuit in a group of approximately 500. The direct step-by-step system is somewhat handicapped in this respect by the fact that the whole operation of searching for and finding a disengaged trunking circuit has necessarily to take place in the short interval between two successive pulls of the automatic signalling dial on the subscriber's telephone. In the case of machine-driven systems, such as those of the Western Electric Co. and Messrs. Ericsson, where the trains of signalling impulses are received from the subscriber by means of quick-acting "registers" which subsequently steer the call through the connecting switches, there is no such arbitrary time element to contend with.

It has, however, been possible to devise step-by-step switches which can search directly over a bank of 20 trunking contacts, two at a time, without exceeding the small time interval available. It is also quite practicable, on this system, to install suites of 10-contact or 25-contact "pre-selectors" between the various ranks of switches, and thus raise the theoretical trunk-hunting capacity to 100 circuits or 250 circuits. Such pre-selectors installed, say, between second selectors and outgoing junction circuits, would have their brushes joined to the selector banks and their multiple banks connected to the junctions. The selector can only find an outlet to the junctions via a pre-selector, the brushes of which are already standing on an idle line. Thus the actual searching movement is confined to the selector itself, and the time required for the operation is not increased by the introduction of the intermediate pre-selectors. Exhaustive study has shown, however, that by utilizing the methods of graded grouping already referred to, the need for large banks of trunk-hunting contacts, or their equivalent, can to a great extent be obviated, and that a satisfactory amount of traffic per switch can generally be carried even with 10 contacts in the bank level. It appears possible that the savings so effected in switch construction, and by the omission of the intermediate pre-selectors, will in most cases balance the cost of the proportion of additional junction circuits required for the 10-contact system, and selectors having banks of 10 contacts will therefore be used for ordinary services in the exchanges installed in London and throughout this country, unless and until further detailed study of local conditions indicates that facilities for increased searching range will at some points be economical.

It has been mentioned that the theoretical method of attacking problems of switching layout is often exceedingly difficult and leads to results which are tedious to evaluate. The most obvious alternative is to solve such problems by actual observations on working exchanges. There are two objections to this: first that it is difficult to control such tests—i.e. it is necessary to work with the traffic actually experienced, whether this traffic is that required to give salient points on traffic curves or not—and secondly, that the available range of "grade of service" is very small, so that it is not possible to find what deterioration is effected in the service by a given increase of traffic or reduction in the number of switches. For these reasons it has been a practice of the Engineering Department to make use of "artificial traffic" for the production of designing curves, and the results obtained are checked by theoretical calculation and by observations at working exchanges, where possible.

Two methods of producing artificial traffic have been used, one employing numbered counters and the other making use of the numbers in a telephone directory. In the first method 100 counters, numbered "01" to "99," are placed in a bag and shaken. Counters are then drawn one by one at random, each counter being replaced after drawing. The number of such drawings is made equal to the number of "busy hour" calls required for the test, and the number drawn represents for that call the interval of 1/100th of an hour at which

the call originates. By repeating the process and tabulating the results together, the time at which each supposed call originates may be determined to 1/10 000th of an hour. The times of the calls are arranged in sequence and are then available for the analysis of the effect of any desired grouping of switches. The holding time may be constant or variable, as desired. In the telephone directory method, the time at which a call originates (to 1/10 000th of an hour) is obtained by choosing a succession of 4 digits from the numbers in the directory. In general, tens digits only are used, as with the others there would be a tendency for certain digits to occur more often than others.

Each of these methods is, of course, merely an attempt to obtain a sequence of events in time according to the laws of pure chance, and so to represent the entirely fortuitous intervals at which individual calls are made during a short period when the aggregate amount of traffic is fairly constant.

As an illustration of the way in which the fluctuations of traffic are proportionately reduced as the size of a group increases, it may be of interest to consider the case of a number of subscribers each making two calls per busy hour with a holding time of 3 minutes. If these are arranged in a group of 10 having a common outlet, the resulting traffic would be equivalent to 1 traffic unit, and if the calls were made at absolutely uniform intervals they would all be carried by a single switching channel, continuously occupied. Similarly, a group of 250 lines would originate 25 traffic units and require 25 switching channels under the same conditions.

Actually, if this provision were made the following percentages of calls would be lost:—

	Per cent
For 10 lines (1 traffic unit and 1 switch) the loss would be	50
For 100 lines (10 traffic units and 10 switches) the loss would be	21·5
For 250 lines (25 traffic units and 25 switches) the loss would be	15
For 1 000 lines (100 traffic units and 100 switches) the loss would be	7·6

The matter may be looked at in another way as follows:—Assuming that the standard grade of service of 1 in 500 is given, it is found that the average traffic per switch for the numbers of switches quoted above and in two graded cases would be as follows:—

10 Switches will be asked to carry 3·43 traffic units per hour; average traffic units per switch	0·343
25 Switches will be asked to carry 13·76 traffic units per hour; average traffic units per switch	0·55
100 Switches will be asked to carry 76·4 traffic units per hour; average traffic units per switch	0·764
100 Switches (10-contact grading), 43·6 traffic units per hour; average traffic units per switch	0·436
100 Switches (25-contact grading), 64·08 traffic units per hour; average traffic units per switch	0·641

In the first three cases the pre-selectors finding their outlets via these switches are assumed to have a sufficient number of contacts to secure full availability; in the two last (graded) cases the pre-selectors would have only 10 and 25 contacts respectively.

(6) SERVICES RESERVED FOR MANUAL OPERATION.

The conversion of an area to automatic working does not involve the complete elimination of the manual operator. Some classes of traffic can at present be handled more conveniently and economically by manual than by automatic means and, in general practice, all calls for which more than the unit fee is charged will be dealt with by an operator who will record each call on a ticket in order that the proper debit may be made to the calling subscriber. In the Post Office system, operators are retained for trunk and toll circuit calls, extra-fee junction calls, phonogram (i.e. telegraph message) calls, call-office and coin-box station calls, and for "inquiry" and "information" calls.

Until recently all coin-box and call-office traffic was handled manually, but a new form of coin-collecting box has now been introduced which provides for the deposit of the local unit fee automatically. The attention of an operator will only be required for calls involving the deposit of additional coins in the box. The use of this new coin box in association with automatic systems will, in the first instance, be confined to provincial areas.

For all calls to points outside the unit-fee area, the originating automatic subscriber dials a number which will obtain the attention of an operator in his own local exchange, or in the trunk or toll exchange, to whom he gives his demand. The call is than handled and recorded on a ticket in the regular manual fashion throughout.

The method known as "dialling out," which permits the calling subscriber to obtain direct communication with an operator at the distant exchange required, is frequently advocated, but has not been adopted by the Post Office for extra-fee traffic, on account of the disadvantage of removing the supervision of such calls from the operator at the home exchange. The distant operator cannot conveniently be placed in a position to check the identity of the calling subscriber against whom the extra charge is to be debited.

The converse procedure of "dialling in" is, however, in common use. A subscriber on a manual exchange who requires a subscriber on an automatic exchange, reached by means of a junction or direct trunk line, makes the demand to his local operator as usual. This operator then completes the call by dialling from her cord circuit over the junction or trunk line directly into the switches at the automatic exchange, and thus sets up the desired connection without the intervention of an operator at the called exchange. This method of operating is adopted in all cases where line conditions permit, in preference to the alternative method of passing the demand verbally by order wire, or over a signalling junction to a manual operator at the required automatic exchange for completion.

The character of the line has, however, a restrictive effect upon the extent to which "dialling-in" can be em-

ployed. The method is practicable on almost any length of unloaded physical line, but the introduction of loading coils and repeaters and the use of phantom circuits give rise to certain difficulties. The transmission constants of a loaded line introduce a marked degree of distortion in the dialled impulses, but in the few cases where this trouble would be sufficient to affect working efficiency it would be possible to remove the difficulty by the use of special methods and apparatus.

Repeaters and phantom circuits are, however, obstacles which have not yet been fully overcome. A solution has been found to the cognate problem of sending calling and supervisory signals over such circuits, and considerable progress has been made with the solution of the dialling problem. A method which promises a satisfactory result involves the use of high-frequency alternating currents, the application of which to the line at the sending end is controlled by the dial impulses. At the receiving end these trains of high-frequency alternations operate on the grid of a valve having in its plate circuit a relay which, in turn, controls the stepping relay of the selector switch.

In ordinary local areas of medium size an endeavour is always made to change over from manual to automatic working simultaneously at all the exchanges in the area, but this is often impracticable and in such cases one or more exchanges remain manual whilst the remainder are automatic. Under such conditions the methods of "dialling-in" and "dialling-out" are both adopted for interchange of traffic between the two systems, and each call is dealt with by one operator only.

There is no objection to allowing an automatic subscriber to dial out to the operator at a manual exchange in the case of unit-fee traffic, since the registration of the call is automatic and the operator, who has no extra charges to record, is not concerned with the identity of the calling subscriber.

(7) The Problem of very Large Areas.

Although it has long been recognized that the mechanical switching possibilities of automatic selecting apparatus are theoretically unlimited, there have been difficulties of a very practical kind in applying it to the telephone service of the largest area systems which have grown up in manual exchange practice. Up to a few years ago it was necessary to envisage an automatic intercommunicating area as laid out upon a perfectly uniform and rigid scheme of exchange numbers for the subscribers in all parts of it. The first digit of each number had to choose a line to a particular district, every subscriber in which must have a number commencing with that digit. There might be another digit to choose a particular exchange in the selected district, in which case all the subscribers' numbers on that exchange would have to commence with the same two digits. A further four digits would suffice to choose any subscriber's line in an exchange of 10 000 lines, or in a group of smaller exchanges of 10 000 lines' aggregate capacity. Such a system would be a straight 6-digit system or its equivalent and, as one or two initial digits have to be reserved for special purposes, it would serve a maximum of about 700 000 subscribers' lines. If it were possible to construct the whole system *en bloc* and to transfer to it all existing subscribers on a given day, on which day a brand-new telephone directory would be brought into use, the fact that every number on the system had been changed might not present too serious a difficulty. In reality, of course, the process of transfer must generally extend over several years. The economic advantage of the automatic system is not usually sufficient to justify the scrapping of adequate and up-to-date manual exchanges, and there is generally a long interim period during which the two systems must exist side by side. So long as a rigid numbering scheme was essential the successive transfers of groups of subscribers, as additional automatic exchanges were opened, occasioned in each case a certain amount of dislocation of the service. The continual change of indefinite groups of numbers in the directory, and the consequent alterations in the methods of initiating and handling the traffic concerned, were exceedingly troublesome to subscribers and operators alike. Another condition necessarily attending the layout of an area under a rigid numbering scheme is that in all parts of it a definite allocation of spare numbers must be made at the outset, in order to provide for future development at each particular point during a period of many years. Similarly the layout of main switching centres, the number, capacity, and approximate positions of all exchanges, the routing of traffic between them, and the capacity of the routes followed by external junction lines, must be settled long in advance of the maturing of full requirements. Telephone development is affected by so many uncertain factors—commercial, social and political—that it is very doubtful whether even the most careful forecasts of ultimate development could be relied upon to avoid the probability of enormous expense and inconvenience in providing for errors and in correcting them. A further possibility of danger arose from the fact that the handling at manual exchanges of calls for automatic subscribers absorbed more of the operators' time than ordinary calls. As the proportion of such transfer calls increased, the traffic capacity of each manual exchange would be correspondingly reduced and additional operators' positions, with in some cases extensions of buildings, would be necessary to serve the existing manual subscribers at unconverted exchanges. There would be many cases in which such extensions could not be made and a very critical position might arise. So serious did these aspects of the matter appear that telephone engineers responsible for providing the means of carrying on uninterrupted service in the large and immensely important areas represented by New York, London, and other great cities, hesitated to embark upon the task of introducing the automatic system in these areas.

As already mentioned, the preliminary installation of a semi-automatic system throughout the area, followed by a final quick change-over to full automatic, presented a solution—although an uneconomical one—of some of the difficulties of the transition period, but it did not provide any way out of those affecting the subsequent development of the area on the basis of a rigid numbering scheme.

A notable attempt to solve the London automatic

problem was described in a paper * by Messrs. Laidlaw and Grinsted, read before this Institution in 1919. The authors proposed to divide London into nine regions, each expected to serve about 100 000 subscribers, and to mark the names of these nine regions on the subscribers' calling dials, adjacent to digits 1 to 9. The main switching exchange in each region would bear the regional name, and would be reached, by the first pull of the dial, from any subscriber's station in London. Access would be obtained through it to all the other exchanges in the region. Subscribers' numbers would all be changed and would consist of the regional name followed by 5 digits, or possibly by 6 digits. In a 5-digit system, for example, "Wimbledon 1829" might become "South 71829," the digit 7 being used to steer the call into the Wimbledon exchange. ("Wimbledon 19" would become "South 70019.") The initial digit "0" would be used to gain the attention of an operator for all service purposes and for the completion of all calls to points not included in the nine London regions. The proposal was very ably worked out, but it was felt by the Post Office that it failed to provide the traffic and engineering conditions necessary for the satisfactory introduction of automatic working in the London area. It postulated a rigid numbering scheme, with eventual alteration of all existing subscribers' numbers; an inflexible routing scheme which involved, *inter alia*, the provision of direct junction circuits from every main exchange to all the regional centres. Only 10 exchanges in each region of 100 000 lines could be selected by means of the second digit, but the most economical layout of the regions would seldom be secured by 10 exchanges of 10 000 lines each. In some cases the number would approach 20 exchanges of correspondingly reduced capacity. An exchange of 4 000 lines, for example, would therefore have to be reached, through a nominal 10 000-lines' centre, by 4 separate third digits, each representing the selection of a group of 1 000 lines. Junction circuits would have to be provided for each group independently, instead of as a common stock available for the full 4 000 lines. Such conditions tend to involve excessive provision of external plant. The scheme also dictated a certain artificial sequence of exchange transfers—inasmuch as in every case the main regional exchange would have to be made automatic before any other exchange in the region could be dealt with—which would have been liable to involve heavy economic wastage. Some of the interim arrangements proposed for the transition period would also have led to troublesome repercussions in practice. (These remarks are, I think, quite consistent with high appreciation of the value of the contribution made by Messrs. Laidlaw and Grinsted to the general study of the subject.)

(8) The "Panel" System of the American Bell Companies.

Such was the London position until in 1919 we began to hear rumours that the long-continued and quite unadvertised efforts of the American Telephone and Telegraph Co. and its associated manufacturing concern, the Western Electric Co., had succeeded in evolving a system which obviated all the well-known difficulties, and that it had actually been decided to commence its installation in New York. The basis and general arrangement of the new system—the "panel" system—had been known in this country for some time, but details of its most recent development were lacking until Mr. McQuarrie of the Western Electric Co. visited this country early in the year. Mr. McQuarrie's description of the new operating features which had been grafted on to the system came to me as a veritable flash of light. It was at once evident that, by the invention and application of the digit translators, numerical call indicators, etc., which he described, most of the old bogies had been disposed of, and that a way had been opened for the direct application of the automatic system to telephone areas of the very largest size. Initial preparation could be made at all exchanges in the area without affecting the service, and thereafter the installation of automatic plant could begin at any

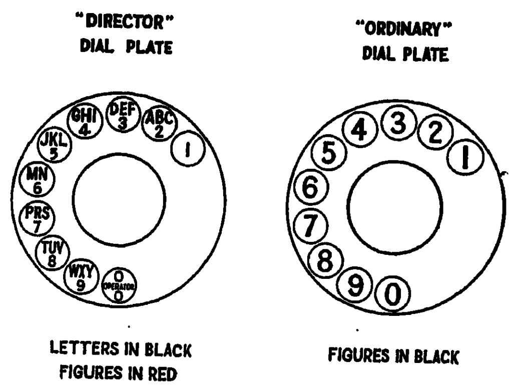

Fig. 13.—Automatic dial plates.

points where new exchanges were required. The routing of calls through various switching centres could be arranged in accordance with the actual needs of the traffic and could be modified from time to time as development might dictate. There was no need for any wholesale change of exchange names or of ordinary subscribers' numbers; all that was necessary was to alter a few names which were alphabetically or numerically similar to others, and to level 2-digit and 3-digit subscribers' numbers up to four digits. (Even these comparatively trivial modifications are quite sufficiently troublesome in practice.) The arrangements for interchanging calls between automatic and manual exchanges permitted of rapid operating and tended to raise, rather than to lower, the traffic capacity of existing manual exchanges. Each subscriber, automatic or manual, could make all his calls in a uniform manner and would not require to distinguish in any way between calls for correspondents served by automatic or by manual exchanges. Above all, a directory which would give no trouble to any subscriber could be prepared once for all, in advance of the first exchange transfer, and could be maintained unaltered throughout the whole transition period and into the subsequent full automatic

* "The Telephone Service of Large Cities," *Journal I.E.E.*, 1919, Supp. to vol. 57, p. 158.

period, apart, of course, from ordinary additions and deletions.

The subscribers' calling dial with a combination of letters and numbers, first introduced in connection with the panel system, has frequently been described and is becoming fairly well known, and the same applies to the arrangement of the directory pages.

Fig. 13 shows the finger plate of this dial, as well as one of the ordinary type. The subscriber is required to dial the three initial letters of the required exchange, followed by the four digits of the called subscriber's number. The three letters which appear in each of the finger holes of the dial have, of course, the same numerical significance, and produce the same effect upon the switching mechanism as the digits which occupy the same positions; the use of letters is purely a matter of convenience. The three initial letters of each exchange must represent a different combination of digits from those of any other exchange. Obviously, therefore, the two names "HAMmersmith" and "HAMpstead" must not exist together in the same area, and the same would apply to two such names as "Victoria" and "Thames" since the pulls of the dials

FIG. 14.—Extract from a New York telephone directory.

represented by VIC are identical with those of THA. Fig. 14 shows the arrangement of part of a directory page. The block printing of the first three digits of the exchange names does not at all inconvenience the manual subscriber who passes his calls verbally, and it indicates to the automatic subscriber that these three letters must be dialled in order to reach the exchange in question.

As already indicated, the panel system is so equipped that each subscriber obtains communication with all his correspondents, manual or automatic, in the same manner, and is therefore quite unaffected by the successive conversions of exchanges, other than his own, from one system to the other. So long as his own station remains manual he passes all calls to his exchange operator verbally as usual and, as soon as his own exchange has been converted to the automatic system, he uses his calling dial in exactly the same way for calls to either type of exchange.

This result is achieved by the introduction of "call indicator" equipment of types substantially similar in operating principle to those which have been adopted for the London automatic system, as described later (see Figs. 22 and 23).

A detailed description of the panel switching system and its modes of operation—which represent a remarkable aggregate of invention and design—would occupy several volumes, and only a brief reference to it can be made here. Its evolution was only undertaken after a thoroughly comprehensive study of all existing automatic systems, and with the specific object of producing a system specially adapted to service in the largest and most densely telephoned areas, which would be capable of furnishing every kind of service that the manual system, with its operators, has ever been called upon to supply. A preliminary description, by Gherardi and Charlesworth, was printed by the Associated Bell Companies in 1920, and a fuller general description was presented in a paper* by Craft, Morehouse and Charlesworth, read at a convention of the American Institute of Electrical Engineers in 1923.

The installation of the system has been rapidly pushed forward and it has now been equipped in New York and some other large American cities to a capacity of more than 250 000 subscribers' lines.

The system derives its name from the design of the selector switches, the multiple contact banks of which are arranged in large flat panels over which the contact brushes move in vertical lines. Its moving parts are all machine-driven by means of a system of rotating shafts maintained in continuous motion by specially designed motors of practically unvarying speed. Its electrical design differs profoundly from that of step-by-step systems with straightforward selection by decimal stages. In general the movements of the switches are governed by what is known as "revertive control," that is to say they are not actuated by impulses sent into them but, after having been started, the switches themselves send impulses back into the controlling mechanism, which counts the impulses and stops the movement of the switches when the required position has been reached.

The number of circuit outlets among which a panel switch can exercise selection is not limited, as in the step-by-step system, to 100, but has, in fact, been made 500; that is to say the successive selections do not follow in decimal sequence.

Since the subscriber's calling dial transmits a series of plain decimal impulses, it is necessary to provide means for receiving these impulses and translating them to a non-decimal basis before they are used for controlling the movements of the switches. This function is performed by a combination of apparatus—called a "sender"—situated in the exchange of the calling subscriber. In the sender the decimal impulses sent out from the dial are accepted, stored, translated and finally sent out, in any desired sequence of impulse trains, to route the call through any necessary intermediate switching centres to the required exchange, and, finally, to reach the line of the called subscriber. Complete numbering and trunking flexibility is thus provided.

As already mentioned, the motion of the selector

* *Journal of the American Institute of Electrical Engineers*, 1923, vol. 42, p. 320.

used in the panel system is vertical only; when hunting for a circuit it moves upwards, and when released it returns downwards to its normal position of rest. The movable portion of each selector consists of a long tubular metal rod carrying six triple-contact brushes. One of these brushes fixed at the top of the rod moves over a flat commutator in combination with which it controls the extent of the motion and also extends the three wires of the selector circuit to the other five brushes. These five brushes are spaced equidistantly on the tube and have in front of them the flat panel multiple of 500 circuits. Each brush has access to 100 of the circuits and each selector can therefore make connection with any one of 500 circuits. Motion either upwards or downwards is imparted to the rod and brushes through the medium of magnetic friction clutches placed at the bottom of the rod in association with the constantly rotating power shafting.

The panel with its five sections of 100 lines each, placed one above the other, is fitted in the centre of an iron framework.

Each section is built up of flat punched strips of brass or other suitable metal about 42 in. long by 1 in. wide. There are three strips to each circuit, two of these corresponding to the line wires and one, used for local control purposes, corresponding to the sleeve connection of manual exchange circuits. The 300 strips in a panel are securely bolted together and are insulated from each other and from the framework. The two long edges of a strip are each formed with 30 projections with which the selector brushes can make contact. Selectors to the number of 60, with their vertical rods and brushes, are associated with each 500-line panel, 30 of them being mounted on the front and 30 on the back of the panel. Each of the 500 sets of three metal strips, with their front and rear projections, thus represents, in itself, a multipled line with which any of the 60 selectors can connect the circuit of its brushes.

When a selector is searching it is trying to find either a particular circuit or a disengaged circuit in a particular group. That circuit or group of circuits will appear on only one of the five 100-line sections of the panel, and it is necessary that, of the five brushes on the selector which are all connected together in multiple, only the one opposite that particular section should be active. Each brush is therefore normally retained in an inactive position, and it is arranged that in the process of selection, before searching begins, the correct brush shall be thrown into the active position. This is effected by means of a rod carrying trip fingers, one of which unlatches the selected brush as soon as the brush rod begins to move upwards. The four brushes opposite the other sections of the panel remain inactive and pass over the projecting contacts on the line strips without touching them.

Associated with each selector is a "sequence switch," the function of which is to make and unmake in the proper order the various circuit combinations required as a connection progresses through its various stages. This very important item consists of a central shaft fitted with a number of cams, or segmental contact rings, so cut that the various contact springs associated with them close and open circuits in a definite sequence and at definite points during the motion of the switch from position to position. The switch has 18 positions, in any one of which it may be stopped as required. It is operated by means of an electromagnetic clutch from the motor that drives the selectors.

Fig. 15 is a general view of a selector frame. The five panels are marked P, the commutators at the top are marked C, the brushes are marked B, and the brush-carrying tubes E. At the bottom the clutch magnets are marked M. The sequence switches and other apparatus associated with the selectors can be seen on the frame at the sides of the panels.

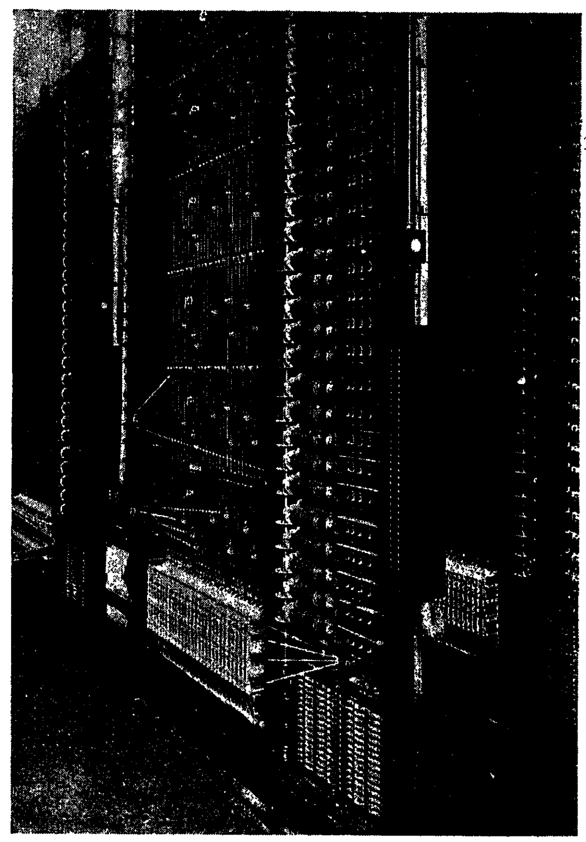

FIG. 15.—Panel selector frame.

Four principal types of selector besides a line-finder switch and a sender selector are used in the panel system. These four are all similarly constructed, but differ in circuit details. Their relative positions in making connections are shown in Fig. 16.

For calling purposes, subscribers are connected in groups of 300 to line-finder switches which are of the same construction as the selectors except that there are 15 panels of 20 lines each and 15 brushes per switch. When a subscriber lifts his receiver to make a call he operates a relay at the exchange, bringing a line-finder into use. The particular brush opposite the 20 group in which the subscriber's line is situated is tripped and hunts for his line. When the line is found the switch comes to rest with the brush on its terminals. At the

same time a sender selector, which may be a switch of the rotary type, hunts for a disengaged sender which it connects to the line-finder and to a district selector associated with the latter. The subscriber now hears a tone signal, and as this is an indication that he may do so, he dials, in order, the first three letters of the wanted exchange name and the four digits of the wanted subscriber's number. The dialled impulses having been received and translated in the sender, a circuit is established between the sender and the district selector. The object at this stage is to extend the calling subscriber's line by means of a junction to the exchange of the wanted subscriber. The district selector has access to a total of 500 circuits; but as 45 of these are used for local service purposes, the maximum number of outgoing circuits which it may use is limited to 455. As the total number of junctions outgoing from an exchange is likely to be very much greater, it is necessary to place the outgoing ends of most of the junctions upon office selectors and to arrange for the district selector to find either a junction direct or a circuit to an office selector having access to the desired junction group.

As soon as the fundamental circuit is established between the sender and the district selector, a clutch on the latter is operated and the brushes move upwards. After they have taken one, two, three, four or five steps the circuit is interrupted by the sender, and the brush trip magnet on the district selector operates, so that when the brushes again move upwards the one associated with the 100-line section of the panel containing the required junction group will be tripped into the active position. There may be several junction groups on this section, and therefore the next selective operation is to find the right group. The fundamental circuit is now re-established, the district selector again moves upwards and, as it does so, sends impulses back to the sender. The sender counts them and, when the number corresponding to the position of the group on the panel is reached, the sender again interrupts the fundamental circuit and the district selector comes to rest with the brush resting on the terminals of the first circuit in the group. If that circuit happens to be engaged, the district selector is re-started and

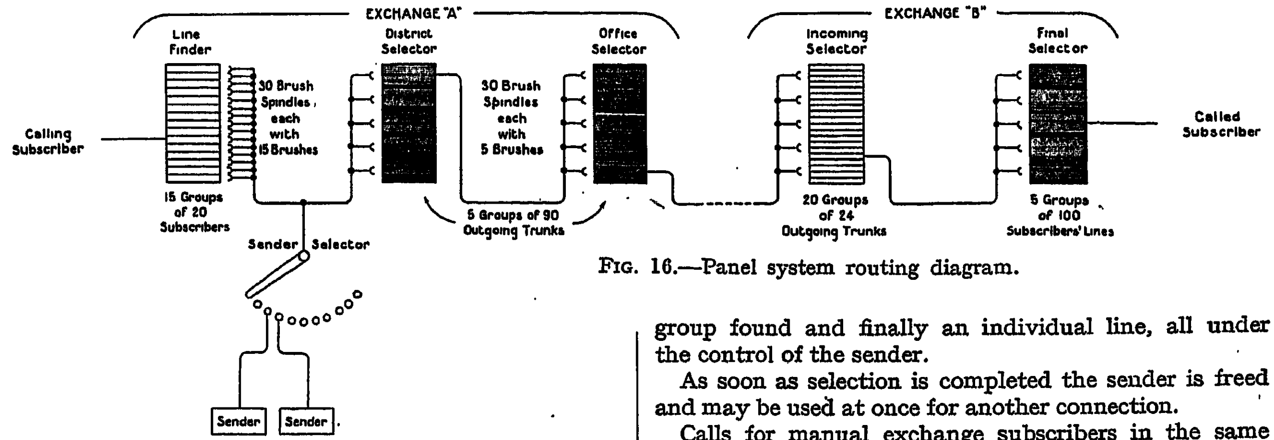

FIG. 16.—Panel system routing diagram.

continues upwards till it finds a disengaged circuit and makes connection to an office selector.

A similar sequence of operations having taken place at the office selector under the control of the sender, connection is made to an incoming selector at the wanted exchange.

Now, as the unit of the system is an exchange of 10 000 subscribers' lines—numbered from 0000 to 9999—and as 500 subscribers' lines are multipled on each final selector, there will be 20 groups of final selectors in a fully equipped exchange. It is arranged, therefore, that each incoming selector shall be equipped with a multiple of 20 groups of 24 circuits each, outgoing to final selectors, distributed four groups per panel. The process of selection at the incoming selector is again a matter of tripping a brush, finding a group, and finally a disengaged circuit to a final selector: this is done by the process used in the previous cases, under control of the sender.

At the final selector a brush has to be tripped, a tens group found and finally an individual line, all under the control of the sender.

As soon as selection is completed the sender is freed and may be used at once for another connection.

Calls for manual exchange subscribers in the same area, which are dialled in exactly the same manner as calls for automatic subscribers, are taken by the sender, translated and sent out to the manual exchanges, where they are displayed on call indicators in front of the junction operators as already mentioned.

It will have been gathered that the "sender" which controls all these operations is a remarkable piece of electrical equipment. In addition to the duties already mentioned, however, it fulfils a multiplicity of other functions. It has to distinguish the type of exchange to which a call is destined, so that it may control the operations associated with the progress of a call to an automatic exchange in one way, and to a manual exchange in another way. It distinguishes between calls for a terminal exchange and those for a tandem exchange, and causes them to be operated in an appropriate manner for each case. It distinguishes between connections which will pass out over loaded and unloaded lines, and it directs the selector switches in the setting up of the proper transmission conditions accordingly.

Certain senders associated with groups of coin-box lines test the calling lines and determine whether the callers have deposited the necessary coins before putting connections through. They also determine in each case

whether a fee is chargeable, and cause the coins deposited either to be collected or returned to the callers. When its work is done the sender must cut itself free and return to its normal condition in readiness for another transaction.

An idea of the electrical intricacy of a 7-digit sender may be gathered from the *skeleton* diagram shown in Fig. 17.* It must be recollected that only a small fraction of its total equipment and wiring is illustrated, and that such items as the multi-contact "sequence switches" are not shown as such, but appear merely as conventionally numbered contacts interpolated in the parts of the wiring scheme to which they apply. In order to read the diagram intelligibly, it would be necessary to have full information as to the time sequence in which these contacts are operated by the driving mechanism. It will be agreed that the sender is a formidable electrical item!

Fig. 18* shows the form of contact brush used on the panel selectors, and gives a view of the machine tools, assembling and adjusting tools, testing jigs, etc., required to manufacture it. The contrast between the tiny brush and the great array of necessary tools illustrates the high degree of machine-shop organization involved in modern quantity production.

The panel system in its entirety includes a multitude of electrical circuits of great complexity. It is the product of many wonderful brains, and its rapid development and installation are the outcome of probably the greatest engineering effort so far made in any field of industrial endeavour. Its future will be followed with keen interest by all telephone engineers.

(9) The Choice of a System for London.

Four years ago the development of the "panel" system had reached a stage which placed it far in advance of other then existing systems in respect of suitability for the equipment of the largest cities. The Post Office was eager to start the introduction of automatics in London, as many large new exchanges were required to provide for development and for the replacement of existing obsolescent or inadequate exchanges, and the installation of these important exchanges on the manual system would have had the effect of postponing by many years the ultimate complete conversion of the area to automatic working. The panel system was, therefore, very closely studied and the opinion reached was so favourable that it was decided to proceed as rapidly as possible with the preliminary arrangements for its adoption. It was admittedly both costly and complex; much design and engineering work still remained to be done before it could be said to have reached a state of comparative finality, and many of its features, which had been developed to meet the telephonic conditions of to-day in New York, could not without modification be applied to the very different conditions of London. On the other hand it was obviously a system of unbounded possibilities and no one doubted that it could be made to meet any legitimate service requirement that might arise. A factor not to be overlooked was that it had behind it the high prestige of the American Bell System, which had staked very large financial commitments on its success, and whose able engineers would, for years to come, continue to strain every effort to bring it to perfection.

* Not reproduced in the *Journal*.

Plans were prepared for a first panel exchange in London, to be known as "Blackfriars," and at the same time the Post Office started to negotiate an agreement with the Western Electric Co., in accordance with which the manufacture of panel equipment would have been commenced in England under conditions that would ultimately have permitted other British telephone manufacturers to obtain a share of the work. While these arrangements were proceeding, the sponsors of step-by-step automatic systems had not been idle or asleep, and early in 1922 the Automatic Telephone Manufacturing Co. called our attention to a notable development of the Strowger system by the Automatic Electric Co. of Chicago, who had succeeded in devising and combining with the step-by-step system a call-storing and translating scheme, which had endowed that system with practically the same elements of numbering and trunking flexibility that had first been conceived in association with the panel system. To this new development the name "Director System" was given. The matter was, naturally, one of first-class interest and, although the immediate proposals were in a somewhat embryonic stage, they were at once investigated very fully.

In association with the Automatic Telephone Manufacturing Co.'s engineers, a miniature multi-exchange system was laid out in such a way as to cover as far as possible all the different types of service required and exchange conditions met with in London, and was installed at the General Post Office as a working model of the director system. (A similar working model formed part of the Post Office exhibit at the British Empire Exhibition at Wembley.) Exhaustive study and trial led to the conclusion that the director system contained all the essentials required as a basis on which to frame a complete equipment of circuits and apparatus admirably fitted for the service of such an area as London, and it was evident that a practicable alternative to the adoption of the panel system had become available. In November 1922 I definitely recommended the adoption of the step-by-step system, with the addition of the "director." The main reasons on which that decision was based may be of interest, and are as follows :—

(1) The first cost of director exchanges was somewhat lower than the probable cost of the panel system manufactured in England.
(2) The fundamental electrical plan of the system is very much simpler than that of the panel. Circuits for particular purposes are easier to design and easier to understand.
(3) The Post Office engineering staff was already familiar with step-by-step systems, and it had been found that men could readily be trained to undertake all the duties of maintenance. The difficulties involved in securing and intensively training the requisite staff for handling the panel system—on the large scale of the

necessary programme—would certainly have been considerable, and might have involved serious delay.

(4) The apparatus to be employed in the director system was all of existing types which had stood the test of years of actual use, and which could be depended upon to give first-class service. The scheme was purely one of new electrical circuits and combinations. It was possible, even at that early stage, to visualize the lines on which circuits for all purposes might be designed and, in fact, to see right through the eventual London system to a far greater extent than was possible in the case of panel equipment.

(5) The director system applied readily and naturally to small, as well as to large, exchanges and to "satellite"* exchanges as well as main exchanges. The panel system had not been developed with a view to serving small or satellite exchanges. The fact that it could be made to do so was not doubted, but it did not appear that the solution was likely to be an economical one. This would be a matter of little importance in New York where the dense population of its large business buildings and apartment houses, combined with its high percentage of telephone development, necessitates that nearly all exchanges must have a capacity approaching 10 000 lines. In the "down-town" area of New York many of the exchange buildings will have capacity for four or more exchange units of 10 000 lines each. In widespread and less opulent London there have to be very many small exchanges and satellite exchanges, and it is essential to have a system which can be applied economically to such conditions. It is estimated that in 10 or 12 years' time there will be at least 130 separate exchanges in the London area. Of these not more than about 50 will be in the business districts of the City and West End, and of this number only about 30 will have an ultimate capacity of 10 000 lines, while about 20 will be limited to 5 000 lines. The remaining 80 exchanges in the area will include about 50 of 3 000 lines, 20 of 2 000 lines, and 10 of 1 000 lines. (In several cases two or three exchange units of 10 000 lines each will be accommodated in the same building.)

(6) The Post Office was already committed to several variations of the step-by-step system on a considerable scale in the provinces. The possibility of using the same system in London replaced the somewhat dismal prospect of adding another and very complex system to the rather divergent group already established, by the much more attractive prospect of being able to standardize a type of automatic system for general use throughout the country. As a direct result of the adoption of the director system, a large measure of standardization has since been accomplished, as referred to later. It will in future be possible to move staff from one district to another as may be necessary, without confronting the transferred men with unknown types of apparatus and circuits in the exchanges.

(7) Prior to the adoption of the director system, it had been ascertained that arrangements could be made for spreading the work among the regular exchange contractors of the Post Office at an early date. The important question of supply was thus greatly eased, as existing British factories became at once available for production purposes. The necessity for placing even the initial orders abroad was avoided, and the Post Office was able to enlist the co-operation of the skilled engineering staffs of all the contractors who had been producers of step-by-step equipment.

* A "satellite" exchange is one provided only with subscribers' line switches and local selectors, and dependent upon an adjacent main exchange for all manual services and for the routing and handling of all its external traffic.

The negotiations in hand for the introduction of the panel system were therefore broken off and agreements were entered into with the Automatic Telephone Manufacturing Co. for the supply of director switching equipment for the equivalent of about 55 000 exchange lines, and with the Western Electric Co., Messrs. Siemens Brothers and the General Electric Co. for smaller quantities. Provision is made for existing patents, and for future patents during a specified period, to be pooled on terms which will enable the Post Office to call upon all the firms to install plant covered by patents in the possession of any of them. At the end of the period of about three years covered by the contracts it will also be possible to utilize the services of other competent firms who may desire to take up the manufacture of step-by-step automatic equipment. These agreements cleared the way for standardization of system, and before proceeding to specify circuits and layout a very careful comparative study was made of the characteristics of the systems identified with each of the firms named, of all of which the Post Office had had practical experience.

Subsequent to the decision to adopt the director system, the firm of Siemens Brothers had submitted analogous developments styled the "translator" and the "by-path" systems, applicable to its type of step-by-step equipment, and at a later stage the General Electric Co. also brought forward a proposal to embody in its system an equipment of devices having the same object, which had been termed the "controller" system. The "translator" and the "controller" systems existed, for the most part, on paper, but they furnished interesting evidence of the readiness and flexibility with which the long-established step-by-step system lent itself to the grafting on of developments designed to achieve a newly conceived purpose.

STANDARDIZATION.

It was recognized that the complete standardization of the automatic system for Post Office use could not be effected in a single step without long initial delay

and the temporary paralysis of some of our sources of supply. The most pressing need was to secure that all future automatic exchanges should be of such design that they would be able to intercommunicate directly one with another, without requiring the addition of any special devices or circuit complications for the purpose. First attention was therefore given to the standardization of electrical circuits and operating currents for all inter-exchange purposes, and this has now been accomplished. Each contractor is allowed to supply plant of his own type of mechanical construction, but all types must be capable of operating in the prescribed manner on the circuits which represent, for the time being, the standard methods of fulfilling particular functions. It will therefore be possible to equip any area, large or small, with exchanges supplied by any contractors who may, from time to time, secure the orders for their installation. The subscribers' automatic telephone and calling dial, and the operating impulses sent therefrom, are rigidly standardized, and the same applies to all trains of operating impulses and controlling or signalling currents sent from one exchange to another. Much progress has also been made in the standardization of the circuits which are purely internal to an exchange and do not affect intercommunication with its neighbours. All our contractors are also encouraged to unify the details of the mechanical construction of their apparatus as much as possible, with a view to the gradual evolution of a fully standardized Post Office automatic system. Such standardization has, of course, nothing whatever to do with any ideas of finality or fixation of practice. It simply means that at any given moment there is one standard way of making or doing any given thing. Improvements emanating from any source can be studied and introduced, not in partial and possibly conflicting ways as in a divergent collection of systems, but on a systematic general basis which greatly facilitates effective progress.

The first standardization study soon narrowed itself down to a choice among various important features in which the systems of the Automatic Telephone Manufacturing Co. and of Messrs. Siemens Brothers differed from each other. These features could not, as a rule, be considered independently; to a great extent the adoption of one dictates the adoption of one or more of the others. The decisions on the points at issue were as follows:—

(1) Impulses over junction circuits to be signalled round the loop, and not over one earthed conductor.
(2) Supervisory signals to manual exchanges and auto-manual positions to be sent by reversal of battery.
(3) Subscribers' talking and signalling current to be fed to the loop at final selectors, or at outgoing junction repeaters.
(4) Main battery to have E.M.F. of 50 volts (25 cells).
(5) Registration on subscribers' meters to be effected by means of a "booster" battery.
(6) Subscribers' lines to enter via 25-point rotary line switches having a "home" position and 24 outlets to selectors.
(7) The "private" banks on the levels of group selectors to have 11 points.
(8) The "busy" test on private bank contacts to be provided by an earth connection.
(9) Trunk-hunting switches to be stepped forward by individual, self-controlled drive.

Six of these points (1, 2, 3, 4, 8 and 9) represent the established practice of the Automatic Telephone Manufacturing Co.

With regard to point (5), the Department's experience with the Automatic Telephone Manufacturing Co.'s standard system of registration—by means of an electro-polarized relay operated by reversal of current when the called subscriber replies—indicates that, although accurate, it requires special testing and voltage-regulation plant to maintain it. For "booster battery metering," which has been adopted as preferable, the subscriber's meter, with the normal exchange voltage behind it, is wired to the "private" or test wire at the subscriber's rotary line switch. The meter is designed not to operate on this voltage. The "test" wire is linked up successively throughout all the switches used in a connection up to the final selector in the case of a local call, or to the outgoing circuit repeater in the case of a junction call. When the called subscriber replies, the operation of relays at the final selector or repeater applies a separate booster battery of 50 volts to the "test" wire in series with the main battery for about ½ second. The meter operates on this and its armature remains attracted on the normal battery voltage—the test wire being normally earthed at the final selector or repeater. It is confidently expected that this method will give complete immunity from false registration.

It should be mentioned that in "director" areas a simpler method of operating the subscriber's meter is practicable and has been adopted. In such areas the first selector switch, which is next in the train of switches to the calling subscriber's rotary line switch and meter, contains a relay operated by the reply of the called subscriber. A separate conductor can therefore be provided, at little cost, between the two switches, enabling metering to be effected by the simple closure of the meter circuit when the called subscriber answers.

The use of subscribers' rotary line switches with a "home" position—point (6)—is made necessary by the system of grading the outlets from the line switch banks to the first selectors. With graded outlets it is, of course, necessary that search over a level shall always start from the first outlet on that level.

The use of an 11th contact on selector levels—point (7)—is dictated by the desire to obtain traffic overflow measurements on each working level.

As soon as the leading characteristics of the general system had thus been determined the process of assimilating it to the director method of operation, and of designing the circuits and plant layout for all classes of service, began. For many months the engineers and traffic experts of the Post Office automatic group

were engaged in almost daily discussions with the engineers of the four large contracting companies who are responsible for the manufacture and installation of the exchange plant. The matter involves the consideration of masses of meticulous technical details, and great numbers of proposals and devices have been suggested, considered, tried out, and accepted or rejected. This work is now complete, so far as the initial system is concerned. Equipment for several large exchanges is now in course of manufacture, and in the cases of the Holborn exchange and the mechanical tandem exchange the work of installation *in situ* has been commenced. It may be mentioned that it takes, under present conditions, about 6 months to plan the traffic and engineering details of a large automatic exchange, about 12 months to manufacture it, and a further 12 months, or more, to install it in position and tune up its circuits for service.

In a field in which invention has been so rich as in that of automatic telephony, it is impossible to choose and stardardize a single system without a certain measure of regret that features of great interest and utility associated with other systems have necessarily to be sacrificed. The facilities for large group selection which are inherent in the panel system were not given up without reluctance, although it is believed that an excellent substitute for them is provided in association with the step-by-step system by the methods of grading smaller groups of outlets and, if necessary, interpolating additional trunk-hunting switches, as already referred to. The "rotary" system of the Western Electric Co. also includes many attractive features which are not applicable to the selected system. The same applies to the striking machine-driven system recently introduced by Messrs. Ericsson of Stockholm and now installed at Rotterdam and elsewhere. The 500-point selector switches of this system and the method of constructing its multiple fields are of great interest to telephone engineers. The Relay Automatic Telephone Co.'s system had also shown itself to be a convenient and economical system, at least for the smaller exchanges. But these systems all differ fundamentally from the step-by-step system and could only be made to intercommunicate with it by the addition of costly and complex special devices for interchanging traffic. The inherent complexity of even a perfectly uniform automatic system serving a large area is necessarily such that any deliberate policy of including in it exchanges of radically different type could not be entertained.

I am far from asserting that the London system will, in 20 years' time, necessarily stand as a model for the world to copy, but I am confident that the adoption of the step-by-step system, with the notable addition of the automatic "director" and other technical developments as worked out for London, represents the most practically suitable and effective way in which the telephonic needs of the next generation can be met in that great and important area.

It is understood that it has now been decided to install a step-by-step automatic system in Berlin, and that the same applies to the system of reconstructed exchanges which will replace those recently destroyed by the earthquake in Tokio.

(10) The Automatic Electric Company's "Director" System.

It has already been mentioned that the addition of the "director" to the long-established Strowger automatic system has endowed that system with facilities which enable any required connection to be set up by means of trains of controlling impulses having no necessary relationship with the impulses sent in from the calling dial of the originating subscriber.

The function of the director is to receive and store the call in its original form, and to proceed to send it out into the exchange switching mechanism, translated into any trains of impulses which may be required by the existing layout of junction routes and switching centres, to steer the call through, link by link, to the line of the required subscriber. As soon as the required connection has been established, the director disconnects itself from the line and becomes available for other calls.

The London subscriber's calling dial will carry a combination of letters and digits similar to that already referred to in connection with the panel system, and the arrangement of exchange names and numbers in the telephone directory will also be identical with that adopted for the panel system.

It should be noted here that the translation effected by the director applies not only to the number of impulses in a train but also to the number of trains sent. The subscriber will be required to signal 3 letters and 4 digits for each call, but the director can transform these 7 impulse trains into any number of directive trains from 5 to 10. This attainable maximum provides more than adequately for any possible future requirement of the London system, or any other system.

The director consists of 9 switches with associated relays and a cross-connecting field. Two switches are of the usual Strowger type having vertical and horizontal movements; these are designated the "A" switch and "BC" switch respectively. Two switches are of the pre-selector type and are designated the "sending switch" and the "sending control switch." Five switches, designated "minor switches," are practically small Strowger switches with rotary movements only. Four of these switches are used as digit-storing registers and one as an impulse distributor.

The "A" digit switches are grouped on separate racks and do not form part of the assembly of an individual director, which includes all the other pieces of apparatus mentioned, mounted on a rectangular frame measuring about 24 in. × 18 in. (see Fig. 19).

The "A" digit switch receives the first train of impulses dialled by the subscribers, which corresponds to the first code letter of the exchange required. Each level of the "A" switch is associated with a separate group of directors set apart for effecting connections with exchanges having names commencing with the same, or an equivalent, letter, and the "A" switch, having been dialled to a particular level, searches to find the "BC" switch of a free director on that level.

The second and third trains of dialled impulses are received by the "BC" switch; the second train lifts the switch brushes to one of the 10 levels, and the third

train rotates the brushes to a particular set of contacts on that level. The "BC" switch is equipped with 6 brushes and 6 separate sets of bank contacts. Thus the dialling of the second and third of the three initial or "code" letters of the required exchange has set the "BC" switch of a director in a particular group to 6 particular multipled contacts, and has closed 6 circuits which will always be closed by any subscriber who dials that exchange code. The 6 circuits thus set up, when suitably cross-connected, enable the switches of the director to send out any desired number of trains of impulses from 1 to 6 (each train consisting of any number of impulses from 1 to 10) and so steer appropriate group (ABC = level 2; DEF = level 3, etc.).

The directors of each group are capable of serving 81 exchanges, and as 8 group levels are available on the "A" switch the total number of exchanges which could be served without mechanical modification of the directors is 648. This is so far above the number of exchanges ultimately required in London that the cross-connection field has been designed to serve 35 exchanges in each director group, or a total of 280. Even with this reduced number abundant spare space can be left, on the directors appropriated to each three initial letters, to avoid any restriction in the choice of

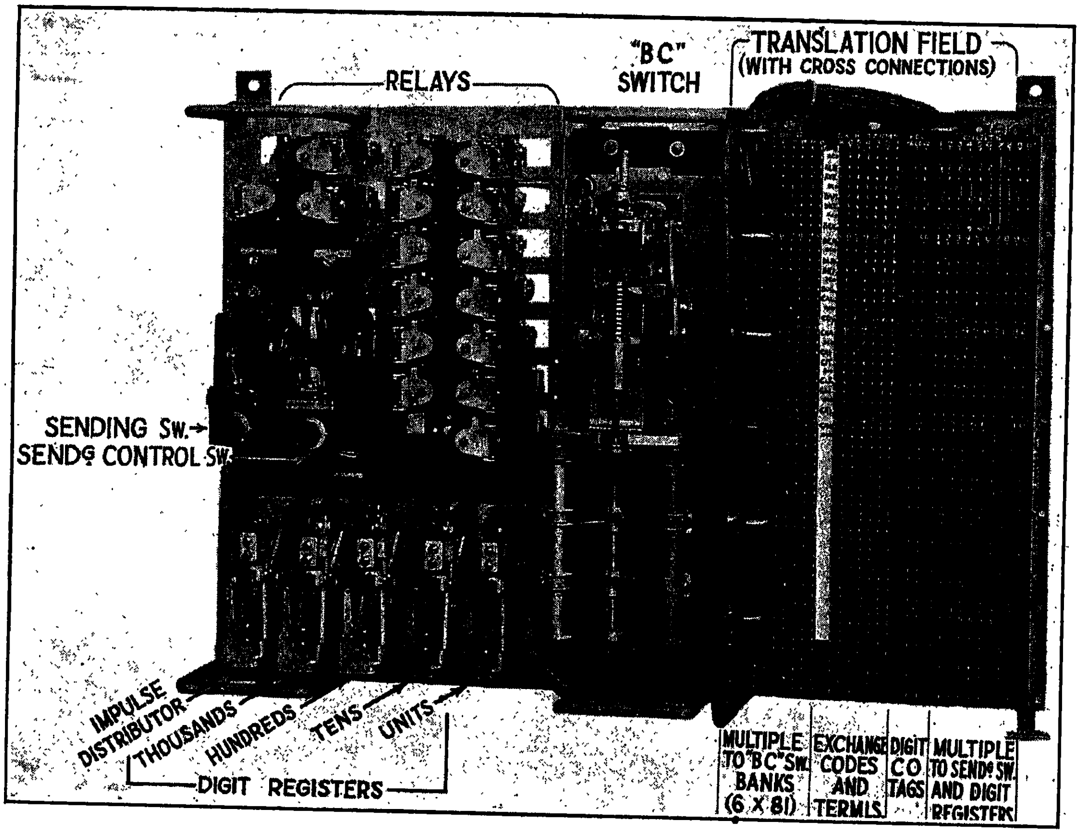

FIG. 19.—View of director assembly.

the call by its prescribed route to any required exchange, where the direct operation of the final 4 trains, representing the numerical digits of the dialled number, will reach the line of the called subscriber.

It will be noticed that the initial letter of the exchange code—absorbed in the "A" digit switch—does not pass into the director and is not subjected to translation. It is found that the total quantity of apparatus required can be reduced by confining translation to the second and third code digits, and setting apart a group of directors to handle calls for the exchanges having initial letters with the same numerical equivalent. The first train of impulses is therefore used to select the level of the "A" switch which gives access to the exchange names on that account, although such restriction could easily be applied if necessary.

Under average conditions a director to which properly graded access is provided will carry about 72 calls in the busy hour and will be occupied with each for about 20 seconds. To serve a busy city exchange the installation of from 150 to 180 directors is necessary.

The operation of the director can be examined in more detail with the aid of Fig. 20. The subscriber on lifting his receiver obtains, via the bank of his rotary line switch, a first code switch in the ordinary exchange system, and at the same time the "A" switch-finder hunts to find a free "A" switch, from which the subscriber receives the "dial" tone informing him that

he may proceed to turn in the call. Suppose the subscriber wants the "Avenue" exchange and dials AVE 2468, which corresponds to 283 2468. The A is received by the "A" switch, the brushes of which are lifted to the second (or ABC) level, and a free "BC" switch in the group of directors associated with that level is found.

The train of 8 impulses corresponding to V is dialled into the vertical magnet of the "BC" switch, via the impulse distributor, the two brushes of which are standing on the first pair of contacts. At the end of this train the impulse distributor takes one step, and the train of 3 impulses, corresponding to E, are received by the horizontal magnet of the "BC" switch. The six brushes of the "BC" switch are now set on the third contact of the eighth level in each bank. The impulse distributor brushes now step to its third pair of contacts.

Dialling proceeds and the trains of dialled impulses representing the called subscriber's number are successively routed by the impulse distributor to the four digit registers which are set in the positions 2 on the thousands register, 4 on the hundreds register, 6 on the tens register and 8 on the units register. The call has now been received and stored in the director, but before this operation is complete the process of sending it forward in its transformed shape has already been begun.

It may be assumed that direct junctions to the Avenue exchange can be reached through two ranks of code switches at the originating exchange and that the translation in the director required to set up these switches is to be "2, 6." That is to say, only two trains of impulses are required, out of the possible six trains provided for, via the six brush circuits of the "BC" switch. If additional ranks of code switches at an intermediate switching centre had been involved, a correspondingly greater number of trains would have been necessary. The translation is effected by cross-connecting the first of the particular six bank contacts of the "BC" switch to contact No. 2 of the "sending switch" bank, and the second bank contact of the "BC" switch to contact No. 6 of the sending switch. The superfluous bank contacts (Nos. 3, 4, 5 and 6) of the "BC" switch will be connected to the "sending control switch," via the terminal marked "D.C.O." (digit cut-off), in order to step that switch to the correct position for discharging the digit registers at the proper moment.

After the three code letters have been dialled in, the impulse distributor brushes will have moved to the third pair of contacts and the sending control switch will be standing on its first contact. The earth-connected brush of the impulse distributor will therefore complete a circuit, via brush 1 of the "BC" switch and the cross-connection, to contact No. 2 of the

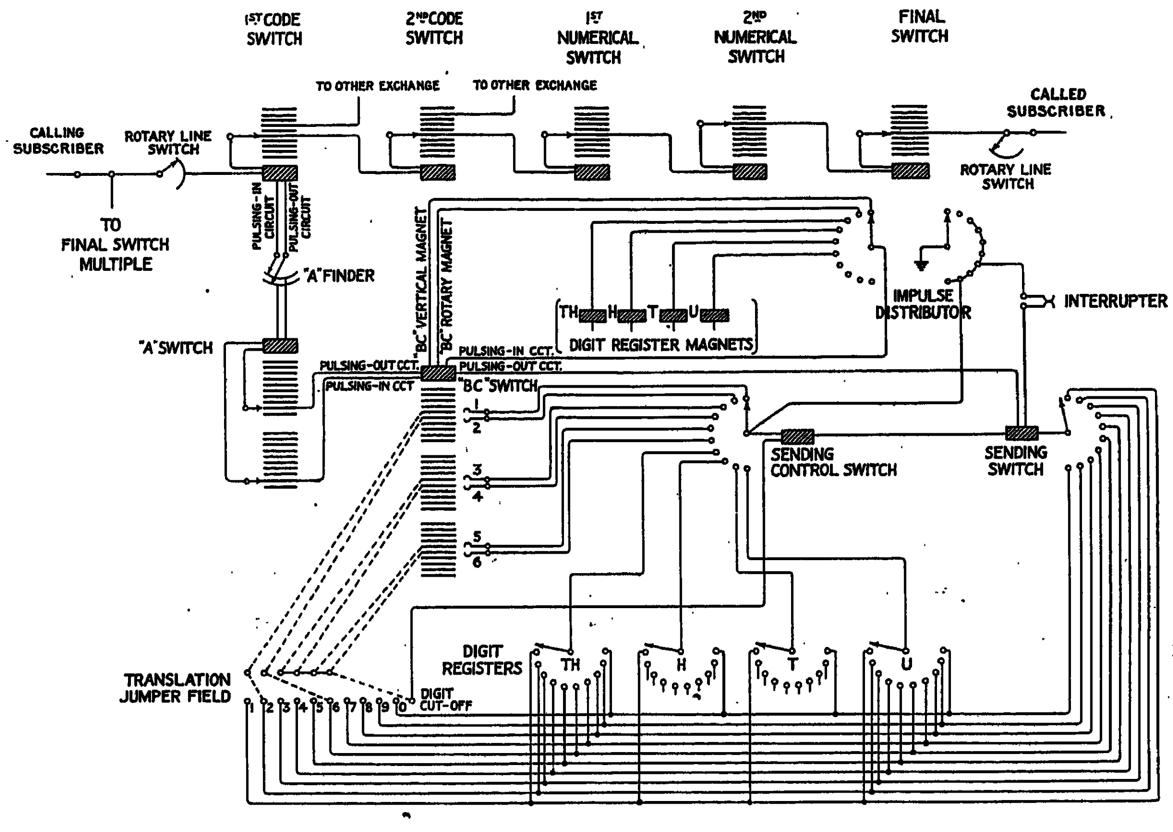

FIG. 20.—Principles of the director system.

"sending switch," which will thus be earthed. At the same moment the earth-connected brush completes a circuit, permitting impulses from the interrupter springs of a continuously running impulse machine to be directed to the sending switch magnet, and the switch begins to step over its contacts. At each step an impulse is sent to the first code switch over the "pulsing-out" circuit indicated in the figure. When the sending switch brush reaches its second contact, which has been "marked" by the sending control switch, it encounters the earth connection and a relay is operated which prevents further impulses from being sent to the first code switch. The sending control switch now steps forward to the second "BC" brush circuit and the sending switch returns to normal. Meantime the first code switch brushes have entered the second level of its bank contacts and found an outlet to a free second code switch.

The sending control switch brush, now standing on its second contact, makes an earth connection, via brush circuit No. 2 of the "BC" switch, with contact No. 6 of the sending switch. The sending switch again steps forward and now sends 6 impulses to the second code switch before its impulses are stopped by the earth on its contact No. 6. The second code switch brushes are stepped to level No. 6 and find a free line to the Avenue exchange, whilst the sending switch again returns to normal and the sending control switch steps to position No. 3. From this position it finds a circuit in turn, via brushes Nos. 3, 4, 5 and 6 of the "BC" switch, which represent superfluous translation circuits and have all been joined, by a cross-connecting wire, to the "digit cut-off" terminal. The brushes of the sending control switch are therefore carried straight forward to position No. 7. Positions 7, 8, 9 and 10 connect with the four "digit registers" on which the Avenue number of the called subscriber has been stored. From these positions the switch will now successively control the sending of the thousands, hundreds, tens, and units digits. As these do not require translation the banks of the digit registers are multipled directly to the sending switch. The impulses for these digits are sent out over the junction line to Avenue and set up the numerical switches at that exchange. Immediately after the units digit has been sent out from the director the latter is released from the first code switch, all its parts return to normal, and the calling subscriber is connected through to the final numerical switch at Avenue, from which the required subscriber is being rung.

The "pulsing-in" circuit over which the subscriber's impulses pass into the director remains entirely separated, at the first code switch, from the "pulsing-out" circuit over which the director passes forward the call through the code and numerical switches until the connection has been completely set up and the director has been dropped. Pulsing-out commences as soon as the exchange code portion of the number has been dialled in, i.e. as soon as the impulse distributor reaches its third contact and connects earth to the sending control switch and to the interrupter of the impulse machine. The periods of storing the call and of sending it forward thus overlap each other and the actual delay in establishing connection with the called subscriber is, on the average, only about 2 seconds greater than it would be if the call were dialled straight into the switches.

As a theoretical example of a more complex case of routing, involving the use of intermediate switching centres and the utilization of all the six available translation channels, it might be assumed that a call, say, from Ealing to Ilford, would be dealt with as follows:—The exchange code ILF (453) would have its second and third digits translated in the director to 234567. Digits 2 and 3 would operate first and second code selectors in Ealing, and gain access via an outgoing junction to a tandem selector in Holborn. Digits 4 and 5 would operate first and second tandem selectors in Holborn and reach a tandem selector in Maryland. Digits 6 and 7 would operate first and second tandem selectors in Maryland and reach a first numerical selector in Ilford. The four untranslated numerical digits of the subscriber's number would then follow and effect connection with the called line via the first and second numerical selector, and a final selector, at Ilford.

The actual circuit arrangement of the director system is necessarily somewhat complex, and a discussion of it in any detail is not within the scope of this paper. (Mention should, however, be made of an innovation as regards the position of the battery feed to the calling subscribers. Hitherto on the Automatic Telephone Manufacturing Co.'s system this has always been located either at the final numerical switch or on the outgoing junction repeater. In the director system as adopted by the Post Office it will be located at the first code switch, thereby rendering outgoing junction repeaters unnecessary, except on tandem routes, and effecting a very appreciable economy in London and other large areas where the percentage of junction traffic is large.)

Director Translations.

Fig. 21 is a sketch of the arrangement of the translation jumper field. On the left of the drawing six sets of bank contacts each connected to a set of 81 terminals are indicated. Each of these six sets of terminals reproduces the bank contacts of the "BC" switch corresponding to each of the six brushes and is wired out to these terminals as indicated by the brush, or "wiper," numbers.

Levels 2 to 0 and contacts 2 to 0 on each level only are so wired out, level 1 and contact 1 being omitted since there are no letters equivalent to digit 1 on the lettered dial. At the centre of the assembly there are 35 sets of six exchange terminals, each set being labelled with an exchange name and wired to the tags representing the positions on which the six brushes rest when the code of that exchange has been dialled into the "BC" switch. Between every two sets of exchange terminals one set of D.C.O. (digit cut-off) terminals is fitted. On the right-hand side are 36 sets of digit terminals numbered 1 to 0, each vertical row of which represents one of the 10 bank contacts on the sending switch and digit registers.

Cross-connections are made between the six exchange

terminals and the 10 digit terminals as required to give the desired translation.

The terminals marked "CO" are used for clearing the director when it is required to route a call by code translation only, without numerical digits. Certain service calls will be dealt with in this manner.

The terminals marked "OPER" are used to route a call to an operator after the dialling of digit 0 by the subscriber. Such a call will find a director but will

(1) *Subscriber to subscriber calls* (subscriber dials 3 code and 4 numerical symbols).

(*a*) *Translated to* 1 *code selection, followed by* 4 *numericals*, e.g. if the subscriber dials "AVE" 1234, the "AVE" exchange terminals will be connected as follows:—

Terminal 1 will be jumpered to the digit terminal corresponding to the pulses required to be sent to the code selectors.

(*a*) *Subscriber dials special service 3-letter code,* not followed by numericals, e.g. TOL. The same method is followed as under 1 (*a*) or 1 (*b*), i.e. the exchange code terminals are jumpered to the digit terminals necessary to route the call to the destination required. The first unused exchange terminal is jumpered to the nearest " C.O." terminal instead of the " D.C.O." terminal, and the remaining terminals are left disconnected.

(*b*) *Calls to operator* (*subscriber dials* " 0 ").—The

to be released immediately the third code digit is dialled, and the subscriber receives the " number unobtainable " tone signal.

Call Indicator Working.

Until the conversion of London to automatic working is fully completed, which may occupy a period of from 15 to 20 years, manual working will exist side by side with automatic working and arrangements are necessary to ensure smooth operation between the two systems during the interim period.

Traffic from automatic to manual exchanges will be handled by means of " call indicator " positions at the manual exchange, as illustrated in Fig. 22. The automatic subscriber will manipulate his calling dial in an identical manner for all calls. If the call be for a manual exchange the operation of the three initial letters of the exchange name will steer the call through to an available incoming junction operator's position at that exchange, and the further operation of the four numerical digits will cause the required subscriber's number to appear visually on a " call indicator " in front of the junction operator. This operator will, without speaking to the calling subscriber, connect the circuit manually to the required subscriber's line. She may use any one of her plugs and cords for this purpose ; the act of plugging into the subscriber's line jack brings into operation a " cord trunk finder " which connects the plug and cord to the junction upon which the displayed number has been pulsed.

In the converse case for a subscriber connected to an exchange not yet converted to automatic working, two methods are available by which the manual exchange operator may deal with the call if connection with a subscriber on an automatic exchange has been asked

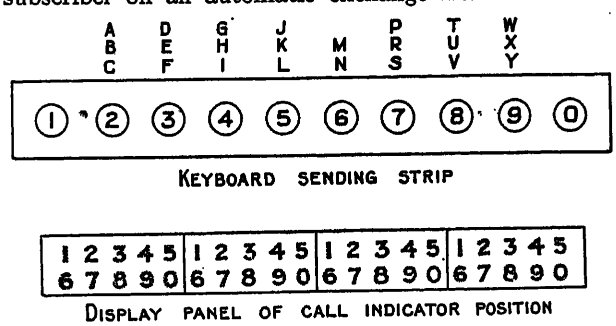

FIG. 23.—Key sender and call indicator.

for. The first method (see Fig. 22) provides that she shall pass forward the call verbally, by order wire, to an incoming junction operator at a special " B " switchboard in the automatic exchange. The latter operator will assign a junction circuit, by pressing an assignment key, and will set up the call by means of a set of plunger keys known as a key sender. The automatic plant does the rest and clears the key sender for further use as soon as the call has been steered through to its destination.

In the second method the operator who answers the call from the subscriber at the manual exchange is herself provided with sets of key senders, on one of which she can set up the call and so direct it forward through the automatic plant at the distant exchange to the required subscriber's line, without the co-operation of a junction operator. The adoption of one or the other method depends upon the local conditions at the exchanges in the area, but the first method, which avoids the need for special equipment at the answering operators' positions, is generally to be preferred and has been adopted for London. Fig. 23 shows the arrangement of keys on the key senders, and illustrates the manner in which the called number is displayed visually on the call indicator.

In its operating principles the system of " call indicator " working adopted for London is similar to that invented for use in connection with the panel system, but the London system contains several novel features which warrant a further brief reference. It is termed by the Automatic Telephone Manufacturing Co. a " coder call indicator system " and its object is to minimize the number of automatic switches necessary to display a call at a manual exchange, and to provide facilities for even traffic distribution of calls from all exchanges among the operators. Its operation is briefly as follows :—

At the originating automatic exchange the director impulses, instead of passing directly to line and to the distant exchange from the outgoing switch, are stored in the relays of an equipment assembly termed a " coder," which is at the same time connected to the junction line. At the manual exchange the connection of the coder to the line at the distant end routes the line to a set of incoming " decoder " relays by means of a " marker " controlled by a " marker distributor." Five markers and one marker distributor are provided for each call indicator position. When the junction line had been routed to the de-coder of the call indicator position the coder at the originating end is permitted to discharge. The decimal settings of the coder relays are translated and transmitted over the line as coded impulses of positive, light negative, and heavy negative currents, and stored in the de-coder relays. As soon as the display lamps are freed from the previous call this setting is transferred to a group of numerical relays which cause the called number to be displayed by the lamps in the display panel in the usual way. The arrangements are such that while one call is on display at each position, an indefinite number may be stored on coders at the automatic exchange. Whilst one call is being displayed, five markers per position will be connected to junction lines associated with an equal number of waiting coders, and the traffic will thus be kept in order of priority.

The discharge of the coders into the de-coding relays occupies 1 second, and transference from the de-coder to the display panel is immediate.

At the manual exchange, traffic reaches the positions in cyclic disengaged order in quantities that correspond to the operators' abilities, and in queue formation at each position. Positions at which either all receiving relay sets or markers are engaged are treated as busy and passed by the marker distributor. A call displayed on the display panel is not directly associated with any one cord circuit on the position. The plugging-in of any idle cord to the multiple jack of the required number immediately starts a finder switch, which hunts for the calling line, connects the cord to it, and switches out the lamps on the display panel.

The cords are not normally used for the completion of service calls. Such calls are operated by the depression of a service key which causes a finder switch to hunt for the calling line and connect it to a service operator's position. Busy calls receive the engaged tone by the operation of a key in a similar manner. This reduces the number of cords required, and is a factor of value in some cases where the cord capacity of manual exchange " B " positions is restricted.

Each call indicator position is equipped with 36 cord circuits and it is expected that each operator will handle 450 calls during the busy hour. This is probably a conservative estimate.

It will be appreciated that before the first equipped automatic exchange can be brought into use the whole of the existing manual exchanges in London must be equipped for call indicator working. It follows, therefore, that during the initial stages of automatic working over 90 per cent of the automatically originated inter-exchange traffic in London will be handled at call indicator positions. This percentage will gradually decrease as more automatic exchanges are brought into use, and will finally be extinguished. An automatic subscriber, however, apart from any local knowledge which he may possess, will be quite in ignorance as to whether his call is going to another automatic exchange or to a manual exchange. His operations will be alike in both cases—he will dial three code letters and four digits, and in both cases he will receive the same tones, etc., to indicate to him the progress of his call. When complete conversion to automatic working has been effected, the whole of the call indicator equipment will have disappeared, together with all coder equipments at the automatic exchanges themselves.

It may be urged that this method of tackling the problem is wasteful, inasmuch as call indicator equipments will be progressively thrown out of service during the period of transition. An obvious alternative would be to install automatic equipment at each manual exchange, of a capacity sufficient to deal with the incoming junction traffic and having the subscribers' lines multiplied on the final selectors in parallel with the multiple on the manual board. Then when the time arrives to convert the manual exchange to full automatic working the automatic plant already installed could be worked into the full scheme at that or another exchange and little wastage of plant would result. The possibilities of this scheme were fully considered, but serious objections to its adoption revealed themselves. These arose mainly from the lack of adequate building accommodation for the interim automatic plant, from the extensive changes to subscribers' numbers to provide for automatic private branch exchange service which would be immediately necessary, and from the need for expensive additions to the manual exchange power plant in order to permit the use of standard 50-volt automatic switches. Considerable difficulty has, in fact, been experienced in many cases in finding adequate accommodation for the plant required at manual exchanges for the call indicator equipment, although the space required is much less than that needed for the alternative scheme.

Moreover, the wastage of call indicator apparatus will be minimized by the use in other large areas such as Manchester, Birmingham and Liverpool, of equipment recovered from London exchanges, and probably much of it will remain in service during the greater part of its economic life.

Cordless "B" Positions.

Traffic originated at a manual exchange for an automatic exchange can be handled in two different ways, as already indicated. In the method adopted, each automatic exchange is equipped with special manual "B" positions and demands are passed, by order wire, to these positions from the "A" operators at the originating manual exchange. The operating procedure at the "A" positions is identical with the procedure to manual exchange "B" positions. The "B" operator at the automatic exchange sets up the call on the automatic switches by means of key sending equipment. As this operator is not required to handle any other class of traffic, key sending equipment is used in preference to dials, since quicker and more efficient operating is obtained thereby.

The other of these alternative methods would require that all manual exchange "A" positions in London should be equipped with dials and dial keys, and, since it would not be possible in many cases to dial from the manual exchange cord circuits directly into the automatic switches, it would be necessary to equip most of the incoming junction lines with "dialling-in" repeaters at the automatic exchange. Further, the increased amount of operating per call at the "A" positions would so increase the operators' load that a large number of additional "A" positions would be required in London to handle the volume of traffic during the busy hour. The cost of adopting this alternative, without serious interruption to service, would be so great, as compared with the cost of the method adopted, that the latter was preferred without hesitation.

In order to cater for traffic from manual exchanges, each automatic exchange will therefore be equipped at the outset with a suite of cordless "B" positions equipped with key senders (see Fig. 22). The key sending equipment consists of a strip of digit keys associated with four sender finders which route the digit keys to a free sender. The registers which are wired to the bank contacts of the sender finder consist of four groups of four relays, one group for each digit. These relays are operated by the digit keys either singly or in combinations of twos or threes to obtain all digits from 1 to 0. The setting of the relays determines the "marking" of a contact on the sender switch by means of which impulses are sent out to the exchange numerical switches in a manner very similar to the method used for sending out the numerical impulses from the director.

The junctions from the manual exchange are brought through the cordless "B" position and carried on to a first numerical switch on which they terminate. At the position each junction is associated with a group of relays, and an assignment key and lamp for each junction are fitted as part of the face equipment of the position. The operating procedure is simple and is as follows:—

The "A" operator at the manual exchange passes a demand by order wire to the cordless "B" operator. The latter allots a junction and immediately depresses the assignment key of the allotted line. This causes the allotted junction and the operator's digit keys to be connected to a free sender with associated registers. The operator then depresses in proper sequence the four digit keys corresponding to the four figures of the called subscriber's number. These four figures are routed by means of a control switch to the four groups

of register relays, which are operated and locked in the proper combination simultaneously with the depression of the digit keys. (After the depression of the last key—the fourth—the set is at once available for another call.) The bank contacts of the sender switch are thereby marked and impulses are sent out to the numerical switches. Sending cannot commence, however, until the operator at the manual exchange has taken the allotted junction line. When all sending is finished the sender and registers are disconnected from the junction line and the latter is switched through, via the numerical switches, to the called line.

A supervisory lamp is associated with each junction line at the cordless "B" position. After depression of the assignment key on an allotted junction the operator must not proceed with the setting up of the required number on her digit key strip until a signal is received on this lamp to indicate that a free sender has been found. The provision of senders is on such a basis that no delay is likely to occur at this stage. The supervisory lamp will flash until the originating "A" operator takes the allotted line, after which it will glow continuously until the "A" operator clears at the end of a conversation.

Should the "A" operator connect to a line other than that allotted, the supervisory lamp on that line will flicker rapidly to indicate to the "B" operator that a wrong connection has been set up.

Centralization of Manual Boards.

When sufficient automatic exchanges in London are in use the cordless "B" positions and special "A" positions for operator service, etc., instead of being equipped in each automatic exchange, will be centralized, the centres being so chosen, to serve a group of adjacent exchanges, that economical use of line plant is achieved. There will be a number of such manual centres in London when the automatic traffic in the individual areas has reached a certain density. Great advantages in the design and cost of automatic exchange buildings will result from the centralization of manual board traffic, since these buildings will not be required to accommodate the manual switchroom and operators' quarters.

The Mechanical Tandem Exchange.

In the London area there are a large number of comparatively small exchanges with small groups of junction lines to and from each of the larger exchanges.

As a result of the traffic inefficiency of small groups, and of the fact that order-wire working is ruled out, the busy-hour loads carried by these junctions are very low and their operation is uneconomical. Frequent consideration has therefore been given to the introduction of one or more tandem junction exchanges, at which all the junctions to and from each small exchange could be concentrated and thus form a group suitable for order-wire working. Such a scheme could not, however, be shown to possess any economic advantage, on account of the cost of introducing a third operator on each tandem connection. The development of the automatic call indicator scheme increased the possible speed of operating and so favoured the introduction of tandem junction working, and the advantage of introducing automatic tandem switching plant was, naturally, considerably increased by the decision to adopt the automatic system at London local exchanges. The installation of a mechanical tandem exchange has therefore been pressed forward, in advance of the completion of the first local automatic exchanges.

The mechanical tandem exchange is now being installed in the same building as the Holborn automatic exchange. In it will be concentrated the outgoing and incoming junctions from the smaller exchanges as well as a number of junctions to practically all the other London exchanges.

At the beginning of its life, and for the period which will elapse before conversion to automatic working in London is completed, the mechanical tandem exchange will be required to route traffic as follows:—

From manual exchange to manual exchange.
From manual exchange to automatic exchange.
From automatic exchange to automatic exchange.
From automatic exchange to manual exchange.

The method of handling this traffic is indicated by Fig. 24. Traffic from the "A" positions of a manual exchange will be dealt with in a similar manner to the traffic incoming to a cordless "B" position at an automatic exchange. The "A" operator will "order wire" the call to the cordless "B" operator at the tandem exchange, who will set up the call to the automatic switches via her key sender. In this case, however, since the exchange code must be set up in addition to the subscriber's number, the sender is associated with a translating unit, similar in principle to the director, and with a coder. If the call is for a manual exchange it will be directed to a call indicator position at that exchange, and the numerical portion of the required number—transformed into the correct impulses by the coder at the mechanical tandem exchange—will effect the required display on the lamp panel at the call indicator position. If, however, the call is for an automatic exchange the cross-connections in the translator jumper field will be such as to suppress the operation of the coder, and the numerical digits will go out to the switches at the automatic exchange in the regular manner.

Traffic originated in an automatic exchange will be carried direct from the levels of the outgoing switches to the first tandem switches at the mechanical tandem exchange. In the case of a call for a manual exchange a coder—interposed between the manual levels on the first tandem switches and the second tandem switches—will come into operation as soon as the second tandem switch has been operated, and the numerical portion of the required number will be stored in the coder and converted, as already described, for display at the call indicator position. A call for another automatic exchange will pass out via levels on the first tandem switches which are not equipped with coders, and the call will be routed straight through the switches as determined by the impulses from the director at the originating automatic exchange.

As the conversion of London to automatic working proceeds, the traffic incoming to the mechanical tandem exchange from manual exchanges, and the traffic outgoing to call indicator positions, will decrease and will ultimately fall to zero. The whole of the traffic will then be purely automatic and will be routed direct through the switches, as at other main switching centres in the London system. The cordless "B" positions and their equipment will no longer be required for their original purpose, and it will probably be desirable to utilize them for passing traffic from towns in the London toll area into the automatic system. This question will be considered in due course, as the cordless "B" positions at the mechanical tandem exchange are freed from local traffic.

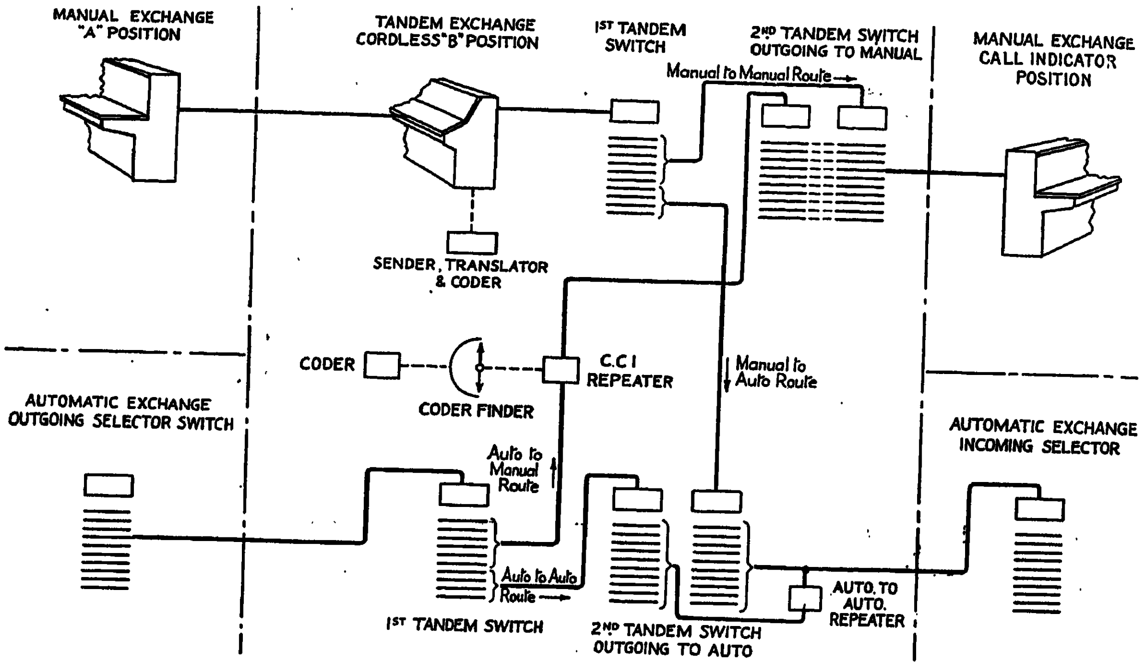

FIG. 24.—Mechanical tandem routing scheme.

Power Consumption.

At a city exchange of approximately 10 000 lines, and at the mechanical tandem exchange, the operating current at peak load will exceed 2 500 amperes. Two sets of 50-volt storage batteries, each having a capacity of 10 000 ampere-hours, are provided. During busy hours the load on the batteries is eased by running the charging machines in parallel with them.

Various Classes of Services Provided.

The subscribers connected to an automatic exchange will be divided into two groups: (a) those to whom trunk calls are permitted and (b) those to whom trunk calls are barred. The distinction is of course of the subscribers' own seeking, but it is necessary that the department should guard itself against improper use of the trunk lines by those subscribers who are not entitled to this service. A subscriber who requires a trunk connection will dial TRU if on a director exchange. (The letter "O" is used for this purpose at non-director exchanges in the provinces.) In the group where trunk calls are permitted the call will be routed to a record operator, but in the group where such calls are barred the call, if made, will be routed to a special operator and dealt with accordingly.

Subject to this restriction the following classes of service will be provided:—

Subscriber to subscriber—direct.
Subscriber to subscriber—over junction circuits.
Subscriber to subscriber—over trunk lines ("revertive" calls).
Subscriber to subscriber—over toll lines ("no delay" calls).

Coin-box stations and call offices to and from all other subscribers in the system direct, or over junction, trunk, or toll lines.

Private branch exchange traffic with night traffic on selected lines in each group of exchange lines.

Inquiry, information, and directory services.

Dictating messages for onward transmission as telegrams, express letters, or letters.

Receiving telegrams in lieu of delivery by messenger.

Calling for the services of express messengers.

Tone Signals.

A system of tone signals designed to give a calling subscriber knowledge of the progress of his call has been standardized for use in both London and the provinces. Before commencing to operate his calling dial the subscriber should listen for a "dial signal tone," which indicates that a free selector in the first

rank—or, in London, an "A" digit switch—is available to receive the dialled impulses. Dialling must not commence until this tone—which is continuous at a frequency of 33 per second—has been received.

If the called subscriber's line is engaged, or if, at any stage of the call, all outlets from a selector switch level are busy, a "busy tone" will be sent out. This tone has a frequency of 400 per second and is applied for "off and on" periods of 0·75 sec. The tone is associated with a flashing signal on the supervisory lamp of an operator's cord circuit in the case of a call from a manual exchange subscriber.

When dialling is completed the subscriber will immediately receive "ringing tone" to indicate that the required subscriber is being rung, or "busy tone" to indicate that he is already engaged. The ringing tone is provided by means of a leak from the ringing circuit through a condenser of small capacity on which current pulses at a frequency of 133 per second are superposed. This tone is applied to the line with the same interruptions as the ringing current itself, i.e. a double beat of 1 second with a 2-seconds' interval. The double beat consists of two rings of 0·4 second duration separated by an interval of 0·2 second.

In areas where the director is not used a further tone known as the "number unobtainable tone" is employed to indicate to the subscriber that he has dialled a ceased or unallotted number. In London this tone will be used to indicate to a subscriber that he has incompletely dialled the required number. Calls for ceased or unallotted numbers will be routed to an operator.

Alarms and Guarding Devices.

A complete system of alarm and guard devices is provided to facilitate supervision of the working of the exchange and to call immediate attention to any irregularity in the operation of the switches. The alarms are given by a lamp associated with a bell or buzzer and are divided into the following categories:—

(1) Individual switch alarms.
(2) Individual panel or shelf alarms.
(3) Individual rack alarms.
(4) Group alarms.

The alarms are operated in trains.

A fault or irregular condition which brings in an individual switch or panel alarm will also bring in the appropriate rack and group alarms. The maintenance officer will thus be guided from the group alarm to the rack alarm and then to the panel or switch on which the fault or irregular condition has occurred.

Switch alarms are provided on those switches which are normally connected with a subscriber's line by the act of lifting his receiver, without dialling. Such switches are the first group selectors in non-director areas and the first code switches in director areas. The alarm lamp will indicate in this case a loop on a subscriber's line and, should this loop persist for 3 minutes without impulses being dialled, a clock-controlled relay set will come into operation and cause the rack and group alarms to operate.

Individual switch lamps are also provided on the final selectors in non-director areas to call attention to the condition where a called subscriber's line is held after the termination of a conversation by the failure of the calling subscriber to restore his receiver. In director exchanges the corresponding lamp is provided at the first code selector.

On other ranks of switches the alarm lamps are provided on the basis of one lamp per panel or shelf of 20 switches. The most probable irregularity in the use of switches in these ranks is that they may be improperly held by a subscriber leaving his receiver off after incomplete dialling of the required number; this happens so rarely that alarms on the basis of one per switch would not be justified.

In addition to the foregoing supervisory alarms, signals are provided to call immediate attention to fuse failures and to "release" failures on switches of all ranks.

Private Branch Exchange Lines.

Most private branch exchanges have more than one line to the exchange and it is of course necessary to arrange that, if a call be received when the particular line representing the exchange number of the private branch exchange (PBX) is engaged, the calling subscriber shall not receive the "busy" signal unless all the lines to the PBX have been searched and also found to be engaged.

It is therefore necessary to arrange that the group of lines to a PBX shall be connected to consecutive positions on the bank multiple of the final switches and to provide all switches on which such groups of lines terminate with means for continuing their rotary motion as a hunting operation throughout the group—after the impulses of the units train have carried their brushes to the first line of the group—until an idle line is found, or the whole group has been searched without success.

Switches provided with this facility are known as "rotary final switches" or "rotary connectors." In the case of PBX groups of two or three lines no special difficulty arises, apart from the fact that all the lines must appear on one level of the switch and that a few spare positions for future growth must also be left upon that level. This tends to a certain amount of plant wastage, and also generally involves changing the exchange numbers of a proportion of the subscribers in order to get them properly grouped on the levels of the switches when a transfer to the automatic system is made.

When, however, the present or probable future requirements of a PBX exceed 10 lines, and therefore exceed the accommodation of a normal switch level, it is necessary to take special steps to ensure the availability of all the lines when a switch is hunting to complete a call for the PBX number. Line-hunting over groups up to 20 in number can be provided by utilizing rotary final switches having 10 double levels of 20 contacts. Each such level absorbs only 10 line numbers in the subscribers' multiple series, the remaining 10 having auxiliary numbers. This scheme is therefore economical from an exchange plant standpoint,

as the line capacity of the exchange is not reduced by the existence of lines 11 to 20 in the group, or by the retention of some of these auxiliary positions as spare for the future requirements of the PBX in question.

The private branch exchanges serving some of the large London stores have 150 exchange lines or more, but it is generally possible to divide the lines so that a group not exceeding 100 is available for outgoing traffic at the public exchange. In such cases additional switches of the pre-selector type are connected to the normal outlets of special third numerical selectors which act as final switches. The 10 outlets of the level appropriated to the PBX in question on each switch are multipled on a graded basis to "homing" pre-selectors having access to all the PBX lines in a common group of approximately 50 or 100, according to requirements. Each pre-selector is associated with a set of repeater equipment which provides facilities for battery feed, busy test, ringing and registration.

In this way all the requirements of very large private branch exchanges can be met in a perfectly satisfactory way, although with a certain sacrifice of uniformity as compared with systems deliberately designed for searching over large groups of lines.

(11) The Subscriber's Automatic Telephone Set.

The earliest Post Office automatic exchange areas were equipped with subscribers' apparatus supplied by the contractor whose exchange system was in use in each particular area. This led to the introduction of various types of instrument circuits and calling dials developed to suit the characteristics of the various systems. The first circuit employed was that of the Automatic Electric Co. in which the talking current from the exchange circulated directly through the transmitter and receiver in simple series; the receiver was of the electromagnetic type, i.e. it had no permanent magnet but was magnetized by the exchange current. This is an admirably simple circuit, but investigation showed its grade of speech transmission to be somewhat inferior to that of the standard common-battery circuit, which was utilized in connection with the automatic systems supplied by the Western Electric Co. and Messrs. Siemens Brothers. Another consideration in favour of the latter is that its adoption greatly facilitates conversion of standard common-battery manual exchange telephones to automatic working. When the question of standardization of subscribers' automatic telephones arose, the electromagnetic system was therefore discarded and the standard common-battery telephone circuit was adhered to.

Standard impulse.—After consultation with the contractors responsible for the principal systems, a standard impulse suitable for all types of exchange equipment was agreed upon. This was defined as a "break" period followed by a "make" period in the ratio of 2 : 1, i.e. the break occupies two-thirds of the total impulse period. In practice, dials are accepted if the "break" period comes within a range of 63 per cent to 70 per cent of the total. The standard rate of delivery of impulses is fixed at 10 impulse periods per second. All subscribers' dials are carefully maintained to function at this speed, but in order to reduce dialling time and to speed up operating, the dials used by operators on manual switchboards are specially adjusted to deliver impulses at the rate of 10·5 to 12 per second. The impulsing mechanism is only in operation during the return journey of the finger-hole disc after its release by the finger, so that the rate of impulsing is independent of any human factor.

Standard dial.—Following on the standardization of the impulse the provision of a standard dial for universal use was taken in hand and developed after consultation with all the Post Office exchange contractors. The dial produced as a result of these efforts embodied novel mechanical details designed by Messrs. Siemens Brothers, and is illustrated in Fig. 25.* At the rear of the dial a circular disc with 10 recessed gaps rotates in unison with the front finger plate. A spring, riding on the periphery of this disc, actuates a pair of contact springs which break and make a normally closed circuit as the spring rides in and out of the gaps when the disc rotates. These are the impulsing springs proper and it might

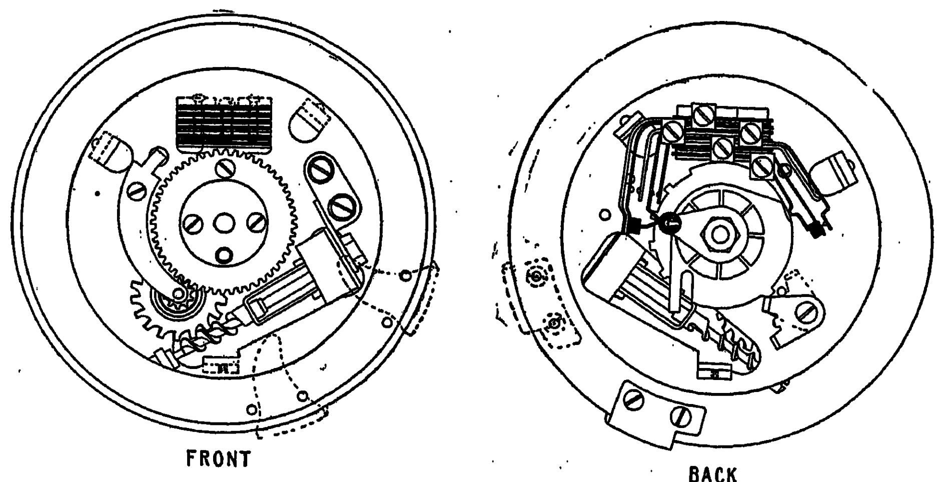

Fig. 25.—P.O. standard automatic dial.

* Photographs forming part of Fig. 25 are not reproduced in the *Journal*.

here be noted that this device, which secures the springs being pushed into contact for the "make" portion of the impulse and allows them to fall apart for the "break," eliminates "contact bounce" and gives a much cleaner impulse than the earlier device in which two contact springs normally held together by their own resilience were forced apart to give the break portion of the impulse, and allowed to fall together for the make portion.

During the forward rotation of the dial the riding spring is prevented from falling into the gaps in the circular disc by means of a friction sliding-cover plate, so that the impulsing springs are unaffected. The gaps in the disc are so spaced that they do not come into action until a certain portion of the return journey has been traversed. This provides an interval between the receipt of successive trains of impulses which gives the switching mechanism at the exchange ample time to perform its "trunk-hunting" operation after each train. Systems in which the call is first stored at the exchange on quick-acting registers, and subsequently released through the mechanism, do not require this hunting interval, and provision is therefore made on the dial for placing the finger-stop in an alternative position which reduces the length of pull for each digit and so speeds up the action of the dial.

In addition to the impulsing springs the dial also includes a set of auxiliary contact springs which make certain desired local changes in the circuit of the telephone while the dial is being operated. These springs are held in their normal position by an insulated stud attached to the circular disc. They assume the "operated" position as soon as the rotation of the disc begins, and maintain it until the disc has again come to rest in its normal position. The speed at which a dial returns to normal under the influence of its restoring spring, and consequently the rate at which its impulses are delivered, is "governed" by means of a geared centrifugal friction break whose retarding effect increases proportionately with its speed.

Complete instrument circuit.—The inclusion of the dial in the circuit of a subscriber's telephone can be effected in several ways, and the selection of the most suitable circuit arrangement has been by no means easy. The operation of the dial effects a rapid succession of interruptions in a circuit which includes exchange relays having considerable inductance. In the absence of special precautions these interruptions are accompanied by inductive surges or "kicks" which may run up to peaks of 500 or 600 volts and impose destructive strain on the insulation of instrument or exchange circuit wiring.

Other possible troubles arise from the alternate charging and discharging of the condenser in the bell circuit, which will cause the bell to tinkle in response to each train of impulses, and from the series of disconcerting clicks which may be heard in a subscriber's receiver while the impulses are passing.

The high dialling voltage can be materially reduced if the wiring be so arranged as to connect the condenser of the telephone across the break contacts of the dial during its operation.

The irregular tinkling of bells is always a nuisance and becomes a serious defect in the working of extension circuits, since the tinkling of the main station bell, when an extension station dials a number, is liable to be mistaken for an ordinary ring. For this reason it has hitherto been necessary to "bias" all bells used on automatic telephone sets, in the endeavour to obtain adequate security against tinkling under all conditions. The bell is "biased" by fixing an adjustable spring to the armature in such a way as to hold it normally over to one side, with the bell hammer resting against one gong. This gong must be the one which the hammer would strike when responding to tinkling impulses, in order that the impulses—which are always in the same direction—will have no audible effect on the bell. The addition of the "bias" spring not only represents an additional item of expense, in regard both to first cost and maintenance cost, but materially reduces the reliability of the bell. Any accidental reversal of the line connections renders it ineffective, and this remedy for tinkling can only be regarded as the lesser of two evils. The latest circuit arrangement overcomes the need for biasing and is greatly to be preferred.

Clicks in subscribers' receivers are obviated in all modern circuits by arranging for the auxiliary contact springs on the dial to short-circuit or disconnect the receiver during the operation of dialling.

Fig. 26 shows several circuits which have already been employed in order to reduce the undesirable local effects of dialling, and illustrates the successive stages in the development of the present standard circuit, in which they are all successfully overcome. It will be remembered that dialling takes place when the receiver is off the hook.

"A" shows the Automatic Electric Co.'s original circuit employing the electromagnetic receiver without induction coil. The bell is cut out of circuit during the process of dialling, and is therefore not subject to tinkling in so far as the action of its own dial is concerned. If, however, more than two telephones are connected to the same line, the main station bell is subject to tinkling when an extension station dials. No attempt is made in this circuit to suppress the high inductive dialling "kick," and high-grade insulation is therefore needed in all wiring. The auxiliary springs on the dial automatically short-circuit the transmitter and receiver during the period the dial is in motion, so that no clicks are heard.

"B" shows the earliest circuit of the Western Electric Co. which was applied to a standard common-battery instrument with induction coil and utilized a dial without auxiliary springs. It affords standard transmission, dials through the transmitter, and allows the subscriber to hear loud dialling clicks in the receiver. The dial is placed in series with the line circuit. The condenser is alternately charged and discharged as the dial springs make and break, but the presence of the induction coil and transmitter and receiver in bridge across the condenser reduces the magnitude of the charge and provides a discharge path clear of the bell, which is consequently immune from tinkling. It also involves the use of a 4-conductor cord between the table telephone and the bell box, in place of the standard 3-conductor cord.

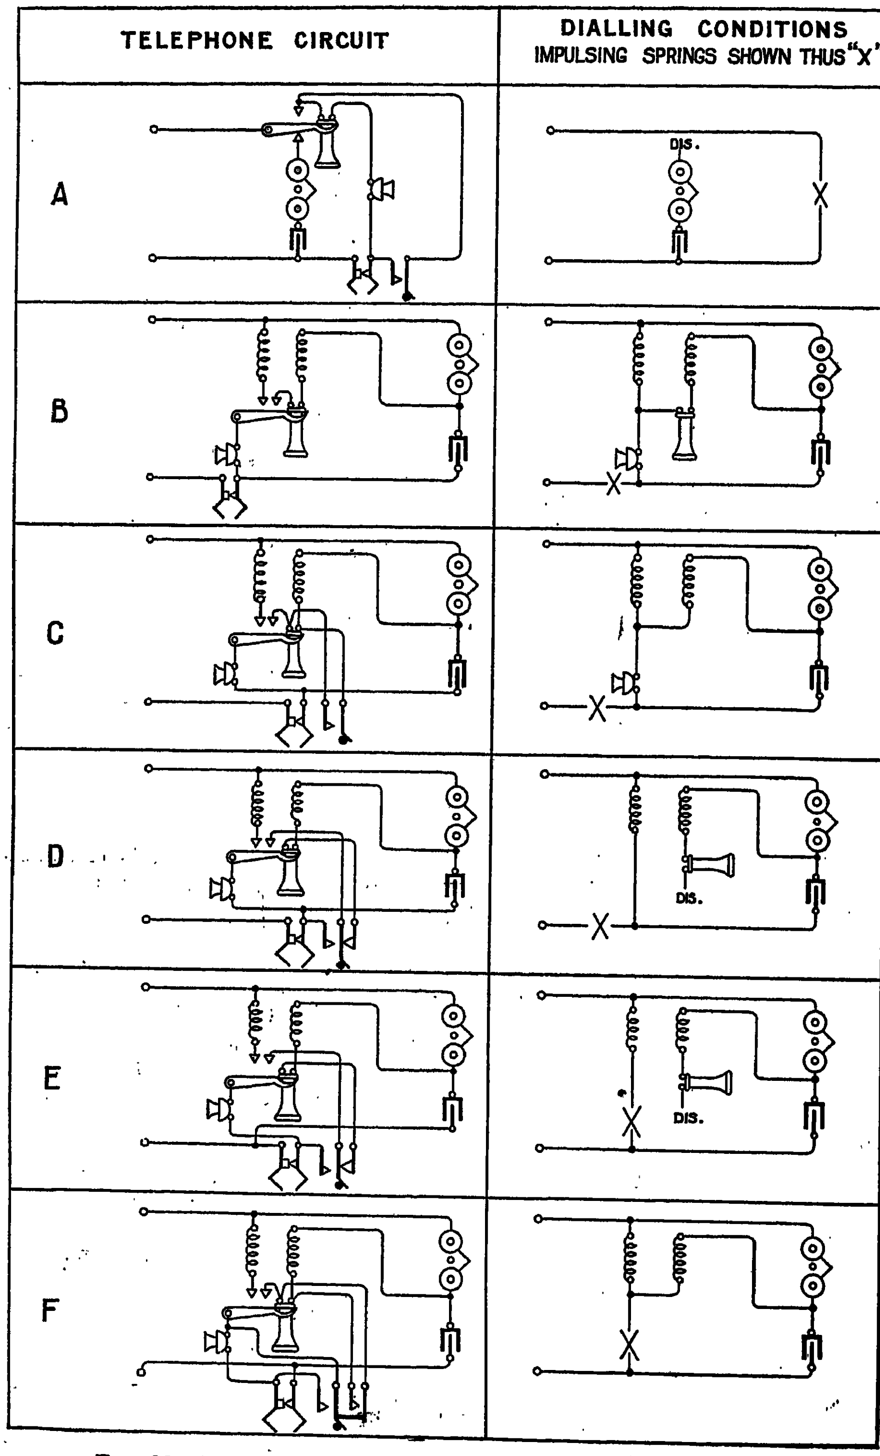

FIG. 26.—Development of subscribers' automatic telephone circuit.

"C" shows a more recent circuit provided for the Post Office by the Western Electric Co. It is identical with the circuit shown in "B" but includes two auxiliary springs, which short-circuit the receiver whilst dialling is in progress and prevent the subscriber from hearing dialling clicks. A 4-conductor cord is required.

"D" shows a circuit provided by Messrs. Siemens Brothers. It is very similar to that of "B" and "C," but the auxiliary springs short-circuit the transmitter and disconnect the receiver. The condenser is alternately charged and discharged as the dial springs make and break, but the magnitude of the charge is small because the condenser is charged through the high impedance of the 1 000-ohm bell and is shunted, at the moment of charge, by the primary (17-ohm) winding of the induction coil. The whole of the discharge current flows through the bell but is insufficient to cause tinkling. A 4-conductor cord is required.

"E" shows an arrangement which is used in some of the more recent installations in this country and is, I think, still the standard circuit of the American Telephone and Telegraph Co. Its chief advantage lies in the fact that it introduces a dial into the standard common-battery telephone without the need for more than three conductors in the cord to the desk set. The bell and condenser are connected permanently across the line, and the condenser serves to absorb high-voltage kicks during the dial operation, but its efficiency in that respect is reduced by the high impedance of the bell in series with it. The voltage across the condenser is alternately increased and decreased, as the dial springs break and make, and the bell is subjected to the full force of its charge and discharge. The bell therefore requires to be effectively biased in order to suppress tinkling.

"F" illustrates the arrangement and connections of the auxiliary contact springs in the new Post Office standard circuit—with 3-conductor cord. This circuit secures immunity from tinkling without resorting to biasing, and suppresses—or at any rate reduces to a negligible quantity—the high inductive dialling kick. When dialling is proceeding the condenser is bridged in series with the secondary 26-ohm winding of the induction coil across the "break" springs of the dial, in which position it momentarily prolongs the current after "break" and effectually prevents the high-voltage surge from the exchange apparatus from reaching a dangerous peak, while at the same time its action—as it is in series with only the low impedance of the induction-coil windings—is so rapid that no troublesome amount of impulse distortion is introduced. Immunity from tinkling is secured, as in the foregoing arrangement "C," by providing for the condenser to discharge mainly through the windings of the induction coil, which act as a shunt upon the bell. Dialling clicks are eliminated by short-circuiting the receiver. A separate pair of auxiliary contact springs is used to short-circuit the transmitter also, in order that constant dialling conditions may be maintained notwithstanding any alterations which it may in future be found desirable to make in the mean resistance of the standard transmitter.

The adoption of this very satisfactory instrument circuit was made possible by the fact that the new standard dial provides a robust and positive method of actuating the auxiliary contact springs. Springs which would short-circuit both the transmitter and receiver would undoubtedly have been employed several years ago but for the fact that one hesitated to attach to the earlier types of dial a spring set with more than one moving member. The spring set now used includes two separate moving members, and they are actuated in a manner which is, I think, safe and certain. Unfortunately this possible feature of the standard dial was not at once noticed, and those first obtained were fitted with spring sets of the then standard type, as shown at "E." It has, however, been possible to arrange that all on order for the London automatic service shall be converted to the new type in the course of their manufacture. The economy which will be effected in London alone, by obviating the need for fitting biased bells, is estimated to approach £100 000.

It will generally be admitted that the modern automatic calling dial is a remarkably simple little piece of

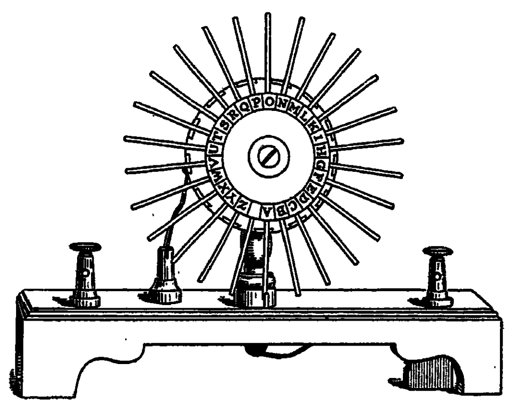

FIG. 27.—ABC dial sender.

apparatus, as compared with the immense complexity of the machine which it controls. This simplicity is the result of a long period of evolution since someone in the Automatic Electric Co. first had the happy thought of making a rotating disc with finger-holes for the purpose of sending the trains of impulses required for the Strowger automatic system. The master patent which secured a monopoly for this device ran from 1898 to 1912, and during that period a great deal of ingenuity was extended in inventing competing forms of dials and other signalling devices for other automatic systems which would not infringe the patent. It may be of interest to state that throughout this period an old and forgotten telegraph transmitting device was in existence which in all essential respects anticipated the terms of the master patent. This was one of the earliest forms, if not the earliest form of transmitter used in connection with the Wheatstone ABC telegraph system. A "clear-up" in one of the old store-rooms of the General Post Office in 1913 unearthed a specimen of this apparatus marked "Cooke and Wheatstone 1839" (see Fig. 27). It includes a disc provided with pivotally arranged finger-holds, which can be rotated from any position to a fixed finger-stop, for the purpose of trans-

mitting, by means of a current making-and-breaking device, a predetermined number of impulses of electric current, in harmony with the finger-holds—all of which terms represent the explicit claims of the master patent, so long considered unassailable. When it was discovered and brought to me as an interesting telegraph relic the patent had just expired.

(12) Tariffs for Automatic Systems.

The "message rate" tariff now in force in the British Post Office telephone service represents the only strictly equitable basis of general charge for such a service. It has the advantage of placing the small and large user on precisely the same footing, inasmuch as each will pay for his service in proportion to the broadly averaged overall cost of providing it and the use he makes of it. Under this method a fixed sum known as the installation rental is paid annually by the subscriber in respect of the plant provided for his individual use, and a uniform fee for each effective local call is collected to cover the cost of the plant provided for the common use of all subscribers, and the cost of operating. Additional charges are levied on a radial mileage basis for the use of long junction and trunk plant, affording connection with places outside the local fee area.

It is sometimes argued that the general introduction of the automatic system, and the elimination of the cost of operators to handle local calls, will bring in new conditions which would justify the restoration of the "flat rate," which connotes a uniform charge to all subscribers of a particular class, independent of the number of calls originated by each of them. This argument shows an entire misconception of the facts of the case. The introduction of the flat rate in connection with an automatic system would, of course, simplify the mechanical plant by making it unnecessary to provide metering arrangements for the registration of local calls, and would save a large part of the cost of collecting revenue from subscribers, but these points apply with at least equal force to the manual system, and in both cases they have to be subordinated to much more important considerations. In the automatic system, as in the manual system, part of the plant is provided for the individual equipment of each subscriber's line and part for the common service of all subscribers. The second part, which in all busy exchanges is much the larger of the two, depends entirely upon the amount of traffic to be carried; it has therefore no association with the annual installation rental, and a due proportion of its cost can only be properly charged against each subscriber in accordance with the traffic he originates. In a typical city manual exchange the ratio of individual to common service plant is about 1 to 2½; in an automatic exchange carrying equal traffic it is about 1 to 5. The actual cost per line of automatic plant in a busy city exchange is two or three times as much as in a suburban exchange forming part of the same system but having an average calling rate proportionately lower. At present only the local unit fee per message is registered electrically on the subscribers' meters in automatic exchanges, and all charges for calls beyond the local fee area are manually recorded on tickets by operators. It is, however, probable that in the near future it may be convenient to extend automatic metering to calls for which double or treble the unit fee is chargeable, and so enlarge the effective areas to which a purely automatic system of working can be applied. Schemes which provide, more or less satisfactorily, for such differential metering have already been devised, and the Post Office has been careful to keep the way open for future development in this direction by clearing all odd calculations out of its message tariff. All mileage fees are now so graded that the charge for any distance is an even multiple of the local unit fee, and could therefore be registered by adding a corresponding number of units to the record on the subscriber's meter.

One important respect in which the tariff considerations applying to the automatic and manual systems differ is that in the former the duration, or "holding time," of a call has a much more important effect upon the cost of providing the service.

In both systems switching and junction plant has to be provided on the basis of "traffic units," representing number of calls multiplied by holding time, but in the manual system the plant cost is rather overshadowed by the cost of operating the calls. The overall cost of providing service depends therefore to a much greater extent upon the number of calls than upon their duration, and no great error is made by assuming that all subscribers make calls of the same average duration. With the automatic system, on the other hand, the plant cost factor is of paramount importance. The various selecting switches through which a call passes may be looked upon as operators who have not only to make the connection in the first instance but are each required to give it their exclusive attention as long as it lasts. An exception to this is the "director" which will be used in London merely for the purpose of setting up calls, but the cost of directors is a very small fraction of that of the total traffic-handling plant.

It results, therefore, that the cost of providing service to any subscriber depends upon the aggregate duration of his calls in the busy hour, and not upon their number. One call of an hour's duration will cost the system practically as much as 60 consecutive calls of 1 minute. Under automatic conditions there is much to be said for the introduction of a method of charging for all telephone service on a time-and-distance basis, and the development of time-measuring methods applicable to local exchange working has received a good deal of attention from telephone engineers. Several patents already cover the application of this principle in such a manner that, immediately on the reply of the called subscriber, the meter of the originating subscriber will register one or more units in accordance with the distance between the parties, and repeat the registration at the end of each period of, say, 3 minutes. This does not fit in very well with the adoption of varying charges at different periods of the day and night, which is also a reasonable thing in telephony from the standpoint of keeping the plant occupied and revenue-earning outside the normally busy hours. A preferable system would appear to be to record normal time units by metering impulses at short intervals of, say, 12 seconds

throughout the period of connection, counting 10 or 12 units as the equivalent of a penny call. For calls to points outside the local area the record might be made at double, triple, or quadruple speed, by drawing impulses from different contact cams in the controlling clock. Reduced tariffs during normally slack periods could be introduced by variable driving gear which would slow down the whole impulse system in as many stages as might be desired.

(13) Progress of Automatic Exchange Construction.

The character of the new automatic exchanges to be catered for in London and the provinces in the immediate future is shown in Appendix 2. It will be observed that the schedule includes 161 projected exchanges with a capacity of about 369 000 subscribers' lines. Before this large amount of work can be completed many additional requirements will no doubt have matured. Extensions of existing provincial automatic exchanges will also be necessary in order to meet development.

The steps taken to provide for the special telephonic needs of London and to encourage British manufacturers to make plant of uniform characteristics have already been mentioned.

The difficult matter of acquiring sites, at or near the positions indicated by economic studies of the area layout, and designing and providing the necessary buildings, is proceeding as rapidly as present conditions allow. The contractors concerned in the manufacture of the exchange equipment are all working hard to produce and install the plant by the dates required, and their staffs of able engineers are in continuous touch with the Post Office Engineering Department. The Post Office staff responsible for planning and providing the external cable plant, and for grafting it economically into the London cable network, are also working strenuously under conditions rendered more and more difficult by the rapidly increasing congestion of underground London and the necessity for reducing street openings to the utmost possible extent. In some central districts it is no longer possible to find space for the necessary cable ducts under footways and roadways, and tunnelling deep down in the London clay has to be resorted to in order to gain adequate access to exchanges.

Automatic developments on so large a scale necessitate also the provision of a very highly skilled staff to engineer, supervise and maintain the exchanges. In order to meet this great need, it has been found desirable to set up a very completely equipped training school at the General Post Office for the purpose of giving a thorough training to the staff of the Engineering Department in the theory and practice of automatic telephony, and in the delicate work of switch adjustment, fault tracing and cognate matters. Graduated courses of instruction are held for the skilled workmen who will actually maintain the exchanges, as well as for inspectors and engineers who will be responsible for the performance of the mechanism and the efficiency of the service rendered. The extreme complexity of modern automatic circuits and equipment is illustrated by the the fact that a single automatic switching unit of 10 000 lines comprises no less than 5 000 000 " bank " contacts representing selectable outlets. Any one subscriber in such a unit can obtain connection with any other particular subscriber in the same unit via more than 240 000 different linkages. To reach all the subscribers on the unit he has at his disposal more than 2 400 000 000 different linkages—all this without passing outside his own exchange of 10 000 lines. In his recent book " Fifty Years of Electricity " Dr. Fleming expressed the opinion that the design of modern automatic telephone systems represented " the high water mark of human creative power." Be this as it may, it seems improbable that a parallel could be found, in any other application of science to industry, to the mass of co-ordinated and controlled complexity constituted by the automatic machine required to meet the telephonic needs of such cities as New York and London.

The manufacturing organization necessary for the production of the automatic equipment needed throughout the Empire, and in foreign markets which British manufacturers have been able to secure, is very vast and complex. It is anticipated that, in the near future, an annual output of automatic equipment for a quarter of a million exchange lines will be producible in the factories of this country.

From the first inception of the Post Office telephone system it has been the policy of the Department to discontinue the purchase of telephone plant from abroad and to encourage the establishment, within the United Kingdom, of adequate manufacturing resources for the supply of all its needs. It was well recognized from the first that this would foster the setting up of a British industry which would cater for a far more extensive market than that represented by Post Office requirements, and the complete success of this policy is a matter for lively satisfaction.

Discussion before The Institution, 5 March, 1925.

Mr. E. A. Laidlaw: The present paper is a record of the very striking progress made since 1919, when Mr. Grinsted and I read our paper on the same subject. Our paper was an attempt to deal with the future: the present paper is an account of the past—it describes what the Post Office has decided and done. For this reason it is difficult to discuss in a constructive manner. It would be easy to criticize the decisions and methods adopted, but such criticism would be merely destructive and I wish to avoid that. It is a very great satisfaction to confirm the author's remarks in the last paragraph of the paper as to the complete success of the Post Office policy of drawing upon British resources for the supply of all its needs. This policy has been of the greatest possible assistance to firms like my own, and we recognize it gratefully. I trust that it will continue to be the policy of the Post Office to depend upon the British manufacturer and, perhaps, to an even greater degree than in the past, upon British engineering. If that is done the author may relieve himself entirely of the fear he expresses in Section (9) of the paper. He may then rest assured that the London system in 20 years' time *will* be a model for the world to copy. The system of grading the links between ranks of switches which he describes in Section (5) is entirely British practice, and the standard dial described in Section (11) is a purely British product. It is, I believe, the only dial to have had thorough scientific study applied to its development, which took three years in our experimental departments. It is operating with great success in Australia, Canada, India, Japan, South Africa and South America, and we have even sold a quantity to a company associated with the American Bell interests. I was pleased to note that the A.T. and T. Co.'s * instrument circuit has been superseded by a very much better circuit developed, I believe, by the author's staff. The author referred to the paper by Mr. Grinsted and myself. I should like him to remember that it was read six years ago immediately after the war finished, and written before that, and that its main purpose was to draw attention to the changes in conditions which had taken place and to discuss the technical and economical problems then confronting telephone engineers. We used London merely as an example, in which we were expected to find specimens of every difficulty likely to be met in the application of mechanical operation. We did not intend to attempt to solve the London automatic problem, and this is clearly stated in the paper. We pointed out that the manual system was incapable of fulfilling future requirements, and held up the full automatic system as the solution of the difficulty. We condemned the semi-automatic system. I believe this was about the time to which the author refers, when the Post Office was seriously considering its adoption. In these respects events have justified our opinion. We also, it is interesting to note, fully described a scheme for "telephone unit" metering, arranged to charge the subscriber on the basis of the time and amount of plant occupied on his call. It appears from the author's remarks in Section (12) that he agrees with us as to the correctness and desirability of such a system. Here, again, I am confident that our opinions will be justified by events. Has the author had any investigation made as to what extent the telephone user can be depended upon to listen for the "dialling tone"? Observations which I have made, both at home and abroad, show that practically no one listens to it. A prominent official of one of the telephone companies of the United States using the panel system informed me that they had made an investigation and watched 200 subscribers carefully without their knowledge, and not one listened in for the tone before dialling. The effect of this on the working of the system will undoubtedly be felt, not at the beginning but when the load rises to the figure for which the exchange is designed. I think that it will be extremely difficult to educate subscribers to obey an instruction which they can ignore without trouble on about 95 per cent of their calls.

* American Telephone and Telegraph Co.

Mr. G. H. Nash: In Section (9) of the paper the author states: "Exhaustive study and trial led to the conclusion that the director system contained all the essentials required as a basis on which to frame a complete equipment of circuits and apparatus admirably fitted for the service of such an area as London." Complete as this paper is, in so far as it is possible for such an immense subject to be reviewed in a single paper, I do not feel that the author has done justice either to himself or to that able body of men who report to him and I make no apology for endeavouring to give some idea of what it is these men have done. It is apparent from the quotation I have just given that when the Post Office engineers decided to turn from that wonderfully complete system designed for the New York area—to leave behind the comfort and advantages to be derived from not being pioneers, and to become pioneers—they showed a great degree of courage and resourcefulness. It is well known that the commercial prosperity of a city and of a country is very closely related to its telephone development, and it requires no great stretch of imagination on our part to appreciate what would happen to London, for example, if the telephone service were to break down or become highly inefficient. Following this line of thought, it is apparent that the Engineer-in-Chief and his assistants embody in their persons a great responsibility for the commercial success of this city and of this country. Therefore, when they decided to take a system which, in its then embryonic stage, provided nothing greater than—to use the author's words—"a basis on which to frame a system for London," they demanded a most unusual amount of courage and resourcefulness from themselves and from the other telephone engineers of this country. It requires a telephone engineer to appreciate what a vast thing a telephone system is, but it is given to very few to get a complete view of what does lie behind such a system. I should like to lift one small corner of the manufacturing veil, taking as an example one of the manufacturing firms who are designing and will manufacture the system

for the Post Office. Taking circuits alone, there are something like 90 circuits in the director system which have to be built up and studied individually and collectively. In this one firm of which I speak, we have had 17 men for over a year doing the actual paper design work on those circuits alone—simply as theoretical paper circuits. Another 20 have been continually engaged in setting them up, testing them, finding out their faults and then dismantling them. Other men are engaged in designing the apparatus and in life-testing it before its construction can be proceeded with. I have not said this to call attention to a particular firm,

TABLE A.

175	570	250	395	145

but to demonstrate the amount of work which has to be done. I have heard doubts expressed as to whether the director system for London will be a success and whether the Post Office has been wise. My opinion is that without doubt it will be a complete success. Turning now from this broad review to a matter of detail, the author states that the Post Office has adopted the grading principle for trunking, which means that on any group of trunks from one exchange to another the trunks run straight from a digit-selecting switch in the outgoing exchange to the incoming switch. The actual process of grading allows access of a few switches to the trunks connected to the earlier choices, and the number of switches on the trunks connected to the later choices to be gradually increased. A certain gain in efficiency is arrived at by this means. This problem of trunking efficiency is of interest the world over. There are two particular areas at the moment which, like the Post Office, are confined to using switches with only 10 outlets, where it is of vital importance to know what to do to increase trunking efficiency. The question arises as to whether grading or, alternatively, outgoing secondary switches, shall be used. It will be realized that if there are switches with a large number of outlets the problem does not arise; neither would it arise if one could use pre-selecting outgoing secondary switches, i.e. switches which themselves found the line before it was wanted. All the attempts which have been made to design suitable controlling circuits for pre-selecting outgoing secondary switches have not yet produced a result which really warrants their being included in any automatic system. Such a circuit will no doubt arrive and, when it does, outgoing secondary switches of a pre-selective type will for 10-point switches (I do not refer to other types) completely sweep the board. As things are at present, we have to consider post-selecting secondary switches, and it will be seen from Table A that in order to pass a certain number of traffic units the grading principle may be employed, as the Post Office does, or post-selecting outgoing switches may be used. If outgoing switches are used they have to be paid for, while if the grading system is used more trunks will be needed. The London choice is for grading.

Considering Table A and taking, for instance, traffic units (35) the number of secondaries required on a loss of 1 in 1 000 is given, and it will be seen that an extra 114 switches have to be purchased, with all their attendant apparatus. In col. 3 is given the number of outgoing trunks that would be required, while in col. 4 the number of trunks required with the grading principle is shown to be 81, the difference being 20. The question therefore resolves itself into whether money is to be sunk in 114 secondary switches or in 20 trunks.

Mr. F. Morley Ward: The author seems to have covered the ground so thoroughly and so ably that it is difficult to find any matter for criticism. It is very interesting to see the "grading" diagram described in the paper and to know that the opinion of Post Office engineers as to the saving effected by such a scheme fully confirms my own contention. I believe that this arrangement was originally due to Mr. W. Aitken, who named it "multi-choice" grading. It was adopted by the Relay Co. over nine years ago and has proved a very useful and economical arrangement even for very small groups. It would be interesting to know the reasons which caused the Post Office to make the nine decisions referred to in the paper. Some of these seem quite obvious to British telephone engineers, but others are not so obvious. It would be particularly interesting to know why impulses over junction circuits should be signalled round the loop and not over one earthed conductor, especially when the latter permits of dialling over much longer lines. I believe that Messrs. Siemens have employed dialling over one line and the Relay Co. have gone further and dialled over both lines in parallel. By dialling over the two lines in parallel it has been found possible to work over junction circuits up to 1 600 ohms loop resistance, employing only 32 volts, which, I imagine, must be con-

siderably more than can be done on the Strowger system employing 50 volts. The reversed-battery arrangement which the Post Office has decided to use for signalling over junctions seems to me to be less flexible than the scheme which the Post Office standardized for manual junction working, in which signalling is made in one direction over one line and in the other direction over the other line. The latter scheme has been adopted very successfully by some automatic telephone companies. Perhaps the author will furnish some information on these points.

Mr. W. R. Carter: The author has told us how, during the time that negotiations were proceeding for the introduction of the panel system into London, those interested in other systems were not asleep, and it will probably interest members to learn that prior to the development of the director, the adoption of which is naturally a source of keen gratification to my company, our engineers had devised another method directed to solving the problem of the telephoning of large cities and by which it was possible to retain existing exchange names as part of the numbering scheme without, however, using translation. This method used what has been termed a "universal switcher," a device built up of standard Strowger equipment, and embodying an elaboration of the switching selector repeater principle. Fundamentally, the plan used was to seize a number of junctions, any one of which might prove to be the one wanted, and to reject those not required. That is, if BAR were dialled for Barnet, junctions would be seized momentarily, in addition to others going, say, to Bank and Battersea, or to switching centres having junctions to those places, and these junctions would be released as the dialling proceeded. The weakness of this scheme was, of course, the wasteful use of the junction circuits, but its development will indicate that considerable effort was being directed to finding a solution of the problem. Referring to the reasons given by the author for the adoption of the Strowger director system, I do not think that it is possible to overestimate the advantage of being able to use the same switching mechanisms in a 50-line village exchange as in the mechanical tandem exchange or in any 10 000-line office, and of being able to use any member of the maintenance staff who is capable of maintaining the 50-line exchange without further training in the larger offices. This must constitute a valuable advantage to those responsible for the maintenance of the system. Then, again, the system which has been adopted, whilst maintaining the ideal of one form of switching mechanism throughout, only employs registers and translators in those areas where it is necessary or desirable to separate the trunking and numbering systems. Maintenance considerations also controlled the design of the coder call indicator. The substitution of code impulses for decimal impulses makes it possible to use simple rotary switches and relays only at the manual end and, in addition, reduces the amount of equipment at that end to a minimum, an important feature since there is often but little space available for additional apparatus in existing offices. Post Office practice largely influences the development of the art; innovations suggested by Post Office engineers have become standard, and may be found in service in many parts of the world. In this connection the work of the Post Office engineers in investigating grading methods of interconnecting is likely to prove particularly valuable to the industry at large.

Mr. W. Aitken: The idea of telephoning great areas has always had a fascination for telephone engineers. Prior to 1900, Mr. A. R. Bennett put forward a system having this object in view. In 1903 I read before the Institution a paper * advocating a manual system of three divisions whereby the subscriber, in addition to lifting his receiver, by pressing one or other of three keys could get into any one of three great divisions. In 1914 I advocated, or at least designed, a system (British Patent No. 53) for the tandem working of junctions, a system which is a valuable feature in the present director system. In that case I associated an electro-mechanical coding sender with the jack of each outgoing junction line. In 1919 we had the paper by Laidlaw and Grinsted, who put forward their ideas for automatic development, in which connection I also read a paper in 1911 chiefly on the Strowger system.† Now we have this system, in its director form, put forward and actually being installed by the author, a system which, in my opinion, represents one of the most wonderful creations and designs of the human mind ever known. It is marvellous in its adaptability to the business and social needs of a great community. It is almost confounding in the intricacy and efficiency of its circuits, and it is awe-inspiring in the more than human exactness, discrimination, reliability and durability of its switches. The system of grading trunks from a small group to a large group—first and second choice—was known, at least, in 1910 and was described in Smith and Campbell's "Automatic Telephony" in 1914. Siemens and Halske in 1913 (British Patent No. 12566) divided at one or more places the multiple leads connecting the several parts of the divided leads to different lines of the group, the contacts of the divided leads being preferably the first engaged. In 1914 (British Patent No. 20453) I applied this to manual and semi-automatic systems, with direct trunks, without order wires, an operator pressing a key to glow a group of multiple engage lamps, and first using an idle trunk in the first-choice sub-group until these were all busy, and then taking up second-choice trunks. This was submitted to the Post Office but was withdrawn at a later date. In 1915 I developed a multi-choice arrangement (British Patent No. 15287) on the lines put forward by the author. Unfortunately for the originality of my idea (it was original in this country and in many others, according to the Patent Offices) there was an American patent on the subject and it seemed that what I had put forward had been advocated in America. Like the British patent, however, the American patent had been ignored until rediscovered or invented by the Post Office engineers. The graded wiring of trunks is now put forward as the most valuable contribution towards increasing the efficiency of small switches and making their efficiency approximately equal to that of switches of great capacity. In 1916 I designed

* *Journal I.E.E.*, 1903, vol. 32, p. 705.
† *Ibid.*, 1911, vol. 47, p. 651.

"multiple graded access" (British Patent No. 108714) in which a diminishing number of trunks in each access were multipled a plurality of times over a large group of incoming lines (one or more thousands), the number of trunks in each access having, preferably, no common divisor, such as 19, 17, 13, 11, 7, 5 and so on; 19 trunks, for example, would be multipled over each sub-group of 19 lines in the group, as first choice; 17 trunks over each 17 lines, as second choice, and so on; so that adjacent incoming lines had access to a different set of trunks. My object was to find a means of making systems with small switching access, say to 5 or 6 trunks, efficient, and tests showed that that object was very well attained.

Mr. J. E. Collyer: The automatic telephone programme will give great satisfaction to everyone, and particularly is this the case with regard to London. When one learns from the paper the history of the development, one can appreciate the magnitude of the difficulties encountered and the importance of the decisions that had to be made. When a course is chosen from several alternatives there are bound to be doubts and disappointments. After reviewing the matter carefully in the light of the paper, I think that the Post Office has acted wisely. Speaking as a representative of the engineering staff of the General Electric Co., we are determined to give the Post Office all the assistance in our power in carrying out its programme. The author suggests that such standardization as is taking place has nothing to do with any idea of finality or fixation of practice. One has only to turn to other instances to realize the advantages of standardization. At the same time I feel—in common, I think, with many other engineers—that this matter should be dealt with very carefully and diplomatically at this stage, as otherwise there is a great danger of standardization affecting progress. The fact that something is considered good enough for the time being must not result in the cessation of further effort. In the opinion of many engineers there will be very considerable changes during the next few years.

Mr. G. Deakin: The author sets forth clearly the difficulties encountered by engineers when attempting to solve the telephone problem for very large networks, and his final selection of a system of translation for London is an appreciation of the economies which translation affords. At some later date it will be interesting to compare the results obtained in London with those obtained in Berlin where translation will be avoided. Office-prefix translation is now in use in many cities in America and in one city in Europe, namely, Copenhagen. The idea of spelling the office prefix by placing letters on the dial was conceived by Mr. W. G. Blauvelt of the A.T. and T. Co. The first flexible translating register circuit was produced by Mr. A. E. Lundell, then of the Western Electric Co. of New York. The Copenhagen circuits were developed by Mr. L. Polinkowsky, of Antwerp. It is stated in the paper that a satisfactory amount of traffic can be carried with 10 contacts in a bank-level. Presumably this means that the author is satisfied that such an arrangement is economical, both as regards the inside and outside plant. I have made studies of two Continental cities and in each case found that a real saving could be made by employing larger junction groups. In these studies the junctions were calculated for three conditions as follows: (*a*) undivided groups; (*b*) groups of 30 which are now obtainable in the rotary system of the Western Electric Co.; and (*c*) groups of 10. The average results were as follows: Plan (*b*) required 23 per cent more circuits than plan (*a*); plan (*c*) required 69 per cent more circuits than plan (*a*); while plan (*c*) required 38 per cent more circuits than plan (*b*). These figures are not negligible, but the real answer has more to do with the length and character of the junctions involved. Where the junction routes are short, underground and in cables of many conductors, the annual cost of the excess junctions may not be great, but where the junction routes are long and important the result would seem to be the reverse. I do not dispute the accuracy of the author's statement as regards London, but it comes as a surprise to me. Tandem trunking is one of the economical features of an automatic system, and I presume that the statement with regard to the efficiency of a group of 10 junctions does not apply to all points on tandem routes. The reason for tandem trunking is, as the author states, to increase the efficiency of long and expensive junctions, and one of the ways of doing this is to increase the size of the junction group. Grading will, of course, help, but grading applies to both large and small groups. The paper brings out very clearly the advantages of grading which is now universally recognized as both economical and proper. The real efficiency of any particular form of grading is, however, at the present moment open to dispute, since it seems to be impossible to demonstrate mathematically, to the satisfaction of all, within practical time-limits the efficiency of such schemes as that shown in Fig. 12, which is but one of a very large number of similar schemes that may be applied to the various stages of selection. Furthermore, in trunking from the group selectors, i.e. from the first, second, etc., selectors, the scheme of grading must be very general and capable of immediate application from day to day when increases or decreases in equipment are being made. In planning any scheme of grading the abnormal conditions actually met with must be taken into consideration. This is particularly important in grading small groups, for the reason that a few calls of abnormal duration unfortunately placed may seriously affect quite a large number of switches. The author mentions that cordless "B" positions will be used to establish connections outgoing from the existing manual exchanges to the new automatic exchanges, and gives, as the alternative, dials placed on the "A" positions by means of which the "A" operators may dial direct. This method of direct trunking is obviously not economical, but there are methods of direct trunking which are. I refer particularly to key-set direct trunking from "A" positions over individual junction jacks. This scheme of trunking is made economically possible by the use of large-capacity high-speed power-driven finders. Each "A" operator is provided with 2, 3, 4 or 5 individual jacks, as traffic requires, for connection to each automatic office. On each "A" position is mounted a small 10-button key-set approximately $2\frac{1}{4}$ in. × $3\frac{1}{4}$ in. This key-set is held by clips so that no cutting of the existing keyboards is

necessary. The direct trunking equipment has no connection whatsoever with the "A" cord circuits or with the operator's telephone circuits, so that the existing manual equipment need not be disturbed in any way. The method of operation is as follows: The manual subscriber gives the "A" operator the wanted number, for example, Gerrard 1456. The operator upon hearing the prefix immediately inserts the calling plug into an idle junction jack to the Gerrard office, no busy test being necessary. As soon as the number has been checked with the subscriber the operator depresses the wanted number on the key-set one digit at the time, each time depressing the proper button all the way down. The four buttons may be depressed one after the other, providing the operator is able to do so, within $\frac{3}{8}$ sec. without failure. The operator finishes with the setting-up of the call with the depression of the last button. From now on, the call takes care of itself. The great advantage of this sort of direct trunking over order-wire trunking is that the "A" operator's load may be increased while "B" operators are dispensed with. Direct trunking with key-sets is not new and has been in satisfactory operation in America, in connection with the panel system, for some time. In America, however, multiple outjunction jacks are still used so that an "A" operator must select the junction and connect it to her key-set, and this she does by depressing an office key, similar to an order-wire key, which causes the number of the assigned junction to be displayed before her. This extra operation constitutes quite a little work over and above that required under the afore-mentioned individual jack scheme, but even with the American scheme the relative weight of a trunked call has been brought down from 1·5, which is the well-known order-wire figure, to 1·21. It is confidently expected that the individual jack scheme which will be put into operation in Switzerland early next year will reduce the weight of a trunked call to that of a call completed directly in an "A" multiple. The factors which tend to decrease or simplify the work thrown upon the "A" operator may be briefly stated as follows: (1) No repeating or checking with another operator; (2) elimination of order-wire key or its equivalent, and the associated delay; (3) individual junction jacks reducing time of jack selection; (4) no busy or check testing of junction jack; (5) very short reach, which incidentally reduces cord congestion; (6) no team work required or divided responsibility; (7) operator may plug into junction jack as soon as wanted prefix is heard and before or while the number is being checked with the subscriber; (8) number may be depressed on key-set as fast as the operator can work, and in the most simple manner. Studies have been made to determine what saving might reasonably be expected from direct trunking when applied to manual offices. In one study a network of eighteen 10 000-line offices was considered, nine automatic and nine manual. Each manual office was assumed to complete 10 per cent of the originating calls locally in a subscriber's multiple, to trunk 45 per cent to other manual offices over order-wire junctions and the remaining 45 per cent to automatic offices. In comparison with cordless "B" trunking, the study showed that direct trunking saved fifteen "A" and eighteen "B" positions for each manual exchange of 10 000 lines. The study also showed that the cost of the direct trunking equipment was not much greater than that of the cordless "B" equipment plus the excess "A" position equipment made necessary by the use of cordless "B" positions. In this particular study the net annual saving for each manual office of 10 000 lines was estimated to be 600 000 francs (French). This saving will increase in proportion to the growth of trunking to automatic. Incidentally the capacity of manual switchboards increases with the growth of the automatic system, so that additional subscribers may be added to existing manual exchanges without extending the sections. Direct trunking improves service during the transition period. Order-wire trunking has never been an ideal form of trunking and never will be. It has rarely been successful on the Continent, and in many important instances has been a dismal failure. On the Continent to-day, in large manual networks, there are many methods of trunking other than order-wire in actual use. Even in America, where order-wire working has been very successful, a new scheme of trunking called "straight-forward trunking" has come into vogue. Under this scheme an order wire is not used. I am not able to give any details, but it would seem from the information so far received that the trial installations are very successful. An order wire requires the best possible team work between two operators, and even with the best team work the possibility for misunderstanding is always there. The order-wire method of trunking is a constant source of wrong numbers, double connections and "hang-ups." Furthermore, the order wire at moments of overload and even at other times may be a serious source of delay to the "A" operator, resulting in slower and less satisfactory service and in lower operating loads and more costly operation at the "A" end. When all these points are fully considered, direct trunking under proper conditions appears very attractive.

Mr. W. H. Grinsted: The author has, at more than one point in his paper, drawn attention to the complexity of the apparatus. It is very important to see how this complexity tends to affect the reliability of the system. A connection in an automatic system is made up, like a chain, of a large number of links, and the success or failure of the connection depends entirely upon the reliability of the individual links. The failure of any one link will interfere with the completion of the connection. I am not sure whether it is generally realized what a very large number of links is involved. I am using the word "links" to include not merely the trunks connecting successive ranks of switches but also the separate movements or functions of each piece of apparatus. Taking the London system as an example, and choosing a call between two adjacent exchanges, the number of individual movements of different pieces of apparatus —movements the failure of which would interfere with the success of the connection—amounts to 565 for one call. If we count the number of circuit openings and closures and regard each time a circuit opens or closes as a function, the number amounts to 1 539. Taking the average provincial system, the figures are 169 (reckoning movements alone) and 600 (taking into

account circuit-changes). Carrying this idea a little further, the importance of each piece of apparatus from the maintenance point of view depends both on the number of functions it performs—its complexity in a way—and the amount of traffic passing through it, i.e. the number of times it is asked to function. Taking the director system and calling the traffic carried by a line switch unity, that carried by a selector, on the average, might be represented by 10 and by a director by about 50. Not only is the traffic concentrated on the director to that extent, but the director performs a far greater number of functions. Out of the 565 movements to which I have referred, the director accounts for 234. If, then, we compare the different parts of the equipment on the basis both of complexity (number of functions and movements) and traffic (the number of times it is asked to function) we might represent the importance of the line switch and its associated apparatus by about 10 movements multiplied by 1, whereas in the director the corresponding figure will be about 234 multiplied by 50. That shows how very important the directors are and how large a share of the attention of the maintenance staff they are likely to occupy. Another point which I should like to raise is the question of what I might call the means of self-defence for automatic exchanges. The exchanges are designed to carry a certain traffic, but that traffic is an average traffic. It may or may not be the average of the busiest times. Strictly speaking, I suppose, it should be the mean busy-hour traffic over the busiest season of the year. There are, however, times when abnormal events take place; there are periods of excitement such as elections, fires, races, accidents, etc. Occasionally there are cable breakdowns. On an automatic exchange these events are liable to cause overloads, resulting in considerable congestion. The group selectors are provided with means for dealing with congestion of that kind. The switch, if it cannot find a free outlet, runs over to the 11th position and remains there connecting the busy tone to the calling line. To bring about that state of affairs, however, the call must reach the group selectors and hold one or more of them engaged just at the time when it is most needed. It would appear to be very desirable to deal with overloads like this at the point where the line enters the exchange, namely at the line switch. This involves some arrangement by means of which false calls due to permanent loops and calls which cannot be completed owing to unusual congestion are thrown back on the line switch and held there, while all common switching apparatus is set free to help to cope with the overload. It would be useful if the author would indicate in his reply how a London exchange is arranged to deal with an abnormal load of the kind to which I have referred.

Mr. D. A. Christian (*communicated*): The decision, as recorded in the paper, to signal impulses round the loop in the case of junction circuits is one of far-reaching effect in the matter of circuit design generally. This is more particularly the case if othre signals, such as the supervisory signal, are also effected by loop signals. When signals such as that necessary to hold a call which has been made to an operator are also required, it would indeed appear impossible to retain pure loop working without introducing prohibitive complication. This latter meaning cannot, of course, be read into the decision given in the paper, and the London system does indeed employ leg signals for such cases. Mr. Morley Ward has already mentioned the advantage of increased junction resistance which accrues from leg signalling and has spoken of a system of impulsing over the two legs of the junction in parallel, which still further increases the workable junction resistance. A method of parallel leg working devised by myself may be of interest in this connection, as, in addition to increasing the permissible junction resistance, it also overcomes any fear of interference from variation of earth potentials or inductive surges induced from power systems. The principle involved is to arrange for impulses to pass over the junction legs in opposite directions, so that any interference from external sources strengthens the impulse in one leg while weakening it in the other. This method of parallel leg working lends itself readily to incorporation in a leg signalling and dialling system, based on the principles adopted in British standard manual practice. While the above arrangement offers a convenient method of overcoming possible interference with leg dialling from power circuits, I do not think that its adoption for this reason only would ever be justified. Mr. Bartholomew stated in his reply to the discussion on his paper* that the estimated lost-calls due to earth potential kicks would not be greater than 1 in 600 000, and that the degree of disturbance would have to be 60 times as great before the standard of the service would be sensibly affected. Even so, the loss of 1 call in 10 000 must surely be insignificant compared with the calls lost due to insufficiency of switches or other causes.

Mr. H. S. M. Hall (*communicated*): In connection with the dialling tone referred to by Mr. Laidlaw, there are, to my mind, more disadvantages of the present system than the one which he referred to, namely, the disregarding of the tone by the subscriber. These are: (*a*) If a fault develops on the subscriber's line, he will not receive the tone and will therefore assume that there is no apparatus available to receive his call—thus delay will be caused in reporting the fault; (*b*) the capacity of the dialling tone generator will have to be comparatively large as the tone will be connected in the greater majority of calls; (*c*) to an inexperienced subscriber the tone will indicate that the line is not clear and he will therefore refrain from dialling. I would therefore suggest that the present practice be reversed and the tone only connected when there is no apparatus available to the subscriber. This method would apparently obviate all the above disadvantages.

Mr. J. Hedley (*communicated*): Mention is made throughout the paper of certain essential conditions which have to be catered for in a large area such as London, and I should like to emphasize one or two points. The four essential conditions to which I wish to refer are: (1) Freedom of routing; (2) large groups of outgoing junctions; (3) large groups of private branch exchange subscribers' lines; and (4) satellite

* "Power Circuit Interference with Telegraphs and Telephones," *Journal I.E.E.*, 1924, vol. 62, p. 817.

working. The provision of the 500 line units in the panel system makes it inherently suitable for conditions (2) and (3), whereas in the director system with its maximum of 10 contacts it is necessary to provide special auxiliary equipment to meet these requirements. Even with the provision of this auxiliary equipment, the amount of number changing will be larger with the director system than with the panel system. In these two respects, therefore, the panel system has the advantage. In order to obtain this advantage, however, a non-decimal system has been adopted and consequently conditions (1) and (4) cannot be so economically catered for as in the director system, for the following reasons. In the case of " Freedom of routing," whenever a call arrives in a panel exchange a sender equipment or its equivalent is essential to accept, store, translate and route the decimal impulses for a call to any exchange and for any class of service as sent by the subscriber. It is interesting to note from a historical standpoint that the original design of the director, as exhibited to members of the Post Office Commission who visited America in 1922, dealt with the call in a somewhat similar manner, i.e. on the model provided for our inspection there were eight B and C switches on each director, so that each director was capable of routing a call for any exchange. In making the arrangements for the provision of a model in G.P.O. (West), I suggested that it should be designed to cater for the reception of the first digit sent in by the subscriber on a selector switch (now termed the " A digit switch ") which would route the subscriber to one out of a group of eight directors for the remainder of the call. These eight segregated groups of directors, which are approximately equivalent to one sender in the panel system, are capable of dealing with eight calls simultaneously instead of one in the sender of the panel system. This segregation keeps idle plant at a minimum and incidentally has enabled cross-connection facilities to be embodied on each director instead of through a common exchange intermediate distributing frame as in the case of the panel system. It should, perhaps, also be mentioned that this simple cross-connection scheme was developed by Post Office engineers. With regard to condition (4), a " satellite " exchange is one which depends upon a main exchange, termed the " parent," for the routing of its originating non-fee junction traffic, i.e. the satellite exchange will route direct its own originating local calls and also its own no-delay trunk calls via the toll exchange. It will be apparent that with an exchange designed on a non-decimal basis, as in the case of the panel system with its 500-line units, some equipment equivalent to a sender must be provided to accept, store, translate and route each call. For satellite exchanges, however, such sender equipment should be eliminated. With the director system designed on a decimal basis, all that is necessary is to allow all calls to be received at the parent exchange on directors used jointly by the parent exchange subscribers, and to arrange at the satellite exchange for discriminating equipment to function for the code of its own exchange and when " TOL " is dialled. Under these conditions the parent exchange will be set free, and the satellite exchange step-by-step plant will then operate direct from the subscriber's dial, i.e. there will be no directors provided at the satellite exchange. Circuit arrangements in director areas for such facilities have already been developed by Post Office engineers. In conclusion, I think it can be stated briefly that the main fundamental difference between a panel and director exchange equipment is that in the former the design caters for dealing with all service conditions at one point in the system, whereas the latter is based on designing the trunking scheme to arrange for the provision of plant suitable for the particular call at the most suitable point, i.e. the various classes of calls are summarized and converted into traffic units, and plant is provided accordingly for each particular requirement.

Mr. G. A. Hollings (*communicated*): Speaking as a village subscriber, I am disappointed to learn that so little is apparently being done for rural telephony. This branch of the telephone network is deplorably backward, and rural services are extremely bad. Half the exchanges of this country are rural exchanges, but in many of these there is no night service, and only a partial service is available on Sundays. In some districts the demand for service is refused altogether. Is it not possible in cases where the community is particularly small or remotely situated to install a very small automatic exchange, say from 5 to 10 lines, in a sentry box at the foot of a pole or in the local general shop? It is comforting to know that two Post Office rural automatic systems were installed last year. Presumably these plants were produced by the Post Office itself, but no indication is given as to the principle of their operation. Possibly they are the forerunners of a general scheme for rural conversion. Owing to the diversity of conditions in different countries it is rarely wise for one country to adopt the telephone practices of another, and, as we have seen, the Post Office has not considered it expedient to follow the methods especially suited to New York. I make this remark as I have observed, in the course of experience abroad, that there is a marked tendency on the part of overseas telephone administrations to accept the decisions reached in this country, without paying sufficient regard to the very special conditions that determine the trend of development here. Informed opinion is by no means unanimously in favour of the step-by-step principle; indeed it is suggested in this paper that this principle suffers from certain disabilities in comparison with other systems. Such systems as the Rotary, Relay and Ericsson have all passed with high honours the critical test of practical application. Each has its peculiar merits and claims: the Rotary for the positive action and robust construction of its contacting parts, the Relay for the amazing simplicity and almost motionless and silent action of its apparatus, and the Ericsson for the general beauty and excellence of its switch design. It is to be hoped that these systems will receive a full measure of practical support wherever automatic development is contemplated. The utility of dialling tone is open to question. In every 500 calls about six will fail owing to congestion at various stages of the switching, but only one of these failures will be notified to the calling subscriber. To sum the matter up, a busy subscriber who attentively listens for the dialling

tone on every call may expect to save himself the trouble, about once in 2 months, of performing a useless dialling operation on a call that is foredoomed to failure when the receiver is lifted. The gain is infinitesimal and it is safe to predict that this tone will be generally ignored. In view of the fact that there are three other infinitely more important tones to be interpreted, I think that it would be no loss if this one were suppressed altogether. It would appear that where a 20 000-line or 30 000-line automatic exchange is required it is customary to install two or three separate 10 000-line exchanges in one building. The factors that dictate such a subdivision of the plant are not clear.

Mr. G. Hurford (*communicated*): The ground covered by the paper is so extensive that one has to take for granted the general principles and curves mentioned. There are, however, a few points which are rather sweeping in character. The author states that the theoretical trunk-hunting capacity of 10-contact or 25-contact switches with secondaries would be increased to 100 or 250 circuits; I think it will be agreed that the 100 per cent efficiency of secondary switches indicated, although highly desirable, is never obtained in practice. I am inclined to believe that the author has this in mind as he states on the same page that "the theoretical method of attacking problems of switch layout is often exceedingly difficult and leads to results which are tedious to evaluate." The whole of section (5) gives one the impression that supporters of the large-capacity switch are working along wrong lines, as the author indicates that the same results can apparently be obtained with small-capacity switches combined with suitable grading schemes. Although grading can be used with beneficial results, its efficiency is always less than that of large-capacity switches with direct outlets. The author states that the panel system "has been installed to a capacity of more than 250 000 subscribers' lines." I am not quite sure of the meaning of the word "capacity." The first two panel offices placed in service were those at Omaha, and were cut over in January 1922 with approximately 13 500 lines equipped. In the same year four other offices were placed in service with a total of approximately 24 400 lines. A total of 58 full-automatic panel offices with over 400 000 lines equipped were in service at the end of February 1925. These figures include extensions to the original equipments. Of this number, no less than 24 offices with approximately 184 000 lines, i.e. nearly 75 per cent of the exchange lines in London, are now in service in New York City. The author states that the panel system is both costly and complex, but as he also states that the circuit arrangement of the director system is necessarily somewhat complex, one is led to believe that there is not very much to choose between the two systems on this score. A similar inference might also be drawn from the remark regarding the difficulties involved in training the requisite staff for handling the panel system, and the remark referring to the system for London, stating that automatic developments on so large a scale necessitate the provision of a very highly skilled staff to engineer, supervize and maintain the exchanges. Referring to the conversion of London to the automatic system, the author states that call-indicator equipments will be progressively thrown out of service during the period of transition. Studies of conversions of large areas have indicated that these equipments will go on increasing for a number of years before the maximum is reached. If the automatic systems for Manchester, Birmingham and Liverpool are to wait for call-indicator equipments to be recovered from the London exchanges, then I am afraid that any hopes that these towns may have of being converted to automatic in the near future are doomed to disappointment.

Mr. T. B. Johnson (*communicated*): On page 622 it is stated that "if the number of local calls which might be switched automatically will not exceed 3 000 per day within the 10 years' period, manual equipment will be installed without question." It would be interesting to learn the reasons which have caused this decision, as there would appear to be many cases within these limits which could be worked more suitably by automatic than by manual equipment. In the "border line" cases referred to it should not be overlooked that by the use of automatic equipment subscribers would obtain: (*a*) A more prompt response to calls; (*b*) a quicker reply from the called subscriber; and (*c*) immediate disconnection at the end of the conversation. These important advantages would surely justify the provision of automatic exchanges in all such cases. In the case of Keighley shown in Appendix I, it is obvious that the small balance of cost in favour of the automatic is due to the small proportion of local traffic and the comparatively large number of calls left to be dealt with by the manual operators. These calls are, however, chiefly over short-distance junctions, and on the introduction of a "time and distance" basis would all be removed from the manual operator, thus leaving a much larger balance of cost in favour of the automatic equipment. The same considerations doubtless apply to Maidstone and Macclesfield. An important point in connection with private exchanges is that the operating should not merely form part of some person's duties, but that a thoroughly competent operator should be employed, and that it should be her sole (or at least primary) work. In some cases junctions are held up because operators at private branch exchanges are engaged on other work. The time spent by operators in writing out-tickets for comparatively short-distance calls is so considerable, and the slowing-down of the operating so serious, that the introduction of a "time and distance" basis is urgently necessary. Operators should, as far as possible, be employed on operating only, and the introduction of other classes of work, such as ticket writing, avoided to the utmost possible extent. Although the expense caused by providing for the peak of the load is not so great in automatic as in manual work, it is appreciable. It is thought that reduced charges during the normal slack periods should be introduced, especially as a large number of manual exchanges will be in operation for many years to come. In one large manual exchange (which may be taken as representative of the whole) the calls rise from 600 between 8.30 and 9 a.m. to 4 400 between 10 and 10.30, dropping again to 1 200 at 1 to 1.30 p.m. and rising to 3 400 from 3 to 3.30 p.m. If by reduced tariffs during the slacker periods 1 000 of these calls could be

transferred from the peak hours, the number of operators could be reduced by 10, with corresponding savings in apparatus, wiring and space.

Mr. W. Johnston (*communicated*): The rapidity with which automatic telephony has developed, and the constant changes and advances in the art, have almost bewildered the ordinary telephone engineer who is anxious to do the best possible both economically and technically. The review which the author gives of the whole situation, and the reasons he sets out on page 636 justifying the choice of the step-by-step system for London, are most valuable. I doubt if he is fully aware of the important aid he has given to those outside the British Post Office service who are anxiously struggling with the subject of telephone engineering. On page 638 it is stated that decisions were taken to feed subscribers' talking and signalling current to the loop at final selectors or at outgoing junction repeaters and

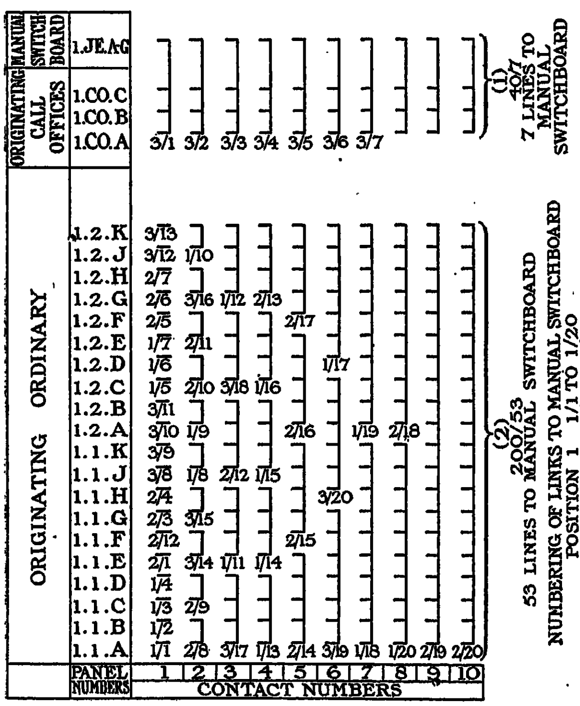

FIG. A.

that the registration on subscribers' meters was to be effected by means of a booster battery, whereas on page 642 this seems to have been abandoned and the system of feeding from the first selector and the simple metering adopted for London. Some years ago I had a Siemens equipment installed in Valparaiso with this system of feeding which seemed a step in advance, and I am glad to have this confirmed. However, the author still apparently retains the final selector feed for the called subscriber, and I am unable to understand the reason for this. With regard to grading, which is very clearly dealt with on page 627, I am glad to find that this is practically the same as arranged by Messrs. Siemens Brothers for the plant at Valparaiso. The gradings at Valparaiso are only between selector levels and do not take the place of secondary pre-selectors. A typical grading is shown in Fig. A, which is on the same lines as the arrangement set out in Fig. 12. It appears to me that the author must have some confirmatory data with regard to the statement on page 629 that "the grading scheme effects substantially the same economy as the use of secondary line switches." I should like to ask him if he could give the exact efficiency of grading as against second pre-selectors, which have given us every satisfaction and the faults on which have been very small indeed. Second pre-selectors should, by giving access to something like 100 selectors, be more efficient, and moreover the use of a 25-contact pre-selector would appear to increase the cost of an exchange both as regards apparatus and floor space.

Mr. E. A. Petithory (*communicated*): It is always interesting to look forward in telephony and, if possible, profiting by past and present experience, to anticipate the probable trend of events. This the author has, by his various decisions, attempted to do. In Fig. 14 is given a reproduction of an extract from a New York telephone directory, showing the method of listing the telephone exchange numbers in connection with the panel system. It is understood that this same method of listing is to be used in the London telephone directory. While this method appears to be, and probably is, very sound, the experience in the United States in cities using this type of numbering has been rather peculiar and in some respects undesirable. In a recent copy of the *Kansas City Citian* I observed that the majority of the advertisements gave no telephone numbers. This seems to be an adopted policy, as the telephone company's advertisement also gave no telephone number. Where telephone numbers were given some were printed correctly, i.e. two large letters followed by the balance of the exchange name, while others gave the exchange name in ordinary type. On one page was printed a large list of telephone numbers, and here the two first or initial letters only were given, the balance of the exchange name being left off, so that the exchange names became corrupted, i.e. MA for Main, etc. The same corruption is, I understand, also taking place in other cities in the United States, such words as "Center" becoming CEN. It is fairly obvious that the same thing is liable to occur in London. It would appear that the Post Office should endeavour to make newspapers and subscribers follow the telephone directory method and not corrupt the exchange names. Such corruptions on advertisements, letter paper, etc., will make it necessary for the user to look up the directory for the correct name, particularly when placing toll and trunk calls. On pages 654 and 655 the author refers to a suggested method of registering normal time units and illustrates a method of operating the subscribers' meters. From the experience that most telephone engineers have had with subscribers' meters, to work them in some cases 10 or 12 times during a call is not at all alluring from a life point of view; further, the interrupters with their various cams and attendant apparatus for switching in the meter impulse, etc., would probably be found to be very expensive. As a practical alternative I would refer the author to suggestions outlined in the

paper * by Messrs. Laidlaw and Grinsted, in which they outline the following method of metering, which eliminates all mechanical difficulties and would probably prove to be economical: "A simple apparatus based upon electro-chemical principles, the record depending upon the time it is in circuit and the strength of the current, which is regulated according to the rate at which the call is to be charged."

Mr. S. H. Pook (*communicated*): It is stated on page 646 that each call-indicator operator will handle 450 calls per busy hour, and that this is probably a conservative estimate. I think that it is very much on the low side. An order-wire operator can take this load, and call-indicator working is much simpler than order-wire working. I have recently seen call-indicator operators regularly taking a load of 500 calls per busy hour with ease, and under test it was found that they could go as high as 600 calls per busy hour. At this point difficulty was found, not from their being overloaded as regards operation, but from the cords becoming so interlaced that they were difficult to disconnect. This was with ordinary call-indicator working, but with the coder call indicator, as suggested for London, the interlacing difficulty should be eliminated to some extent, and it will not be surprising to find that a load of 600 calls will be looked upon as normal. The paper gives the impression that call-indicator working and the number of positions will be at a maximum at the outset. This of course is not so; it will increase considerably until a time arrives when roughly half the lines in the area are working on each system, after which it will begin to diminish. For an area we are at present investigating, the proportion between automatic and manual lines and the ratio of call-indicator working and of total exchange lines for three periods are as follows:—

* *Journal I.E.E.*, 1919, supp. to vol. 57, p. 158.

	Percentage of lines		Ratio	
	Auto	C.B.	C.I. working	Total exchange lines
At present ..	20	80	1·0	1·0
5 years hence ..	60	40	2·5	1·6
10 years hence ..	85	15	2·0	2·6

The well-defined maximum of auto-manual and manual-auto traffic means that at one stage it will be necessary to buy call-indicator and key-sending plant to take the peak traffic over the very short period, and it is under this condition that high loads on call-indicator and key-sending positions are desirable, as it is evident that it will pay to work at a maximum load, relieving the operators more frequently, for a small period in order to obviate the purchase of such expensive and short-lived apparatus. On page 622, annual savings of £14 000 in Sheffield and £7 000 in Newcastle are given. I should like to know if this is the average over the whole period or if it is the annual saving at the beginning or end of the design period, and also the number of lines involved.

[The author's reply to this discussion will be found on page 675.]

North-Western Centre, at Manchester, 17 March, 1925.

Mr. W. J. Medlyn: A few years ago the author visited the United States to investigate the telephone problems there and to consider the solutions applied; a considerable portion of the subsequent report naturally dealt with automatic telephony. The paper shows very clearly that the problem is full of complexities, as stressed by Mr. Herbert who has read the paper on behalf of the author, but no matter how complex the interior constructional design of the system may be, communication engineers, like electricity power supply engineers, aim to present the service which they purvey to the users, or consumers, in the simplest and handiest possible form for actual utilization. I suggest that the success of *any* system in common use depends on the fulfilment of this important condition. It is observed that the principles of economics are stressed throughout the paper; we appreciate that unless this important subject is continuously kept in view no commercial system can be successful. It would be useful to have some additional information in connection with the mechanical tandem exchange referred to on page 647. On reading the description one is left in a state of doubt as to whether during the transition period *all* the junction traffic between *all* the various exchanges in the London area will have to be circulated through the tandem exchange in the Holborn building, or whether this condition will apply only to the smaller groups of junction circuits. Had the former been intended the congestion of the junction cables would present a serious problem. The application of the automatic system to the telephone exchanges in the Manchester district affects us more directly than the introduction of the system in London. The same principles are, however, applicable in both cases, and plans for converting all the exchanges within a radius of 7 miles of the Manchester Town Hall are already well advanced. In Section (4) the author states that in areas of great telephone density it may be economical to establish two or more exchanges of 10 000 lines' capacity in one building. This condition applies to the city portion of Manchester. A site has already been acquired for the erection of a new building in Chapel-street, near to Exchange Station. This building will accommodate three 10 000-line units, i.e. three separate exchanges, and in the York-street premises similar capacity will be found for the conversion of the manual system to automatic. In addition to these six exchanges there will be 31 others within the 7-mile radius, making a total of 37, as compared with a total of about 74 within the 10-mile radius in the London area. The director system will be installed. The Stockport exchange, which is already automatic, will be modified to provide

equipment suitable for working into this system. The long-distance lines will continue to be terminated in the trunk exchange at the Head Post Office in Spring-gardens, but a " toll exchange " for intercommunication over the shorter lines connecting Manchester with the surrounding centres will be provided in the Chapel-street building. The telephone conditions in Manchester will therefore be identical with those which have been decided on for London as regards long-distance trunk exchange service, toll exchange service, and direct intercommunication between all subscribers connected with the various automatic exchanges in the local area. It is hoped that some of the new automatic exchanges will be brought into use in three or four years' time. The author mentions on page 644 that he estimates a period of about 15 to 20 years will be necessary to complete the conversion in London. Probably about the same period will be necessary to complete the work in the Manchester district. At the end of the paper the author touches on the question of the encouragement of home industries. It has recently been stated that the telephone industry in this country finds employment for upwards of 100 000 people, and it is gratifying to us to know that a goodly share of this activity is distributed among the business undertakings in the South Lancashire and neighbouring districts. Some of these undertakings supply apparatus equipment, cables, overhead wire, underground conduits, and storage batteries. It is satisfactory to know also that, in addition to catering for home supplies, these firms have been able to build up a considerable export trade.

Mr. H. H. Harrison: The " director," which is the outcome of the deliberations of many minds, has gone through a process of evolution. An early scheme embracing the use of switching selector repeaters operated as follows. If a letter, say M, was dialled, a group of trunks was seized going to all the exchanges whose first initial letter was M. As dialling proceeded, the junctions were discarded one by one until, finally, a free junction to the required exchange was the only one retained. This system had obvious drawbacks, the most serious being that a number of junctions were uselessly held until the third or discriminating letter was transmitted. The " universal switcher," as this arrangement was named, was quickly seen not to be the solution of the problem. The advantages of the " director " system appear to me to be as follows. The outstanding advantage is that the trunking scheme and the directory numbering are no longer interdependent. The director makes it possible to take advantage of the efficiency of large groups of trunks. That, of course, is due to the fact that one is able to extend the principle of tandem trunking. It is no longer necessary to provide, as formerly, for trunk groups from each exchange in an area to every other exchange in the same area. Tandem trunking can be carried out to an extent that would be impossible with a manually operated network. The " director " provides a simple means for re-routing calls when traffic conditions alter. This can be accomplished without changing the directory in the slightest degree. The only point of resemblance between the A B C dial sender shown in Fig. 27 and the calling dial which was used prior to the appearance of the Post Office standard dial, is the fact that it has radial finger-holds and is pulled round to a fixed stop. Beyond that all resemblance ceases. If the standard dial is examined it will be noted that in its operation two processes are necessary, a preliminary or setting process, and a subsequent transmitting cycle. The dial can be set at any speed within the operator's capabilities, but the dialled impulses are sent out at a regular rate. This last is secured by a small governor inside the dial mechanism. In the A B C sender, however, the setting and transmitting cycles overlap completely and if it is operated irregularly, which is almost certain to happen, wrong numbers will result. One other matter which deserves brief mention is referred to on pages 654 and 655. If a large area is divided into zones for tariff purposes the director possesses peculiar advantages. In a large exchange system without director facilities, the route is set up from exchange to exchange and differential metering is not easy to accomplish. With the director, however, the code dialled, and the digits into which it is translated, represent at the originating exchange that one and only one route is going to be taken; and a meter or meters can be operated in accordance with the route to be taken.

Mr. B. O. Anson: It is not unlikely that the first question to be asked by an inquiring mind would be: " Is a ' director ' really necessary ? " The reason for asking this question is that it would be quite possible to operate a telephone system with the dual purpose directory, enabling automatic subscribers to dial the code of the required exchange if the assumptions were made, (*a*) that every exchange had junction circuits to every other exchange, and (*b*) that the junction circuits were found on the banks of a train of switches corresponding to the numerical equivalent of the exchange code. These two assumptions immediately bring to light the important functions performed by the " director," for in the first place the provision of direct junctions from every exchange to every other exchange would preclude the adoption of tandem working, a most important aspect of automatic telephony. It would consequently commit the Administration to the provision of extremely inefficient junction networks often made up of very small groups of long circuits. To enable a subscriber to find junctions to the required exchange from the natural point on automatic exchange banks would mean that traffic would have to pass over six selectors, three for finding the junction and three for finding the required subscriber after the junction has been found. It will therefore be seen that the junction line would be sandwiched between two very expensive trains of switches, and the consequent design of such an exchange would be very costly. The importance of adopting a " director " is evident from the consideration of certain large metropolitan exchanges where as much as 75 per cent of the traffic may be to a very few neighbouring exchanges, say five or six, the remaining 25 per cent being spread over all the remaining exchanges in London. It is quite possible with the " director " system to hand over this 75 per cent direct to the junction lines by passing the traffic through only one rank of switches, namely the first code selector. As against that requirement we have, at

the other extreme, traffic that must pass through tandem exchanges because it is so small in volume. To permit of a wide range of conditions in this respect arrangements have been made for the "director" apparatus to send out as many as six trains of standard impulses. We therefore see that the three-letter code can be translated down to one train of impulses for very big blocks of traffic and translated up to five or six trains of impulses for very small blocks of traffic, and within these two extremes the practical problem is given its solution. In designing a manual exchange, attention has to be paid primarily to the operations performed by the telephonist, and for this reason the equipment is in the main based upon the busy-hour calling rate. With automatic plant, however, the designer must have regard to the average holding time of the call, as costly equipment is held engaged throughout the conversation. The speed and precision of an automatic telephone service are such that its superiority over manual service in large areas is undoubted and it is therefore reasonable to assume that, with a better service, subscribers will tend towards greater dispatch in their telephone service, and the telephone will play a greater part in their lives. This should mean that the average holding time for a call will fall, but, as the subscriber will not have less business to transact but in all probability more than in the past, the total calling rate should go up. It would follow, therefore, that the natural effect of good service should be shorter calls whilst producing more of them, and, as the plant is provided on the "holding time" basis and the revenue collected on the "calling rate," there should be a prospect of greater profit for a telephone administration under automatic than under manual conditions. Another factor that illustrates the advantage of automatic over manual service is the ratio of day traffic to "busy-hour" traffic. At a manual exchange a call must be operated whenever it occurs, and it costs more to operate a call during the night time and on Sundays than during the day time. With automatic equipment, however, it is necessary to provide plant to cope with the busy hour, but the equipment, once provided, is available to give service with equal efficiency day and night and there are no extra charges incidental to the night and Sunday calls, beyond the consumption of current. Whilst, therefore, the development of the telephone habit should produce a progressively greater proportion of traffic outside the busy hour, the automatic system will make that development more profitable than would the manual system. It is usual to assume that the automatic system would not have been adopted had it not "proved in" financially as compared with the manual system. The greater speed and accuracy of the automatic system, combined with the fact that the manual system rapidly deteriorates under heavy development because of the increased junction traffic incidental to development, makes the former so superior that its ultimate adoption can hardly be doubted, even had the annual costs been higher: subscribers would willingly have paid more for the better service.

Mr. J. Cowie: In the case of the common-battery manual system it is the operator who has to get the correct number, whilst with the automatic system it is the subscriber, and should a wrong number be obtained it is his own fault. I recently saw it stated that the advantages of the automatic system are: (1) Secrecy; (2) speed of call; and (3) instantaneous and automatic clearance of connections. These points will no doubt be clear after an examination of the demonstration set. In conclusion I should like to say that if the manufacturers in this country can deliver automatic telephone plant promptly when required, the Post Office Engineering Department has in its employment engineers, inspectors and skilled workmen who are willing and able to carry out the change from manual to automatic systems. They will do their work expeditiously, successfully, and with a minimum of inconvenience to the general public.

Mr. T. Cornfoot: I should like to say a few words from the subscribers' point of view. On page 617 in the introductory remarks the following statement is made: "In this economy of effort the subscriber has shared, and in modern 'manual' switching systems the only manipulative act required of him is that he should lift the telephone receiver from its rest before speaking, and replace it when he has finished." In the next paragraph the author says: "The adoption of the automatic system represents a reversal of this policy of economy of operation, so far as the subscriber is concerned, since it throws upon him the whole of the manipulation required to effect the ordinary local calls which generally constitute the bulk of his transactions." On page 622 the statement occurs: "Many authorities . . . argued that personal communication with the operator was necessary in order to reassure the public and to ensure proper use of the plant. To meet this frame of mind several systems known as 'semi-automatic' have been introduced." On page 621, however, the author, after reviewing the number of exchanges installed and the experience which the Post Office has had with them, says that it was also proved that the automatic method of working was generally acceptable to the British public. I read the other day that the conditions of the telephone industry are severe because all that the user can see of the complicated mechanism is a simple instrument, and while he is waiting for the operator seconds seem like hours and he becomes quickly irritated and forms wrong impressions as to what is happening, or rather what is not happening. It may be that the solution or cure for this is to allow the subscriber to manipulate his own call and to eliminate the operator altogether. Perhaps that is what the author refers to when he suggests that it has been proved that the automatic method of working is acceptable to the British public. If this is so, then the more completely automatic the system can be made and the larger the local fee areas the more satisfactory it will be. At the end of page 629 the author refers to a subject which has been widely discussed, viz. the method applied to the production of artificial traffic to calculate the total number of simultaneous calls at any one time during the busy hour. Telephone engineers seem here to have adopted a common-sense method of dealing with a very difficult problem.

Mr. G. H. A. Wildgoose: It is interesting to observe that after an extensive trial of automatic systems—there are eight systems mentioned in the paper—under actual working conditions, the Post Office has found no cause for regret. Again the statement, made by Mr. Cornfoot, that the British public has taken kindly to this method of working, is very encouraging. The experience in connection with the one public automatic exchange in Stockport supports this statement; the service was so acceptable to the public that the Post Office was compelled to make immediate provision for additional plant to meet the demand for subscribers' circuits. Previous speakers have alluded to the pending introduction of automatic working in the Manchester area. The preliminary arrangements in connection with this scheme have already given rise to several interesting problems. At the moment one such problem relates to the plant required to provide the necessary junction services, and it is assumed that the arrangements in general will follow those adopted for London. I think that has already been brought out clearly, but I should be glad of information on the following points: On page 623 it is stated that "junction circuits can be provided much more freely in an automatic system." On page 625 the author says: "The number of junctions required depends upon the traffic, which can be estimated from records of the traffic under existing conditions." It would be of some assistance to know whether, after determining the number of circuits which would be required on a manual basis, a multiplier is applied to ascertain the number which will be required under automatic conditions, and, if so, whether a different multiplier is used for various groups of junctions, toll circuits and trunks. Will the existing standards of transmission efficiency, so far as they are applied to the line portion of the circuits, be still maintained, or will they be modified in any way? On page 624 the author draws attention to the economy which will accrue from the introduction of the automatic system, and Mr. Anson has given very good reasons why the automatic system should be adopted, apart from the question of cost. It is interesting to note that the economy will be a progressive one, and it would appear that in about 20 years' time it will be somewhere in the neighbourhood of 30 per cent in favour of the automatic compared with the manual system.

[The author's reply to this discussion will be found on page 675.]

North-Eastern Centre, at Newcastle, 23 March, 1925.

Mr. J. R. M. Elliott: The first thought which occurred to me after reading the paper was the complete answer which it constituted, coming as it does from the head of a Government Department, to critics who have complained from time to time of the lethargy and apathy of the Post Office authorities in this country in recognizing the value of the automatic system of telephone working. The present paper alone, apart from the author's previous contributions to the literature of telephone practice, at once reveals him as the master mind behind the scenes in the complex problem of converting from manual to automatic the system of telephone working throughout the country. Of all the valuable information which the paper contains, not the least important in my opinion is that relating to the measure of standardization evolved by the Department, which makes it possible for each contractor to supply plant of his own type of mechanical construction. This will undoubtedly have the effect of promoting healthy competition, but one disadvantage associated with this arrangement will be that as the automatic system is extended, the mechanical portion of the equipment at exchanges will be of such a varied assortment as to make it difficult for maintenance workmen to become familiar with the details of each contractor's mechanism. This aspect of the matter will no doubt have been duly considered, but the author's views on the subject will be of interest. Much of the information contained in the paper is new to telephone engineers in the North of England, but we are not without practical knowledge of automatic equipment as we have experience of the working of the Western Electric rotary system at Darlington which was installed in 1914, and of the Strowger system at Marton near Middlesbrough. Then again we have three relay automatic private branch exchanges at works on Tyneside, and the results at all of these places have been eminently satisfactory. The author refers to substantial economies which are expected to result from the conversion of the plant in the Sheffield and Newcastle areas from manual to automatic. In this connection it may be of interest to know that it is intended to build in Newcastle three new exchanges, one in the centre of the City, one in the East end, and one in the West end, and this will involve the conversion to automatic of the exchanges at Gateshead, Gosforth, Benton, Wallsend, Dunston, Lemington, Blaydon, Hebburn and Whickham. Unfortunately, the site acquired for the central exchange, on which initial building operations were actually commenced some months ago, is required by the corporation in connection with a proposed new road, and it is probable that the difficulty which will arise in securing a new site will seriously delay the project as a whole. In addition to the provision intended for the Tyneside area, conversion from manual to automatic working has been decided upon at West Hartlepool, Hartlepool, Stockton and Middlesbrough. In bringing new automatic exchanges into operation in London, the author explains that the process is to be gradual, but in the cases of provincial areas of medium size involving a number of exchanges, in which Newcastle is included, the conversion is to be done simultaneously. In my opinion this is an unfortunate decision, as it will be many years in an area like Newcastle before equipment can be provided for all the exchanges concerned to permit of simultaneous conversion, and the public, who have for years been advocating automatics, will become more and more discontented with the magneto system, which they regard as being out of date. New Post Office buildings will shortly be opened at Gosforth and Gateshead and it was fully

expected that as a first instalment automatic exchanges would be provided in these two buildings. A simultaneous change-over from manual to automatic of a large number of exchanges in an area may be spectacular, but I am afraid that a considerable amount of initial confusion will be inevitable, as the method of calling will be new to subscribers and the exchange equipment will be new to the majority of our maintenance workmen. The matter is of such vital importance to those responsible for the conversion of an area, that I hope that the author may be able to give in explanation more information than is contained in the paper on the justification for simultaneous as against gradual conversion in an area in which several exchanges are to be treated. As the time approaches for the introduction of automatics at Newcastle, the need will arise for rearranging many of the telephone systems rented by the colliery companies in the counties of Northumberland and Durham. I may explain that in the early days of telephones in this part of the country, the keen competition which existed between the Post Office and the Telephone Company, coupled with the demands of colliery companies for intercommunication facilities between their offices, collieries, staiths, weigh cabins and other points, led to the establishment of a large number of complicated systems. The composition of many of the circuits on these systems is such that when they are extended to the trunk lines, and in some cases even the public exchange system, they constitute an inefficient link in the chain of communication in consequence of their transmission efficiency being inadequate for the purpose. Endless trouble from these sources is caused not only to the Department and the railway companies concerned, but to distant subscribers. The remedy is for these systems to have outlets to the various public exchanges serving the area in which these circuits are situated. This is a matter of considerable importance locally and it would be interesting to learn from the author the extent of the requirements of the proposed automatic exchanges so far as these colliery systems are at present constituted.

Mr. F. G. C. Baldwin: The paper indicates that during the past 15 years or so much valuable research and practical experiment in automatic working has been conducted by engineers of the Post Office in conjunction with engineers of manufacturers of telephone switching apparatus. The table on page 621 shows the steady development which has been going on in the installation of automatic exchanges. Expressing this development in another way, the approximate number of direct exchange lines connected to automatic exchanges was 14 000 in 1919, 16 500 in 1920, 17 600 in 1921, 17 700 in 1922, 19 000 in 1923, and 26 500 in 1924, while in 1925 the estimated number is 37 000. A result has been achieved which has never before been reached in the history of telephony in this country. I refer to the standardization of a system of telephone switching for the whole of the country, a feat which I think cannot be overestimated and which is bound to have far-reaching results in the future telephone service of this country. Standardization in telephony, through circumstances which there is no time to mention, has been but a dream of telephone engineers ever since the telephone was invented, but from what appears in the paper we now seem to be within measurable distance of obtaining it. In Fig. 4, 100 per cent of the number of subscribers are within a radius of 1 mile. I should like to know whether this needs some qualification, or whether it may be taken that the introduction of automatic switching has the economic effect of so placing the exchanges that the subscribers' lines are reduced in length to that figure. The paper deals specifically with large and densely telephoned areas, but in the table on page 621 three rural exchanges, which are of very small size, are included. I shall be glad if the author will say what prospect there is of the universal extension of automatic working in the country districts. One of the principal difficulties in connection with manually operated village exchanges is the question of operation and of night service as well as day service; there is also the question of accommodation. The introduction of automatic working would entirely eliminate the first-mentioned difficulty and give a night-and-day service equal to that of any other exchange. The principal difficulty met with in the provision of rural automatic exchanges is the supply of electrical energy, but perhaps the efforts of those engaged in the development of electric power supply in country districts may help in this direction.

Mr. C. Whillis: In connection with the system of grading described on page 628, is any attempt made to grade the subscribers in the groups of 75 on the basis of individual calling rates and thus further to equalize the traffic carried by the switching plant? It would appear that, apart from psychological difficulties, the director principle might be applied to the metering circuit in junction working to record the appropriate junction fee and thus obviate the intervention of an operator. If this could be done the amount of manual switching equipment in automatic exchanges could be very materially reduced.

[The author's reply to this discussion will be found on page 675.]

South Midland Centre, at Birmingham, 1 April, 1925.

Mr. G. Richardson: It is specially pleasing to learn from the paper that there has been such cordial co-operation between the Post Office experts and the experts of the large manufacturing companies in solving the many difficult problems that had to be considered. This close co-operation cannot be otherwise than beneficial to both sides in tackling the big task that lies ahead. I propose to give a brief outline of the scheme which the Post Office has in hand for installing the automatic system throughout the Birmingham telephone district, which includes the adjacent Black Country telephone areas. There will be four areas, namely, the Birmingham area, the Walsall area, the Wolverhampton area, and the Dudley area, each of

which will be unit-fee areas. When the conversion to automatic working has been completed, subscribers in each area will be able to obtain another subscriber in the same area by direct dialling over the automatic equipment. Calls to a subscriber in another area will require the assistance of an operator who will be placed at a manual board installed at the main exchange of each area. As regards the Birmingham area, which is, of course, the largest of the four, the first step to be taken will be the extension to practically double its present size of the existing large telephone building in Hill-street. This building work will be put in hand almost immediately. In the enlarged building will be installed two 10 000-line automatic exchanges, and to these exchanges will be transferred the present Midland manual subscribers and the present Central manual subscribers. These two exchanges will remain quite independent units, as they are at present. It should be noted that the present Central exchange building in Newhall-street will thus be made vacant. Further, as regards the Birmingham area, there will be five new automatic exchanges of a substantial capacity built in various parts of the city in positions which have already been determined by a close development study. These exchanges will not replace any of the existing exchanges, but will be additional. The positions of these additional exchanges may be roughly indicated by mentioning the following provisional names for them: Calthorpe, Bearwood, Harborne, Northfield and Aston. The building programme also includes fresh buildings for the existing exchanges, as in the majority of cases the present exchange premises are not suitable for the installation of automatic plant. I have already mentioned that the Newhall-street building, which contains the present Central manual exchange, will be vacated by the transfer of the Central subscribers to one of the 10 000-line automatic units to be installed in the enlarged Hill-street building. It is intended to utilize the Newhall-street building for the installation of a modern toll exchange, which will be readily accessible to all the subscribers in the four areas, and through which will be given a "no-delay" service to and from exchanges within a very wide area outside the Birmingham telephone district. Finally, the long-distance trunk service must be mentioned. In this connection it is intended to replace the existing trunk exchange at the Birmingham Head Post Office by a new exchange of the latest type, which will be operated in conjunction with the telephone repeater station. The repeater station has been in existence at Birmingham for some years, and at the present moment is being considerably extended. The proposals for the Black Country areas are also extensive. It is quite evident, I think, from what I have said about the proposals for the Birmingham area that the application of the system described in the paper means that we have a very busy time in front of us. The Post Office will need the co-operation of the building trades, and also the co-operation of the automatic equipment manufacturers, which, from past experience, I am sure we shall have in full measure.

Mr. W. C. Burbridge: Section (4) of the paper deals with the layout of the external line plant and exchange positions in an automatic telephone scheme and is of interest not only to telephone engineers but to all concerned with the best method of conveying electricity from source to consumer. It is obvious that large electric supply undertakings have to face problems which in broad principles are much the same as those concerned in telephone engineering, although they differ greatly in detail. The positions of generating and substations and the kind of main and distributive network must demand some kind of economic study, and I believe it is the practice to make calculations of some sort to determine the centre of gravity of an electric supply area. Is there, however, anything analogous to the detailed studies made by large telephone administrations? Does the electric supply undertaking have any method of forecasting the approximate number, class and location of potential users of electricity? Does it visualize the total or partial displacement of gas by electricity for lighting, heating and cooking, the places where, and the periods when, such conversion may be expected to accrue over a period of, say, 20 years? The Post Office does, of course, carry out very detailed studies of this kind. Such a study was made for Birmingham and the Black Country immediately before the war. It was overhauled in 1919 and used as the basis of the automatic schemes mentioned by Mr. Richardson. A general revision was made in 1923 and the forecasts are constantly being verified and amended. On page 624 it is stated that the costs of the line plant in London in 1945 under the automatic system would be nearly 30 per cent below those of a manual system. The amount of the saving is surprising, and I doubt if it could be paralleled in any city or district outside London. When it is borne in mind that the junction mileage under an automatic system is considerably greater than that under a manual system, it will be realized that the saving on subscribers' line mileage has to be enormous. That is, the area served by one automatic exchange must be very small compared with those served by one manual exchange. Now this means that there must be sufficiently large groups of subscribers on the boundaries of an existing exchange area out of which to form new areas. In other words, the telephone density on the fringe of existing areas must be great, approaching uniform density. Fig. 4 shows that such actually are the conditions in outer London, but it is far from being the case in Birmingham, or indeed, I think, in any large provincial city. Where there is not an approach to uniform density the approximations described in the paper are not likely to yield such a reasonable approach to accuracy as would enable sound conclusions to be formed, and other short-cuts have to be devised. I have referred to the increased mileage of junction lines in an automatic scheme. This is partly due to the multiplication of exchanges, but it is also a product of the routing of calls. Under the manual system, direct junctions between adjacent exchanges are the rule whenever the traffic is sufficient to justify it. As an illustration, Halesowen has direct junctions by the shortest route to Cradley Heath. Under the automatic system these places will be in separate automatic areas. Cradley will be in the rigid

numbering system of Dudley, Halesowen in the director system of Birmingham. Intercommunication by direct dialling between the two systems is not yet regarded as practicable; consequently Halesowen traffic to Cradley must circulate via the Birmingham manual exchange and the Dudley manual exchange. Notwithstanding this handicap, however, is it not the fact that an automatic system does effect direct economies in routing which go some may to balance this excess? Under the director system it should be possible to group the junctions from smaller outlying exchanges at some large exchange on the route nearer to the Central exchange. For example, the Victoria exchange in Birmingham is so situated with respect to two main cable routes that it could become the director exchange for six satellites, and so enable seven separate groups of junctions into Birmingham to be pooled into one group with an appreciable percentage of saving.

Mr. G. W. Billingham (*communicated*): With reference to the change-over from manual to automatic working in the Birmingham area, it may be of interest if I give a few facts relative to the external or line plant requirements. Unlike electric supply undertakings, the telephone requires a separate circuit to be provided for each line, irrespective of whether it is an exchange, extension or private line, and in order to provide continuous service during the preparation for the change-over dual lines must be provided, one line to the existing manual exchange and one to the new automatic exchange, which involves either entirely separate plant or lines in parallel. When such a conversion takes place in the same building, very little, if any, additional line plant is necessary. Where the exchange is situated in a new building near to the old exchange, additional line plant will be necessary, involving the laying of new ducts and cables, probably for a short distance only. The Central Birmingham case, however, presents difficulties of some magnitude from several points of view. From a scrutiny of the Birmingham maps it will be observed that the City is practically divided into two parts by New-street station and the railways running East and West. The telephone users on the North side considerably overbalance those on the South side. This is apparent from the fact that the Central exchange which serves the Northern portion has 6 000 direct exchange lines as against 3 000 on the Midland exchange serving the South side, the telephone dividing line between the two exchanges being New-street. In providing communication between the two exchanges and also cables for the subscribers' lines, there are four street routes available for our ducts and cable requirements, viz. No. (1)—route distance 770 yards; No. (2)—route distance 813 yards; No. (3)—route distance 1 130 yards; and No. (4)—route distance 1 220 yards. For economical and transmission reasons it is necessary that the route be kept as short as possible. Owing to the difficulties in obtaining a suitable site for a new exchange, it has been decided to house both Central and Midland exchanges in the existing Midland exchange, after considerable enlargement, and this building is situate in Hill-street. If it had been possible to utilize the Central exchange for the automatic requirements (for which, however, it is too small and impossible of enlargement), probably very little additional external line plant would have been necessary, but as in this case the greater load has to be added to the lesser a considerable augmentation of the existing ducts and cables between the two buildings will be necessary. It will be seen that this work will present considerable engineering difficulties when it is recognized that the roadway cover across the railway bridge in Hill-street is but 12 in. and this space is already occupied by Post Office plant, electric light, gas, water, and other public services. To lay additional ducts across this section on routes (1) or (2) at present appears impracticable unless arrangements can be made with the railway company to suspend a formation of steel pipes underneath the bridge from the girders, but it is at present doubtful if the clearance between the bridge and the rails will permit of this method being adopted. On route (4) the depth of cover across the Worcester-street bridge varies from 6 in. to 12 in., and last year it was found impossible to lay a further 6-way duct across, which necessitated a deviation via Bell-street to the Bull Ring. This route is too circuitous and costly to recommend its adoption for the extension of the lines from the central exchange to the new exchange at Hill-street. On No. (3) route the position is more favourable, as a tunnel only has to be negotiated on the top of which there is approximately 10 ft. of cover. The only difficulty likely to be encountered on this route is the congestion of service pipes at Broad-street corner, which may necessitate deep trenching and tunnelling to negotiate. Route No. (3) will probably be adopted although it will be necessary for distribution purposes to split the total number of ducts entering the automatic exchange building between the front entrance in Hill-street, and the back in John Bright-street. On completion of the duct lines the cabling work presents little difficulty. As previously mentioned, it is necessary during the progress of the work to provide continuous service, and the extension of the existing lines has to be carried out with extreme care and caution to avoid interruption of the service. The preliminary cable work will consist principally of teeing all circuits into the automatic exchange in order to test and prove out every circuit and to make a clean-cut change-over of probably 10 000 circuits by means of direct tee joints, or by transfer strips temporarily provided at three exchanges, viz. Central, Midland, and Automatic. The tee connections will be made at four principal points, viz. Broad-street corner, Temple-row, Worcester-street, and Midland exchange. Apart from the laying of the ducts and cables, considerable jointing work will be necessary and it is anticipated that about 24 jointers will be permanently employed on this work for at least six months. About half a million wire joints and tees are involved and each circuit will have to be identified and proved at each cutting-in point. The details of the work involve a considerable number of consecutive operations, each one depending upon the others being absolutely correct. These jointing operations are all set out on schedules and blue-print diagrams before the work is commenced.

The Author's Reply to the Discussions before The Institution and at Manchester, Newcastle and Birmingham.

Colonel T. F. Purves (*in reply*): I recognize that my paper contains a good deal of technically contentious matter, regarding which it is out of the question to expect universal agreement, and I appreciate the generally helpful and constructive character of the comments made upon it by so many speakers and contributors.

I agree with Mr. Laidlaw and Mr. Hollings that a considerable proportion of subscribers will probably not listen for the "dialling tone" before making a call, at least in cases where the tone is a subsequent addition to an automatic system with the operating of which they have already become familiar. But when the tone has been a feature of the system from their first acquaintance with it—and this will apply to the great bulk of British subscribers—I think it will be used much more systematically, even if in more then 95 per cent of the cases no trouble will arise from ignoring it. If a call has, for any reason, been ineffective, and the familiar ringing signal is not heard, subscribers will generally learn to listen for the dialling tone before making a second attempt. The tone is also very useful if it is desired to originate a call immediately after completing an incoming call from a private branch exchange, or from a manual or trunk exchange, as its presence is an indication that the connection has been cleared by the operator and that the line is again available. I may remark that the dialling tone is produced by the simple interruption of a battery circuit by an additional running commutator on the general tone-producing machine. There are no difficulties, and little expense, involved in its provision. Mr. Hall suggests that the tone should only be audible where a primary outlet to connecting plant is not available, but under these conditions its presence would be such a rarity that its meaning would probably be forgotten altogether or be confused with that of the "busy" signal. I think it is preferable to utilize the tone as a positive indication that the line switch has found an outlet and that calling conditions are normal. The fear that a subscriber whose line is faulty may assume that the absence of the tone indicates non-availability of outlets, and may therefore refrain from reporting the fault, has not much foundation; subscribers speedily become familiar with the many audible indications that a line is "alive," as compared with the "dead" condition of a faulty line.

Mr. Nash makes a kindly and generous reference to the amount of work and responsibility which has to be shouldered by the Post Office engineering staff in connection with such questions as the equipment of the London telephone system with automatic plant, and I greatly appreciate his expression of confidence in the success of the system which has been adopted. At the time when I had to take my courage in both hands and decide to turn away from the practice of the great American Bell telephone organization, for whose example we have so high a regard, I should have been very gratified indeed to know that, even before our first exchange had been installed, one of the leading engineers of the Western Electric Co. would so express himself. Mr. Nash presents an interesting table in which the number of secondary selecting switches, which would provide full trunking availability, is compared with the additional trunks required to furnish the same standard of service by means of 10-contact switch levels on a direct, graded, basis. I agree that a perfectly satisfactory circuit for secondary pre-selecting switches has not yet been forthcoming, although some telephone administrations appear to be prepared to adopt secondary switches to a considerable extent. Their use, of course, introduces additional switching points which undoubtedly complicate the tracing of calls and, to that extent, hamper the work of the maintenance staff. It is not easy to visualize the service-degrading factor introduced by outgoing secondaries, but it is obvious that without such devices the system is cleaner and easier to maintain. It is felt that the present system introduces quite enough complication and innovation for the maintenance staff to assimilate at the outset, but the Post Office has by no means "burned its boats" in this matter. The economies due to the utilization of large groups of selectable junction circuits, and the possibilities presented by the use of secondary switches as a means to that end, are fully appreciated. In the first automatic exchange installed in London, provision is being made for associating outgoing secondary switches with junctions to selected exchanges, so as to obtain actual working experience in the handling of junction groups up to a maximum of 100 lines. If satisfactory service is afforded by this method, there will be no hesitation to adopt it in cases where the overall annual charges will be sufficiently reduced by so doing, which are, of course, likely to be those cases in which the junction circuits are long and of heavy gauge.

[I have had Mr. Nash's calculation of the amount of plant required—with and without secondaries—to handle 35 traffic units carried a little further, and it may be of interest to give the results. The full debit of variables, to each system, would be as follows :—

Graded Scheme.	*Secondary Scheme.*
81 Junctions	114 Secondary switches
81 Incoming selectors	61 Junctions
	61 Incoming selectors.

On this basis the balance of annual charges is in favour of the graded scheme for junction circuits up to about 4 miles in length. For circuits over that length it would pay to employ secondaries. The average length of junction circuits in the London area is less than 4 miles, and the average length of junctions between the main exchanges is a much smaller figure, so that the economic balance is at present in favour of grading as a general policy. But in practice the use of secondary switches would probably be combined with the grading system, and consequently it might not be necessary to employ so many as 114 secondaries. The use of 25-point secondaries would also tend to reduce the

number of junctions and incoming selectors necessary, and, neglecting for the moment the various disadvantages of secondary switches, the economic balance might be so shifted that the use of secondaries would represent a saving where the length of the junction circuits is appreciably less than that quoted above. The number of junction circuits in the group also affects the comparison. It will be appreciated that the use of 20-contact selector banks would materially alter the basis of the calculation in a sense more favourable to grading. As already indicated, the whole question is being closely studied.]

Mr. Morley Ward inquires as to the reason for the adoption of the plan of sending dial impulses around the loop of a junction circuit, instead of over one conductor of the line or over both conductors in parallel. Mr. Christian also refers to the same point. This matter was given very close study, as it was fully realized that the adoption of loop-impulsing would mean a considerable reduction in the permissible maximum resistance of junction circuits, and that, with the impulse-receiving relays at present available, it would in some cases involve the use of heavier-gauge junction circuits than would have been necessary from the standpoint of speech-transmission efficiency. The main consideration in favour of loop-impulsing is, of course, that it provides security against the inductive interference of power and lighting circuits with the telephone signalling impulses. Tests were made from the Central exchange, to various points in London, by means of recording apparatus connected in earthed circuits. The records showed a certain amount of inductive interference, although surges of sufficient magnitude to affect dial signalling were so rare that it seemed improbable that they would in general affect the number of call failures to any recognizable degree. It was felt, however, that abnormal conditions due to faulty power circuits might sometimes cause more or less acute local trouble, and also that the general development of electrical supply systems, and of railway electrification in London and throughout the country during the next decade, might, in spite of the statutory safeguards of the Post Office against prejudicial interference with its communication services, have the effect of progressively worsening the conditions. It was therefore thought desirable to standardize, from the commencement, a system which would enable the department to demonstrate, in any case of trouble, that its own plant was so constructed as to secure the greatest possible immunity from outside electrical interference.

I am glad that Mr. Morley Ward mentioned the early pioneer work of Mr. William Aitken in connection with the invention of multi-choice grading: this might well have been referred to in the section of the paper dealing with that subject.

Mr. Carter and Mr. Harrison both refer to the ingenious pre-director development known as the "universal switcher." This system was the subject of interested attention by the Post Office, but we did not at any time feel inclined to adopt it. In addition to the wasteful use of junction plant, which both speakers mention, it required a completely predetermined numbering scheme, and therefore did not obviate some of the main difficulties involved in the introduction of an automatic scheme in large multi-office areas.

Mr. Deakin has given much information that is both interesting and valuable to a student of the subjects he refers to. I am not quite sure that, in his references to the method of grading illustrated in Fig. 12, he is not overlooking the fact that the advantage of grading from 24-point pre-selectors is not merely the 15 per cent increase obtained in the traffic-carrying capacity of the first code selectors. By suitable selection of subscribers' lines for connection in each group of 75, and by grading as indicated, the large block of traffic originated by 1 200 subscribers is turned over with approximate uniformity to the outgoing multipled circuits of the selector groups. It is thus presented to the succeeding graded ranks of switches in more manageable form, and the effect of this is to improve the carrying capacity of these subsequent switches, as well as that of the first code selectors. Special traffic curves making allowance for this fact are used in designing the layout of automatic exchanges. The maximum increase in traffic-carrying capacity that can be claimed for ordinary grading from 10-point selector banks throughout the switching system is about 30 per cent. It should be noted also that a graded system using 20-point selector banks has still to be studied, and that this may modify the economic comparison with outgoing secondary switches. A factor to be borne in mind is that the largest groups of junctions are required between large exchanges and that such exchanges, in London, are fairly close together. The circuits in these large groups of junctions thus tend to be both short and of light gauge, and their cost is correspondingly low. As regards tandem working, it should be remembered that the mechanical tandem exchange is being introduced to supersede the direct trunking of small groups of three or four lines. The change from these very inefficient groups to groups connected on a graded basis to 10-point contact banks represents a very material advance.

As regards the system of service to be adopted for communication between manual and automatic exchanges, it must be recognized that a system which may be specially adapted at the outset to requirements may be unsuitable at later stages. There is no question that the most convenient method of equipping the first group of automatic exchanges in London is the provision of "Cordless B" positions, but a time will no doubt come when it will be economical to install sending equipment at the "A" operators' positions in the remaining manual exchanges. A study of the comparative economics of dials and key-senders for this purpose has been scheduled for attention in due course. It may well be that considerations of space available in the different manual exchanges will dictate treatment of each on its individual merits. A powerful factor in favour of key-senders will always be the fact that the introduction of these high-efficiency devices reacts favourably on the load which can be carried by "A" operators, and has the effect of increasing the traffic-carrying capacity of manual exchanges and avoiding the extension of obsolescent plant.

I am rather surprised by the emphasis with which Mr. Deakin depreciates order-wire working in general, in spite of the fact that I have always had a decidedly soft side for the alternative of a properly developed direct trunking system. I can assure him that, although his remarks may be justified from the experience and practice of some administrations, they do not apply in this country, where the order-wire system has always proved reasonably satisfactory. The system has to be kept clean; split order wires and tandem order wires are things to be avoided, and perhaps these points have been ignored by those administrations in whose service he reports that the system has been "a dismal failure."

Mr. Grinsted has brought into prominence the very large number of separate switch movements, and circuit openings and closures, involved in the setting up of a connection in the automatic system. It would, indeed, be a hopeless mental task, even for the most expert automatic engineer, to visualize all that is taking place during the few seconds he is engaged in turning in a call on his telephone dial in a "director" area. The figures Mr. Grinsted produces show in a striking way the extreme need for the most efficient maintenance of exchange plant.

His suggestion that congestion at the switches might be minimized by some method of instantaneously throwing back, to the incoming line switch, false calls caused by permanent loops due to line faults, as well as "busy" calls blocked at any point by traffic congestion, is legitimate and the subject is well worthy of attention. It has, indeed, already been considered very carefully, but no way of effecting the desired result has yet been found without involving an additional circuit complication which has to be repeated so frequently throughout the exchange that it is not considered desirable to introduce it at present. The aggregate switch occupation caused by "busy" calls will probably not be great, as the subscriber will in most cases release the switches at once by restoring his receiver to the switch hook. False calls due to faulty lines can, with a proper system of alarms and guide lamps, speedily be traced back to the main distribution frame and there plugged out. The London exchanges are therefore being arranged to deal with abnormal loads of this kind by the ordinary supervisory methods of maintenance hitherto employed at all automatic exchanges.

Mr. Hollins has touched upon one of the disappointing features of automatic telephony, namely, its failure to provide economically for rural telephone service. Mr. Baldwin also referred to the same point. This subject is not altogether within the scope of the paper, but I may say that continuous attention is being paid by the Post Office engineering department to the special problems of rural automatic exchanges. Even at the smallest automatic exchange it is necessary to have a few costly fundamental items for the use of all the subscribers in common, and when the number of lines is small the cost per line of these general items is very high, especially if an electrical power supply is not available. It is then necessary to install an engine and secondary-cell-charging machine, with comparatively high capital and maintenance costs. These restrictions represent part of the price which this country has to pay for its low general development of the use of electrical energy. The extension of rural automatic exchanges will probably follow rapidly on the extended distribution of electrical power in rural communities.

I have already referred to Mr. Hollings's remarks on the subject of the dialling tone.

Mr. Hurford has taken rather too literally my round figures of the increase in trunk-hunting capacity secured by the use of secondary switches; I quite agree that 100 per cent efficiency could not be obtained in practice. Actually the efficiency of, say, a 10-point primary pre-selector, working into a 10-point secondary pre-selector, may be taken as approximately 85 per cent.

I am sorry if Section (5) of the paper is calculated to give the impression that designers of large-capacity switches are thought to have been working along the wrong lines. This inference was certainly not intended to be drawn in any general sense. Indeed, in Section (9) I say that the facility for direct selection in large groups is a feature of great utility which was reluctantly given up on account of its essential incompatability with the system which had been adopted for standardization in this country on broad considerations of preponderating advantage. My statement of the capacity of panel automatic exchanges in the service of the American Telephone and Telegraph Co. was based on a summary of the position, prepared in America, which I receive every six months. The latest summary referred to the beginning of this year and included 53 exchanges, with total equipment for 273 167 lines.

Mr. Hurford states that his much larger figures (58 exchanges with capacity for more than 400 000 lines) include extensions to the original equipment. It therefore seems probable that the summaries in my possession represent the line capacity of each exchange as it stood at the date of the "cut-over."

I quite agree that the amount of call indicator equipment in London will go on increasing for several years before it passes the maximum and begins to become surplus. Mr. Pook also makes a reference to this point. The amount of such equipment used in any particular manual exchange will, of course, steadily increase until the exchange is converted to automatic working, and therefore the last exchange to be converted will have the whole of its "B" positions equipped with call indicators. There is no intention that the initiation or the progress of the conversion of provincial city areas to the automatic system should be in any way dependent upon the rate of recovery of surplus call indicator apparatus in London.

Mr. T. B. Johnson gives figures which illustrate the exceedingly "peaky" traffic loads of the British telephone system. This condition, which I think is without parallel in any other administration, seems to imply that the effective business day in this country is an exceptionally short one. It has a very prejudicial effect upon telephone economics, and justifies careful study of the possibilities of improving the load curves by the skilful manipulation of varying tariffs. The advantages of the automatic system which Mr. Johnson enumerates are, of course, fully admitted and would be sufficient to turn the scale in its favour in many

cases where the manual system shows an economy from the strict financial standpoint of annual charges. The general conditions (given in the paper) which at present determine the use of manual or automatic plant are based entirely upon economic results. At the moment the demand for automatic plant is greater than the supply and, in order that the available product of manufacturers may be utilized to the best advantage, it is necessary to install a considerable amount of manual plant. The line is therefore drawn at a point which excludes from automatic treatment cases not financially advantageous, and as a rule these are also the cases where the service advantages of the automatic system over the manual system are at a minimum.

In reply to Mr. W. Johnston it may be said that the location of the calling subscriber's battery feed at the first code switch is a special arrangement made practicable by the traffic conditions usually found in "director" areas. The general location of the talking and signalling bridge on the outgoing repeater or final switch is a consequence of the adoption of loop signalling over junction circuits. The statement that a good grading scheme effects substantially the same economy as the use of secondary line switches, is intended to be an expression of the general economic position resulting from the adoption of grading as a policy. There may be points in an automatic exchange where the use of secondary switches would be more economical than grading, but, in general, the reason for not adopting the secondary switch is a service one rather than a financial one, particularly with reference to the use of such switches in external junction circuits. The reference in the paper was made with particular regard to the conditions of Fig. 12, which apply to 25-point pre-selectors, and it is certainly not economical to utilize 25-point secondary pre-selectors instead of grading.

Mr. Pook expresses a hope that the effective busy-hour load of call indicator operators will much exceed the 450 calls quoted in the paper, and it is quite reasonable to anticipate that this will prove to be the case. The load figure of 450 calls per busy hour was adopted for purposes of design in order that there should be no question as to the adequacy of the plant in the early stages of the change of system in London. The estimated annual savings of £14 000 at Sheffield and of £7 000 at Newcastle-on-Tyne consequent upon the introduction of the automatic system were calculated upon the estimated number of lines in all the exchanges in each area at the opening date, i.e. 8 800 lines in Sheffield and 10 000 lines in Newcastle.

Mr. Medlyn in the course of his valuable comments asks on what principle junction circuits will be worked through the mechanical tandem exchange. The intention is to serve the small manual exchanges, referred to in this section, almost entirely through the tandem exchange, unless, after their conversion to automatic, some other automatic switching centre should be more conveniently placed to serve them permanently. With the exception of a few direct circuits to exchanges in close proximity, all the incoming and outgoing junctions of these small exchanges will therefore be taken to the tandem exchange. The other exchanges in the area—both manual and automatic—will each be provided with a group of incoming and outgoing junctions to the tandem exchange sufficient to carry their traffic to and from the small exchanges. Some exchanges of medium size which are comparatively widely separated, and have a very small interchange of traffic one with another, will also obtain connection via the tandem exchange. As every manual exchange will have positions fitted with call indicators actuated from the cordless "B" boards at tandem, the existence of this exchange clearly provides facilities for concentrating general inter-exchange traffic on the tandem junctions during slack periods, and this facility will be utilized as a convenient method of enabling ordinary "B" positions to be closed at such times.

Mr. Harrison is not quite satisfied with my more or less whimsical claims for the old-fashioned telegraph ABC dial sender. It is true that in the modern automatic dial the operations of setting and of impulsing are separated, and that no dial could be generally used to operate an exchange system successfully unless the speed of impulsing were thus removed from the direct control of the individual who manipulates the dial. But this independent control of the impulsing speed is no part of the main claim of the original master patent, and the fact that the old telegraph dial would, if produced, have clearly anticipated the patent remains unshaken. Actually I have used this old dial quite successfully for making calls on a telephone automatic system, and I found it quite easy to ascertain and adhere to a sufficiently accurate speed of rotation.

Mr. Wildgoose inquires whether the number of junctions required under automatic conditions is derived by an agreed multiplier from the number previously in use in the manual system. In practice no such comparison is made. The number of junctions needed between each pair of exchanges in the automatic area is calculated directly from the traffic data, on the basis of one lost call in 500. The existing line transmission-standards are worked to without alteration when designing the layout of external plant in an automatic area.

Mr. Elliott expresses some apprehension lest the postponement of complete standardization of apparatus will lead to difficulties when maintenance men are transferred from one exchange to another. I do not think that appreciable trouble need be feared from this cause. The product of the various manufacturers differs only in self-contained detail, which will speedily become familiar to a man who is well acquainted with the standard electrical plan of the system. It is anticipated that it will be possible to arrange a satisfactory basis on which each contractor will provide for subsequent extensions to all exchanges which he has originally installed, as has hitherto been the rule with manual exchanges. The existence of diverse types of equipment at the same exchange will thus be avoided. Mr. Elliott also queries the wisdom of arranging for a simultaneous transfer from manual to automatic working at all the exchanges in an area of medium size such as Newcastle-on-Tyne. There is much to be said on both sides of this question. Simultaneous transfers involve a large amount of difficult co-ordinating work, but it has been concluded that as a rule the balance of advantage is decidedly in favour of this plan wherever

it can possibly be followed. A great amount of long-drawn-out temporary work and the provision of temporary auxiliary plant for interchanging automatic and manual traffic during the interim period is thus avoided. In the particular case of Newcastle the central automatic exchange, and the manual board for the whole area, will, on account of the building situation, mature at a later date than the other exchanges, and much wasteful provision of temporary equipment, which probably could not be justified financially, would be involved in an attempt to introduce automatic working at the smaller exchanges while the central exchange remained manual. But I shall have the case of Newcastle re-investigated before action is taken.

Mr. Baldwin has called attention to a point in connection with Fig. 4 which has not been clearly expressed in the paper. Subscribers outside a radius of one mile are excluded from the graph, the description of which ought to have been—" Number of subscribers within various radii, up to one mile, shown as a percentage of subscribers within 1 mile radius."

In reply to Mr. Whillis's inquiry regarding Fig. 12, it should be stated that the subscribers connected in each multipled group to the line switches are so selected, in accordance with their average calling rates, that each group will carry approximately the same amount of traffic. The grading arrangements on the outgoing link frame are made on the assumption that practical uniformity in this respect has been secured.

I have to acknowledge contributions to the discussion by Mr. Aitken, Mr. Collyer, Mr. Hedley, Mr. Petithory, Mr. Richardson, Mr. Anson, Mr. Burbridge, Mr. Billingham, Mr. Cowie and Mr. Cornfoot, which contain much information and much welcome and valuable constructive matter, but which do not appear to call for any specific reply.

DISCUSSION ON "SELECTION OF BALL AND ROLLER BEARINGS FOR ELECTRICAL MACHINES." *

NORTH MIDLAND CENTRE, AT LEEDS, 24 FEBRUARY, 1925.

Mr. H. Green: As manufacturers of rotating electrical machinery we find that ball and roller bearings give exceedingly little trouble. I do not think that we have had on something like 5 000 machines supplied within the past five years five cases of trouble due to ball bearings, and I feel confident that for small dynamos and motors ball and roller bearings are right. A number of breakdowns are due to the fact that many of the bearings fitted are too light, and although the author gives certain formulæ it is not usual for a designer—of small motors and dynamos, at any rate—to know the load which may be applied. If an ordinary ring-lubricated bearing is overloaded it becomes hot and calls for attention, whereas a ball bearing shows no sign of overloading until it is damaged. I have in mind a large double belt fitted from a motor to a line shaft. The belt was at least twice as strong as necessary, and the belt splicer naturally fitted it as tightly as possible, with the result that the bearing was fractured. It will therefore be seen that with ball and roller bearings it is necessary to have a big margin of safety.

Mr. F. Parkinson: Prof. Goodman's experiments have shown that theoretically a ball bearing is in effect a point contact incapable of lubrication. In practice it is found that a lubricant is useful for serving the dual purpose of providing a lubricant for the cage and also for preventing rust or acid attacking the case-hardened faces of the balls or ball races. There is much misconception on this question of lubrication of ball bearings. My own firm in their assembly of ball bearings make no provision for lubricators. This practice is based upon experience, as I believe that the experience of ball-bearing manufacturers is that more damage is done to bearings by the use of the wrong quality of grease than by omitting lubrication altogether. If a Stauffer grease cup or other means of filling the bearing housing with grease is provided, the tendency is for the attendant to supply new grease periodically whether it is required or not, and very often this grease is not entirely free from moisture or acidity. The lantern slides shown by the author raise another point in regard to this lubrication problem. They show elaborate arrangements for retaining the lubrication, but if our ideas are correct these elaborations are entirely unnecessary. We claim that the correct way to grease the bearing is to fill the housing with a grease of the correct kind for the purpose and then to seal the housing completely so that no grease can escape. To achieve this we have patented a special housing, and our experience, which covers more than 10 years, is that there is absolutely no necessity to replace this grease. Many instances have been brought to our notice where motors have been in constant operation day and night for more than 7 years without the bearings being touched in any way, and no new

* Paper by Mr. T. D. Trees (see vol. 62, p. 782).

lubrication has been supplied. If for any reason it is necessary to take the motor apart for general cleaning purposes, then obviously the proper thing to do is to wash out the bearings with paraffin, fill the housing with new grease and seal up. We claim that the sealed housing for bearings is an essential feature to ensure complete success. The second point that occurs to me is based upon an experience which dates back 15 or 20 years with a certain well-known make of motor. At that time it was the practice to fit ball bearings on turned motor shafts, and many cases of serious trouble occurred due to the shaft creeping inside the ball race. This wore down the shaft and allowed the rotor to foul the stator. A turned shaft when examined under the microscope will be found to consist of a number of ridges due to the cutting tool, and when a ball race is pressed on such a shaft the effect is to shear off the tops of the ridges. The consequence is that the area of contact between the inner race and the shaft is reduced very considerably. In designing our machines we benefited by the earlier experience of our competitors who had used turned shafts, and we formed the opinion that the correct application of ball and roller bearings to a motor shaft involves grinding the motor shaft to the same close limits as those to which the ball bearing itself is made. The results of the correct fitting of ball bearings and the correct housing of ball bearings are remarkable, as out of over 60 000 motors fitted with ball and roller bearings our experience is that not one machine in 10 000 has given any trouble due to the bearings.

Mr. H. Moss: I gather that in the author's opinion the bearings fitted in many machines to-day are inclined to be on the small side, or the light side, for the amount of work they have to do. If that is so, is that the cause of the ultimate failure of the machine? For a motor or dynamo manufacturer to fit a bearing that is smaller than it should be seems to be a foolish policy, because the cost of the bearing would be only a small percentage of that of the machine. Buyers and sellers of these machines would like to know that the manufacturer is putting in a bearing suitable for the work it has to do. Mr. Parkinson raised a point which seemed to be somewhat at variance with the paper. A large number of lantern slides have been shown illustrating different methods of lubrication, yet a user or manufacturer of long experience like Mr. Parkinson has supplied thousands of machines and does not find it necessary to provide any means to lubricate those machines. If it is not necessary to provide lubrication or any means of renewing it, why do manufacturers continue to make those provisions? It is adding to the initial cost and leaving openings for dust and dirt to get in by inserting a lubricant which may not be suitable. It would have been of interest if the author had touched upon the type of lubricant or grease that should be used for ball and roller bearings. As there seems to be such a difference of opinion between the manufacturers of bearings and the manufacturers of machines who must be using thousands of those bearings, it is difficult to determine whether the bearing manufacturer or the motor manufacturer is right.

Mr. R. J. Mitchell: The author would like to stereotype the question of the sizes of bearings for the rather vast range of electrical machines which the British electrical industry manufactures to-day, and doubtless that is a counsel of perfection, but it appears to be a fact that the modern engineer is so busy with his own job, and often so much obliged to become a specialist in two or three branches of knowledge, that he hesitates to add further branches to his list of specializations. The result is that in our opinion he acts very wisely when he consults the ball-bearing manufacturers and to a considerable extent follows their advice. He is perfectly safe in a commercial sense in so doing. The infinite care taken by manufacturers to do their utmost not to mislead the user on the choice of bearings cannot be too strongly insisted. It comes to this: If the growth of the industry is to continue in the satisfactory manner in which it is now developing, it will be far better for engineers generally to go to the bearing manufacturers and give them all the trouble—which they are very willing to take—of examining the proposed application, and in such cases giving the bearing manufacturers the fullest possible information about the mechanism into which it is proposed to install the bearings. The calculation of load capacity appears to be a subject of infinite difficulty. Palmgren wrote a most elaborate paper on the load capacity of ball bearings, at the end of which he came to the conclusion that the matter was too intricate to be the subject of exact mathematical analysis and determination. When one considers a series of steel spheres, and examines the relations of the compressed surfaces with semi-circular tracks and tries to form some clear and accurate mental picture of the phenomena incidental to the rotation of the outer race it is found impossible. I would suggest that it would be difficult to discover a more complex problem than that of a ball bearing under, say, an accelerated rotation under load. On the constructive side I put forward the suggestion that many manufacturers might help themselves greatly by presenting more accurate ideas about load capacity, for after all it *is* the load capacity for so many millions of revolutions at stated speed that counts in practical work. If we take a certain agreed standard bearing and make repeated tests of that bearing for a long period—I know that a good deal of such work has been done in this field and I suggest that it be persevered in—the results could be exchanged between one manufacturer and another, and even published in the ordinary engineering Press, so that one might by such means plot a few vital points on curves, connecting load with speed. After 20 such bearings had been tested a good idea would be obtained as to how to estimate load capacity sufficiently accurately for many commercial purposes at any practical speed required. The load tables published in makers' catalogues do not in any way overstate what the bearings listed will carry. The trouble is that in the majority of cases they understate. The author mentioned that with certain types of motor-generators he did not advocate more than one locating bearing. That is of course a point which we should fully endorse. Due to the fine clearances inherent in the ball bearings themselves it is very necessary indeed not to impose deliberately any deformations on bearing systems of more than a fraction of 1/10 000 in. at the most. This being

so when a locating ball bearing is used on a shaft, any other ball bearing on the same shaft should have a slight end-play. I feel that Mr. Parkinson has not completely stated the case when he says that he does not recommend lubrication. In fact, in his later remarks he implied that he did recommend lubrication, because evidently he is taking steps to ensure that the right lubricant is put in the bearing in the first instance and is kept there. That is what we want. In 99 per cent of the cases of returned bearings there are two reasons only why the bearings have failed. These are caused in both cases by ignorance and are (1) ill fitting by brutal methods, and (2) dirt. If one can ensure when a precision bearing is first mounted that the lubricant is clean, neutral, does not contain water, and is not subject to oxidation, and if one can further ensure that nothing gets into or escapes from the bearing housing, one can be sure that there will be no lubrication trouble with that bearing. Another speaker mentioned that he thought that a precision bearing would work quite well without lubrication. I have often heard that statement made, but many tests made in our test shops do not entirely confirm that claim. I think that a certain small amount of lubricant in roller or ball bearings performs a useful purpose. A considerable amount of rubbing takes place between ball or roller and cage, and the presence of lubricant is therefore undoubtedly helpful. When testing bearings it is sometimes found that after a certain time at a given load and speed the temperature will commence to rise, sometimes to such a point that the housing of the bearing cannot be handled. If the test be stopped at that point it will generally be found that the bearing is not damaged. Sometimes heating is attributed to the lubricant, which, having arrived at a certain temperature, begins to decompose chemically. By substituting a lubricant which is more suitable for higher temperatures we find that conditions of operation are possible which were previously believed to be impossible and which with the previous lubricant could not be maintained.

Mr. J. Speirs: Although I appreciate the work which Prof. Goodman has done, as a practical engineer I am not a convert to his suggested use of wood linings or linoleums. These may be very well in experimental work at a university but I am very doubtful if they would serve any useful purpose in general engineering, and linoleum would certainly add to the difficulty of keeping the bearings clean. One point about the load-carrying capacity that particularly interests me is the question of arriving at a formula that would enable the designer to fix the size. Such a formula would only be useful for electric machines for ordinary work and would not be reliable for all classes of motors. The nature of the load is the determining factor in load-carrying capacity and this is one of the difficulties in connection with published load tables. No published load table is of much use for any other purpose than the comparison between one size of bearing and another. While a formula that would allow a certain amount of liberty might be arrived at, I do not see the possibility for many years of this becoming a safe practice even in the electrical trade. Another feature in connection with the nature of load is the suitability of the bearing itself to resist the inaccuracy of the parts that surround it —this is very important. The firm with which I am connected—and this is borne out by my experience—came to the conclusion some years ago that there was only one bearing that was safe for ordinary standard motor work, and that had to be of the medium type. This is not because of its greater load-carrying capacity alone but because the heavier section of the race will resist to a greater extent than the light type of bearing the lack of inaccuracy in the housing. If a light type of bearing is put in a housing that is not perfectly round, the bearing will adopt the shape of its housing; this is almost bound to interfere with the life of the bearing and in some instances would produce trouble quickly. I think that Mr. Parkinson's remarks with regard to lubrication have been misunderstood. His point is that he makes no provision on his machine for the renewal of lubrication, which is entirely different from concluding that he runs the bearings dry. He means that he does not allow anyone to re-lubricate the bearings unnecessarily and, in all probability, with an entirely unsuitable lubricant. I think he has made quite a good point. I am not an advocate of running a bearing dry, as some lubrication is necessary in the interest of the cage. Bearings have been run dry, but it is not an advisable procedure. In connection with the lantern slides showing the application of various bearings to electric machines, one firm is dispensing with the use of the cage for heavy work, but experience does not show that this is perfectly sound. With regard to the question of general design, the first principle is simplicity and the absence of a multiplicity of parts and the consequent absence of errors. The future of the anti-friction bearing is undoubtedly assured and I am satisfied that this paper will do some good, but I hope that it does not immediately cause users of bearings to employ such a formula as the author suggests. To fit a roller bearing and a location bearing in the same housing at high speed is a dangerous practice and one that we have found to be unsound. High-speed bearings must be separated or else their lubrication will be difficult.

Mr. J. W. Adams: The author's remarks with regard to the selection of bearings by manufacturers as being irrational may be quite correct in principle, but in the present state of the art it is somewhat difficult, not to say impossible, for the user of the bearings to accumulate the amount of varied experience falling to the lot of the actual bearing makers. The performance of any good make of bearing and the information regarding such performance is naturally in the hands of the manufacturer, as it is hardly feasible for the user to go to the considerable expenditure of time and money in such a highly specialized branch of engineering. In my opinion the manufacturer is adopting the correct attitude, since his accumulated experience is placed freely at the disposal of the user. The author also states that he does not consider it sound engineering practice to use the maker's experience. From my own experience I would suggest that it is to be regretted that the user does not collaborate more closely with the manufacturer. Failures with both ball and roller bearings, whilst not being common when considering the great extent to which anti-friction bearings are now

used, could be considerably reduced if that collaboration were closer. Quite a number of failures are due to the wrong type of bearing being selected, and I am quite certain that many of the applications put into practice by machine manufacturers would be condemned were such applications submitted for the consideration of the bearing makers. It is, after all, quite a common thing for the wrong bearing to be selected and often incorrectly mounted. The author states that little or nothing has been published by the manufacturers of ball and roller bearings. I have made it a hobby to collect catalogues published by the various bearing makers, and I find that not only do they give interesting information but much of it is extremely useful. Referring to the question of load factor mentioned by the author, I should like to suggest that when dealing with direct-coupled motors the load factor has to be considered just as much as in a belt or chain drive. From a purely technical aspect one would merely consider the weight of the rotating mass. In practice, however, allowance must be made for any error in alignment of the equipment. It often occurs that excessive loads are imposed upon the bearings due to incorrect alignment. This trouble unfortunately happens under circumstances over which either the motor manufacturer or the maker of the bearings has no control, yet one of these is invariably blamed. The author also suggests a load factor of 4 for a belt-driven machine, but I think that it is now a generally accepted practice to estimate on a load factor of 5. He does not take into consideration the time element which, of course, is a very deciding factor in the ultimate life of the bearing. To illustrate the matter more clearly I would suggest a comparison, say, between motors for cranes which run intermittently, and a motor driving fans for the ventilation of mines, such a machine running 24 hours a day and 7 days a week for months on end. The life of the bearing depends entirely upon the fatigue of the material due to alternating stresses on the various elements. The author also gives a corresponding expression for rope drives as compared with belt-driven machines. The conditions, however, may often be more severe when dealing with a rope drive. I have now in mind particularly the textile industry. Consideration must be given to the effect of humidity, which will naturally cause the tension of the ropes to vary and consequently impose much greater loads upon the bearings. In connection with chain drives considerable allowance should be made for any overload due to stretching, resulting in links overriding the sprocket and imposing loads which are usually not allowed for in the original bearing selection. I was rather surprised to notice from a large number of lantern slides exhibited by the author that the position of the location bearing varies with different designers. In some cases the location bearing was mounted on the pinion or driving end, whilst in other cases it was mounted on the opposite end of the armature shaft. While I do not wish to suggest that it should be adopted as a standard practice, I think that the possibility of fitting the locating bearing on the driving end might be considered, as the bearing is partly located by reason of the greater radial load coming upon it, thus permitting the bearing remote from the driving end to move laterally due to any expansion or contraction of the shaft as a result of temperature variation. There must obviously be less radial load to overcome, thus allowing the bearing greater freedom to position itself correctly. The author also suggests that the selection of bearings might be in the hands of a standardization committee. While there is much to be said for this it is quite possible to carry the scheme too far as it tends to cramp design. I believe, however, that the British Electrical and Allied Manufacturers' Association are investigating the matter. If this is correct it is, I think, safe to suggest that the various bearing manufacturers will be given an opportunity of expressing their views. The reference made by the author and by several speakers in the discussion to the subject of care in the handling of bearings is very opportune. It is, I believe, now generally admitted that the makers of ball and roller bearings are working to a precision which can hardly be approximated to by those who ultimately have to mount their manufacture. It is, however, of the utmost importance to exercise every possible care when handling bearings during the process of building up the machine in which they are incorporated. I appreciate, of course, that the conditions obtaining in a workshop are totally different from those found in a laboratory or university, and after all it must be a commercial proposition. The greatest evil, in my opinion, is the utmost ignorance shown by those workpeople responsible for the actual fitting of bearings. I have seen bearings taken out of the greaseproof wrapping in which they are so carefully packed by the makers, laid on a dirty bench, possibly alongside of a vice and fitters in the process of mounting the bearing filing the armature shaft or housing, resulting in the bearing being filled with filings or other deleterious matter before it is actually put into commission. This is not uncommon, as I have found it repeatedly done in numerous workshops where ball and roller bearings are used.

Mr. R. M. Longman: A point not specially dealt with by the author is the question of lubrication, although many of the lantern slides show extraordinary precautions to prevent oil creeping along the shafts. In view of the extremely small amount of lubricant which ball bearings in particular require, the precautions shown seem to be unnecessary. It is of course essential that the right quality of grease or lubricant should be used. A case once came to my notice of a 250-kW rotary converter fitted with ball bearings; on one occasion when these were examined and cleaned a grease very similar in general appearance to the correct grease was by some mischance provided, but it had the unfortunate result of necessitating new bearings in a very short time. This sort of trouble had not occurred previously nor did it subsequently occur with the correct grease. Owing to the length of time which the correct grease will last it seems doubtful whether means for oiling should be provided, as too much oil is often as big a danger as too little, and the damage caused is generally less easy to detect. The value of the constants shown in the curves varies from 1 to 3 in different cases. It would be difficult to know what value actually to use. I agree with a previous speaker in regard to

selecting the larger bearing for the job, particularly as no heat indication of trouble occurs. It is of the utmost importance that after paying the extra price for such particularly high-class material every care should be taken in the handling and the subsequent treatment of the same, i.e. when installing and during subsequent examination.

Mr. J. G. Craven: My remarks will be from a dynamo and motor repairer's point of view. During the past six years we have had a large number of dynamos and motors sent in to us for repairs to the bearings, and I think I can safely say that 95 per cent of the faulty ball bearings were entirely due to faulty workmanship in fitting them. In some the shaft has been slack in the inner race, while in others the outer race has been slack in its housing. Probably 3 per cent of the failures are due to the use of unsuitable lubrication. I doubt very much whether 1 per cent are due to the choice of a wrong bearing. I think that in six years I can only bring to mind our having fitted two ball bearings with which there has been trouble after the machine has been repaired. In one case a manufacturer supplied us with a "tight" bearing, and I agree with the author that the bearings should be "slack" for electric motors. This case was taken up with the manufacturers, who admitted that a "tight" bearing had been supplied, because they had not the "slack" fitting in stock. It was replaced without charge. The customer did not at all appreciate the bearing running for only about six months, nor being asked to pay for taking the motor out, removing it to our works, the fitting of the new bearing—which was supplied free of charge—and the replacing of the machine in his factory. The result was that we made a concession, and carried out the work at net cost. The other instance was a pulley-end ball bearing of a 50-h.p. motor failing a few months after being renewed, due to a very badly designed belt drive, the motor being fitted with a pulley 12 in. dia. × 24 in. face, and only approximately a 6-in. shaft extension. The bending of the shaft, and the consequent strain on the ball bearing, undoubtedly caused the failure.

Prof. J. Goodman (*communicated*): The paper will, in my opinion, serve a very useful purpose in calling the attention of designers and users of ball and roller bearings to the necessity of collecting definite data on the behaviour of such bearings. Owing to the cost of ball and roller bearings the designer has to work with a much lower margin of safety than when using ordinary ring-lubricated bearings; consequently it is of considerable importance to him to know how to select the most economical bearing for his purpose. Unfortunately, however, few designers have sufficient experience or data with regard to ball and roller bearings to enable them to do so with any degree of certainty, hence they are obliged to avail themselves of the advice of manufacturers. The maker of the bearing cannot, however, possibly have the intimate knowledge of the exact conditions of working that the designer has, hence mistakes are liable to occur. To avoid such mistakes the author rightly urges designers to get data which will enable them to select their bearings from makers' lists. How are they to obtain this data? I would suggest that the Institution of Electrical Engineers should draw up suitable data forms with columns to be filled in, giving full particulars of bearings in use, together with the conditions under which they are running, and a final statement as to whether they are a success or otherwise. Such forms should be issued to designers, manufacturers, and users of ball and roller bearings, asking them for information. By this means much valuable data might be collected and afterwards tabulated, from which conclusions might be drawn. The tabulated report should be circulated amongst those who have contributed the information. In the course of a few years definite data would be available to all concerned. Ball and roller bearings have come to stay and the sooner we al know how to use them to the best advantage the better it will be for all parties concerned. The author points out that many failures of bearings are due to bad workmanship in fitting the bearings, rather than to defects in the bearings themselves. This is undoubtedly true. Even with highly skilled workmanship, failures occur due to the springing of frames, deflection of shafts and general lack of rigidity which cannot always be avoided. In view of this fruitful cause of failure I would urge that bearings should be housed with a yielding elastic backing, such as hard wood, fibre, linoleum or other suitable material around the outside of the outer ring of the bearing. Such materials allow a certain amount of "give" and act as a cushion and thereby reduce the ill-effects of vibration and shocks. I have made use of such devices in many cases with complete success, even where the manufacturers of the bearings prophesied failure. The author calls attention to the damage which may be done by shocks from improperly fitted spur gearing. I know of an instance in which some almost perfect spur gearing, ground to the nearest 1/10 000th in., was supplied by a firm of the highest standing for a very particular job, but in fixing the pinion on to the shaft it was badly damaged by rough workmanship. The foreman in charge was not much concerned and set a fitter to chip the teeth with a hammer and chisel and finish off with a file. Needless to say, the gearing and the roller bearing close at hand never worked satisfactorily. Of course the makers of the gearing and the bearing were blamed for the trouble. It does not follow that because the men who are engaged in making ball and roller bearings and who work to extraordinary degrees of accuracy are necessarily the best men to fit bearings on to shafts and into housings. The men who are accustomed to the special tools required for repetition work in making bearings are often very poor hands at doing jobs outside of their own special groove. The fitting of ball and roller bearings to their shafts and housings requires men who have had a special training in such work.

Mr. W. C. Massie (*communicated*): The author indicates that he considers it wrong for designers of electrical machinery to follow the lead of automobile designers, etc., and hand over their ball-bearing problems to specialists employed by the various manufacturers. I submit that the selection of a ball or roller bearing for a certain purpose in many cases calls for much specialized experience and is a problem very different from those which can be tackled out of hand by any engineer and, by reference to a handbook, by a mechanic. That

this is so is evidenced by the present paper which seems to contain little which cannot be found in most of the catalogues and handbooks issued by the various manufacturers. A careful study of these, together with some of the papers recently read before engineering bodies in Great Britain, will enable any engineer to select his own bearings. At the same time the judgment of a specialist based on extensive experience cannot be put into a catalogue or I can assure the author that the manufacturers would have found a way long ago. The formula given on page 784 (vol. 62) for the belt pull is very similar to but not so simple as the standard formula given in catalogues, viz.:

$$\text{Belt pull} = \frac{\text{horse-power} \times 33\,000 \times 5}{(\text{r.p.m.}) \times \pi \times \text{pulley diam. in feet}}$$

and I think that the factor 5 will be found safer than 4. The formula in this form shows that the load on the motor bearing can be varied by varying the size of pulley. This point has not been made in the paper. In the absence of information as to whether they are based on experience, calculation or estimation, Figs. 2 and 3 are of no value and it is difficult to see why an overload factor of 1·5 corresponds to an overload of 100 per cent and 1·2 to an overload of 40 per cent. I am entirely in agreement with the author that the disparity in the load figures given by various manufacturers for the same size and type of bearing is absurd. Differences in material and accuracy of manufacture may account for a small difference, but one is forced to the conclusion that some manufacturers use their load tables to advertise the superiority of their productions by suggestion. In the absence of a standard "life" basis for load figures it is certain that figures given by a manufacturer can only be used in accordance with his instructions. The question of "fatigue" and consequent "life" is being investigated very thoroughly and I do not think that it will be long before some of the manufacturers will publish "life" factors based on actual tests. Probably the late Mr. A. W. Macaulay's treatment of this part of the subject in his paper on "Endurance of Ball and Roller Bearings" read before the Institution of Automobile Engineers in 1923 is the most valuable contribution made to our knowledge of this branch of engineering for many years. On page 789 seven formulæ are given for determining the permissible combined radial and thrust load which can be taken by a radial bearing, but the author's suggestion that they are the varying views of different firms is absurd. Actually they are all correct when applied to the type of bearing to which they relate. The first is applicable to a deep-grooved single-row bearing without a filling slot, and a light type self-aligning spherical roller bearing. The fourth applies to a light type self-aligning ball bearing, and so on. The author persistently refers to self-aligning bearings without making it clear whether he means ball or roller bearings, and he nowhere mentions what is probably the best combination of bearing for heavy duty work in electrical machinery, viz. a double-row self-aligning spherical roller bearing at the located end of the shaft, and a short cylindrical roller bearing at the other end. There are few classes of engineering manufacturers who lay themselves out to supply technical information and advice as freely as ball-bearing firms, and their sole reason for wishing to have bearing problems referred to them is the desire that the bearings may be applied successfully. After all, their business depends on the successes gained. Again, it would be ridiculous for an electric motor maker to refer each motor order he received to his ball-bearing supplier, but it would be simple to plan a scheme with him so that he could tell at once if his standard bearing were capable of a given duty, or what heavier type he could fit in. There is much to commend outside technical advice when it is free and backed by guarantee. I cannot agree with the author that the importance of the use of ball and roller bearings in electrical machinery is exaggerated or that it is an open question whether it is worth while to embody them as a standard. Provided a suitable bearing is fitted it will waste less power, use less oil, last longer and will be less difficult and expensive to replace than the ring-oiled brass bearing and, last but not least, it will not "run hot." On the other hand, it may mean the making of new patterns, the calling-in of outside technical advice and the loss of revenue derived from replacement of worn-out bearings and shafts, and perhaps a little extra initial cost. The use of ball and roller bearings in motors and generators will be universal in the course of time and, I fear, before manufacturers have discovered a way to avoid the necessity of giving free technical advice.

Mr. T. D. Trees (*in reply*): I appreciate the interest shown in the paper and am pleased to note that the discussion has brought out several useful points. In some instances, however, the purpose of the paper appears to have been misunderstood. I have attempted to illustrate on suggestive lines the fact that, when selecting bearings, it is essential to make appropriate allowances for the type of drive under consideration, which is not perhaps as widely realized as it might be.

Mr. Green's remarks on excessive belt tension support my statements on page 784 and emphasize the fact that the blame does not always lie with "selection" but often with the man in the shop. However, although ring-lubricated bearings give some warning by running hot, it is probable that they suffer from as many breakdowns due to excessive belt tension as do ball bearings. I have, for example, known cases of fractured end brackets due to hot bearings of the ring-lubricated type.

Mr. Parkinson's views are very interesting, and there is much to be said for the practice of omitting lubricators or other means which make it so easy to insert any sort of oil or grease. If properly packed with the correct lubricant the motor may run without trouble for six months or longer without recharging. The lantern slides shown have simply been borrowed to give additional interest to the paper and are representative of the practice of various firms, although the designs are in some cases far too complicated in my own opinion.

In reply to Mr. Moss, it is not that I think the bearings are inclined to be on the light side generally, but rather that one may get let down in special cases, where, for instance, the bearing size is checked hurriedly or carelessly by simply taking catalogue load-tables and

applying them without any factors to suit the particular conditions. Reference to the bearing manufacturer will of course guard against such possibilities, but I suggest that the electrical manufacturer should put himself in a better position to make his own selection. With regard to the question as to the means provided for renewal of lubricant, the answer is that this is really a matter of opinion. Some firms make provision and some do not; the provision of lubricators is not so much a vital point as a selling point. No doubt the average buyer prefers to have lubricators.

Mr. Mitchell has dealt quite leniently with my paper, and I expected to have more questions to answer, since he is interested—like the two following speakers—in bearing manufacture. It is not my intention to stereotype the question of bearing sizes. He advises us, somewhat naturally, to consult the bearing maker on every occasion, and states that the calculation of load capacity is a matter of infinite difficulty. This is very true up to a certain point, and in saying this he is not unlike many of us who tell ourselves that our particular business is very complicated. However, the busy manufacturer cannot afford to let his affairs remain "very complicated," and I am confident that the up-to-date bearing maker has certain basic values for each bearing he makes, and when a customer consults him as to the size of bearing desirable for a certain duty he does not have to work from the fundamental with such complex mathematics as are implied. It is really a matter of sound business that he must have simplified methods of selection, with probably many charts, curves and load factors such as are suggested in the paper, which will enable his technical staff to give the necessary advice readily without undue time spent on each question. My proposals are that one can group the various types of loads into certain classes in order to form some opinion as to the requirements to be met, but the bearing manufacturer will no doubt have more groups than may serve our purpose. The scheme can easily be extended in many directions to suit one's individual needs. After saying that it is much better for engineers to consult the bearing manufacturers on every occasion, and after almost convincing us that we should not attempt to undertake the work of the specialist, Mr. Mitchell suggests that we can solve our own bearing problems by taking long test-runs on standard sizes. I am rather puzzled to know why he thinks that the motor maker should incur this trouble and expense and publish the results, when he would have us believe that we cannot solve such complex questions and that he has already this and much more information; yet he refrains from comment on the practical side of the paper.

Mr. Spiers voices the policy adopted by his firm in stating that published load-tables are of little value except for comparison; they prefer to be consulted by the user and therefore do not give load-tables except for the small sizes of bearings. He suggests that it is unwise to use the formulæ put forward, but I am sorry that he gives no other information in this respect. He appears to think that I would avoid collaboration, instead of which I suggest that it is not necessary to have such close collaboration as is essential when no load-tables or factors are published. It is not intended that the formulæ should be used without regard to the nature of the load, but with such a method of comparison the ordinary problems may be solved; when the question is of peculiar difficulty one should consult the manufacturer, but one does not want to be sending him inquiries every day. It is very interesting to hear that light-type bearings conform to the shape of the housing. Although I have thought that the races might offer some approach to the shape of inaccurate housings, I did not think that it was quite so rapid a process as Mr. Spiers tells us. In this connection it may be useful to remark that in cases where a split bearing-bracket is required, the practice I have generally recommended and used is to fit the ball or roller bearing in a separate solid housing in order to prevent the outer race being clamped injuriously when bolting the bracket together. When one is using large bearings of the heavy type this may be unnecessary if care is taken when machining the housing and assembling, but it is always safe practice. I agree with Mr. Spiers in his remarks on lubrication, in his reference to the omission of cages in certain heavy applications and the numerous parts shown in other applications, as illustrated in some of the lantern slides. It is also agreed that high-speed location and journal bearings should be separated.

Mr. Adams says that it is difficult for users to accumulate experience and he regrets that the user does not collaborate more closely. It is, however, not so difficult to accumulate experience. He wants to have every question raised with the bearing maker, but, as already pointed out, it is considered unnecessary to waste days in correspondence when one might settle most questions in an hour. I am afraid that he has read the paper hurriedly or he would have noticed that the questions of incorrect alignment and the life of the bearings are both dealt with. Further, he is quite in error in supposing that I favour the selection of bearings being in the hands of a Standardization Committee; it is definitely stated on page 790 that I consider this to be most undesirable. Also, he has misquoted me in another place "that it is unsound practice to use the maker's experience." My contention is that it is unsound practice to hand over the whole business of selection to the maker and be content to remain in ignorance as to whether the bearings are ample or not, without being able to check their capacity when required. With reference to catalogue collecting, this has also been a hobby of mine, and it is very easy to prove by reference to those issued up to the date of writing the paper that British makers publish little or nothing on allowances or "load factors." What information is given in this direction is Continental in origin and is not found except in the publications of those whose policy is the result of some control from the same source. It is agreed, however, that since they commenced business in this country the firm represented by Mr. Adams have published more data than is usual in British practice. He makes a useful point regarding the effect of humidity on rope drives; this should not be lost sight of, but I suggest that my load factor will allow for this in general cases. The chief difficulty may occur when an operator deliberately wets the ropes in order

to get a tighter drive, which is sometimes done. My own preference regarding location and thrust bearings is to mount them at the end remote from the drive in most horizontal machines; by so doing, the shaft between the drive and the actual rotor can be shorter and stiffer, and in the case where a journal bearing also serves as a locating bearing it seems better to put the additional thrust load on to the one carrying the lighter journal load.

In reply to Mr. Longman, the question of lubrication was considered to be outside the scope of the present paper. Much could be written on this side of the subject, but it is preferred not to go into the matter at the moment except to say that the grease or oil used should be chemically neutral. There are various products marketed for this special purpose. I do not understand his difficulty in regard to the constants varying in certain cases; it seems logical enough to me that they should so vary, according to the speed of the gearing and the materials used, for the reasons I have given in the paper.

Prof. Goodman has carried out a considerable amount of research work and is a recognized authority on ball and roller bearings, therefore his remarks are very interesting and much appreciated, but I must confess to serious misgivings as to the value of his suggested data forms. I feel that it is infinitely preferable to encourage the engineer to select for his own particular needs, with the assistance of the bearing maker if necessary, than to attempt what might be termed a national movement, which would be very slow in operation and unwieldy in its collected data because of the wide range of loads, types and sizes as mentioned in the paper. This idea would institute a basis of averages, rather than a basis of design values. If the average practice in the country is too good, good, or poor, then his collected data will be also too good, good, or poor, as the case may be; and who can determine the best practice for individual needs except by personal experience after all? With regard to his suggestion of elastic backings, I am, like Mr. Spiers, unconverted. In the laboratory such methods may be used, perhaps; but in practice, particularly in electrical machines, I am sure that they would be a fruitful source of trouble. It should be quite sufficient to imagine the result of fitting a yielding bearing housing in the case of motors with small air-gaps. If one is dealing with excessive vibratory or shock loads, then the better way is to interpose some flexibility between the drive and the bearing, and not between the bearing and the housing. Sometimes this can be done by introducing a flexible coupling, or by using non-metallic pinions; but, whatever else may be necessary, I do not agree that we should depart from the solid housing for electrical machines.

Much of Mr. Massie's criticism has already been replied to in the discussion. The curves are based on my own experience, and the apparent inconsistency of the factors for momentary overload in Fig. 3 is explained by the following: A bearing should be able to withstand a certain momentary overload and one need not fit a bearing capable of *continuously* dealing with this maximum momentary load. An electric motor is also capable of withstanding momentary overloads up to a certain value according to its design. If the estimated momentary bearing overload is small it is quite probable that the motor will respond to larger demands than that, should the drive require it; and, conversely, if the estimated bearing overload is large it is probable that the motor will not exceed this output. Hence it is that I use a smaller margin between the factor and the overload on the small values than on the higher momentary loads. I am sorry that I have not made it sufficiently clear that by self-aligning bearings is meant ball bearings. In the paper originally submitted the various types were explained, but this was omitted later. The self-aligning roller bearings to which Mr. Massie refers are of comparatively recent date and are not much required except for really large machines and heavy service. He may not agree that ring-lubricated versus ball and roller bearings is an open question, but it is a fact that several of the leading motor makers prefer to use ring-lubricated bearings, and others are sitting on the fence without conviction either way. The saving in power by the adoption of ball or roller bearings in electrical machines has little relative importance. The loss in bearing friction is very small compared with iron, copper and other losses, and even if one could have really frictionless bearings the motor would gain little in efficiency. Also, in starting up a motor the energy required after the first few revolutions will be practically the same for either type of bearing, because it is chiefly expended in accelerating the masses, and not so much in bearing friction.

In conclusion I should like to thank The Hoffmann Manufacturing Co., Ltd., The Skefko Ball Bearing Co., Ltd., Messrs. Ransome and Marles Bearing Co., Ltd., and Messrs. Rudge-Whitworth, Ltd., for the loan of samples and lantern slides, and for the attendance of their representatives whose contributions to the discussion are greatly appreciated.

DISCUSSION ON "IRON LOSSES IN D.C. MACHINES." *

SCOTTISH CENTRE, AT EDINBURGH, 10 MARCH, 1925.

Mr. W. B. Hird : Designers are always interested in any new investigations or methods of calculation which increase their scientific knowledge of what is actually going on in a machine and which improve the methods whereby they predetermine a machine's characteristics. There are doubtless many cases in which the use of elaborate formulæ and the application of all the refinements that fresh knowledge puts at their disposal are justified. It must nevertheless be conceded that for the ordinary everyday work of a design office the great desideratum is simple formulæ the application of which does not involve long and tedious calculations and which can be relied on to a fair degree of approximation, rather than a more elaborate method which strives for a quite unnecessary degree of accuracy. I therefore welcome the author's view that it is better to use a formula giving both the eddy-current and hysteresis losses than to use a separate formula for each, even though it is true that the single formula cannot be justified from theoretical considerations. The art of the designer consists in judging within what limits these approximate formulæ may be used and at what point more elaborate methods are necessary. As a matter of fact I have for many years used with satisfactory results a formula much on the lines of that given by the author, but with modified constants. The machines on which the author carried out his experiments were somewhat small. This is almost necessary in experimental work of this sort, because big machines are very seldom available. Consistency in the results obtained with four different machines is, however, to be expected when the machines are more or less similar in size and construction, and there may be danger in expecting the results thus obtained to hold true for machines of a totally different type or size. I do not agree with the author's explanation of what happens under the commutating poles. Since any interpole is of the same polarity as one or the other of the neighbouring main poles, it cannot be right to consider the losses as due to a double reversal (one under the interpole and one under the main pole), and at the most the losses due to the presence of the interpoles can only be due to a depression in the curve of field strength between the two poles of similar polarity —not to a total reversal such as the author claims. The formula generally used in textbooks gives 1·6 as the index for hysteresis and 2·0 for eddy currents. The values obtained by the author vary from 1·6 upwards for hysteresis and from 2·0 upwards for eddy currents, the maximum in each case being about 20 per cent in excess of these figures. That difference is no doubt important from the purely scientific point of view, but I do not think that it is very important in practice. An addition of even 10 per cent to the core losses of a dynamo—these core losses being only 20 per cent of the total losses to begin with—does not make any very considerable difference in the final results.

Mr. J. C. Macfarlane : I congratulate the author on his method of extending the proposals* made by Mr. Burge and myself in 1908 to cover load conditions. These proposals applied only to the line of similarly designed machines which we were discussing at that time. I agree that expressions of the type included in the present paper can be made to give sufficiently accurate estimates of the iron loss, even under load conditions, in machines of similar design and construction, but I cannot agree that either the constant or frequency index proposed by the author can be of universal application. Both values depend on such variables as (*a*) the ratio (air-gap length)/(slot-opening), (*b*) the construction and shape of the pole-shoes, and (*c*) the air-gap density. By paying careful attention to these variables, machines have been constructed (with lohys iron stampings 0·018 in. thick in the armature core) having measured light-load iron losses less than two-thirds of those calculated with the author's constants, and for the machines in question the frequency index is not greater than 1·37. The iron loss actually taking place in, or due to, the pole-shoes is, even in modern machines, a considerable part of the whole. The total light-load iron loss can easily be increased by 20 per cent by boring out the pole-shoes alone, particularly if the air-gap still remains small, and an increase of 50 per cent is not unusual if the armature core surface is machined. The paper will be very useful to designers, and expressions of the type with suitable constants can easily be obtained for the designs of machines in which they are interested.

Dr. S. Parker Smith : While some of the facts in the paper are not new to designers, it is a great advantage to have the question of high losses in the iron emphasized as much as possible and also to insist that a great part of this loss is avoidable. Taking the figures on page 48, for example, it is seen that the actual loss was found to be four times the loss given by the makers. Fig. 17 might well be used by some makers, who take no care to reduce iron losses. From time to time during the past 20 or 30 years attention has been drawn to the excessive iron losses in all classes of electrical machinery. Even when due allowance has been made for all unavoidable additional loss in the end plates and other constructional parts of the armature and for all additional losses due to rotating hysteresis, the fact remains that in very many machines at present built the iron loss is at least twice as great as it need be. The causes of this avoidable additional loss are mainly bad workshop methods, such as punching the slots with badly set or blunt dies, filing and drifting the slots after the

* Paper by Mr. E. Hughes (see page 35).

* *Journal I.E.E.*, 1909, vol. 42, p. 232.

core, has been assembled, carelessness or neglect in removing the bad edges from the stampings. Not only in small machines such as those with which the author deals, but also in transformers and turbo-alternators, the iron losses may well be halved by careful workmanship and constructional methods. Mention might be made also of the eddy-current losses which may occur in the armature copper, even when the machine is unloaded. The author is to be thanked for again drawing attention to this important matter and it is to be hoped that his paper will induce some firms to pay more heed to the careful construction of their cores. The repairer also is often to blame in this connection because of his readiness to use the file and drift when replacing coils.

Dr. A. E. Clayton (*communicated*) : The predetermination of the value of the iron losses is naturally a matter of considerable importance to designers of electrical machinery. As stated by the author, the problem is complicated with toothed armatures owing to the fact that the magnetization is neither purely alternating nor purely rotating. It is further complicated owing to the effect of filing, etc., in the slots upon the insulation resistance between core plates; in addition there may be appreciable losses in the core end-plates and in the pole-shoes. It is well realized that the losses occurring with such machines are very much greater than those in the case of transformers working under similar conditions, so far as maximum flux density and frequency are concerned, but the exact reasons for the great discrepancy are not in every case fully appreciated. So far as the teeth are concerned, the magnetization may, for all practical purposes, be taken to be purely alternating. But—and this is most important—the flux does not change according to a sine law, following instead the wave-shape represented by the flux-distribution curve. This has a most marked effect upon the value of the eddy-current losses. Moreover, as regards the teeth, any burring over of the plates, due to filing, will have a pronounced effect. As regards the core, both the intensity and direction of magnetization change, and the effect set up may be called elliptical rotating magnetization. The actual shape of the air-gap flux distribution curve will have but a minor effect upon the core losses, and, in addition, filing out the slots will only slightly influence the value of the eddy-current losses. It follows, then, that to calculate separately the iron losses in the teeth and in the core, formulæ should be used in which the loss constant used for the teeth differs from that used for the core. Since the conditions of magnetization are so widely different, a single value for the constant cannot be expected to give correctly both the tooth loss and the core loss. However, in practice, where the machines all have much the same proportions, the aggregate losses as deduced from a single formula of the type given on page 47 are generally sufficiently near to the test figure. But when such a formula is applied to abnormal machines, such as those in which the core is either abnormally shallow or abnormally deep, the results obtained are very often unsatisfactory. In calculating iron losses in rotating machinery, then, in my opinion, it is desirable to adopt a value for the loss constant for the teeth different from that used for the core. The need for doing this was made very apparent to me some considerable time ago when investigating the discrepancy that existed between the calculated and measured iron losses on a large number of turbo-alternators. I found that whereas the measured losses for 2-pole machines were invariably much less than the calculated figure, those for 4-pole machines were greater than calculated. The ratio (tooth volume/core volume) being much smaller for the 2-pole than for the 4-pole machines, indicated the probability that the tooth losses were under-estimated and the core losses over-estimated. It was then not a difficult matter to determine, for the teeth and core respectively, values for the core-loss constants which gave in all cases a reasonable agreement between calculated and measured figures. On page 45 the author discusses the effect of the wave-shape of the flux-distribution curve upon the eddy losses in the teeth. It appears to me that the value of the eddy losses in the teeth is completely determined by considering solely the manner in which the flux changes in them. When a coil is moved past the pole of a magnet the effect is to cause a change in the flux linked with the coil, this change corresponding exactly to the net rate at which the coil-sides cut through the magnetic field. The E.M.F. established may be regarded as being due either to the coil-sides cutting through the field or to the rate of change in the flux linked with the coil. In every case the rate at which the flux changes in a circuit—quite independent of the manner in which the change is brought about—determines entirely the value of the E.M.F. induced. It does not appear, therefore, that the losses given in Equation (1) will occur in addition to those corresponding to Equation (2). The wave-shape of the flux-distribution curve has undoubtedly an important bearing upon the magnitude of the eddy-current losses in the teeth. Moreover, contrary to the view that appears to be very generally held, the maximum value of the flux density is by no means the all-important criterion, but it is of the utmost importance that the flux shall not change too rapidly. When the flux linked with a circuit changes by an amount Φ, the quantity of electricity which will circulate in the circuit is Φ/r, a value quite independent of the time taken for the change in the flux. The E.M.F. developed is, however, determined by the rate at which the flux changes. The energy produced is determined by the product of the mean E.M.F. developed and the total quantity of electricity circulated, and thus increases in proportion to the rate at which the flux changes. Applied to the case of eddy currents in the teeth, it may then be taken that the quantity of electricity circulated in the eddies is determined directly by the maximum flux density, but that the energy developed is determined by the product of the quantity of electricity circulated and the rate at which the flux changes. It is then the shape of the flux-distribution curve at the pole fringe that is of major importance. This may be illustrated for the case of the two simple rectilinear flux-distribution curves indicated in Figs. A and B, the maximum flux density being the same for the two cases. Fig. A roughly corresponds to the case of an unsaturated

turbo-alternator, and Fig. B is a very rough approximation to the case of a d.c. machine. For a very narrow tooth, the time taken for the flux to change from maximum to zero will correspond to the motion of the armature through 33·3 per cent of the pole-pitch for case A and only 7·5 per cent for case B. The eddy losses for case B are therefore relatively 33·3/7·5 (= 4·4) times as great as for case A. This simple calculation, whilst not taking account of all the factors, is sufficiently exact to illustrate the great importance of the actual flux-distribution curve, and the desirability of employing pole-shoes of a suitable shape.

Mr. E. Hughes (*in reply*): It is not stated in the paper that the commutating poles give rise to a double reversal of the flux as suggested by Mr. Hird. The depression in the flux curve between two poles of the same polarity is, however, so great that the flux density in a tooth midway between two such poles is very low.* It has to be borne in mind that the commutating pole is always adjacent to the weakened tip of the main pole of the same polarity; and the depression in the flux wave is thereby accentuated.

Whatever the relationship of the iron losses to the total losses, there is no question about their importance in determining the temperature-rise of the armature; and every endeavour should be made to reduce them as much as is practicable. It is therefore interesting to learn that Mr. Macfarlane has been able to effect a reduction of about 30 per cent by careful attention to various factors.

It will be readily granted that constants determined from comparatively small machines may not be universally applicable; but the main purpose of the paper has been to deal with methods rather than with numerical constants. The suggestion of Dr. Clayton concerning the separation of the tooth and core losses is a partial solution of the problem—but it is far from being a complete one. There is first the difficulty of separating these losses, and then there is the difficulty of determining the flux distribution in the core—a distribution that depends upon the pole-pitch, core depth, flux density, etc. Such a method would result in arbitrary constants which would not be of universal application.

In his discussion of the eddy losses in Figs. A and B, Dr. Clayton has overlooked the difference between the eddies in the teeth due to rotation and those due to transformer action. He states that when a coil is rotated through a magnetic field "the E.M.F. established may be regarded as being due either to the coil-sides cutting through the field, or to the rate of change in the flux linked with the coil." The first method was used in deriving Equation (1) on page 45 of the paper, whilst Dr. Clayton in proceeding to demonstrate the application of the second method has discussed an entirely different loss. If a loop be rotated in the magnetic fields represented by Figs. A and B respectively, the change of flux linkages per cm of axial length during the sixth of a cycle taken by a coil-side to move

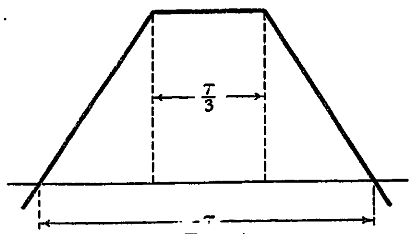

FIG. A.

from position of zero field to that of maximum density, say B, in Fig. A is $\frac{1}{3}B\tau$. If f be the frequency, the corresponding rate of change of flux linkages is $\frac{1}{3}B\tau \div (1/6f)$, i.e. $2B\tau f$. Hence the energy lost during this interval is proportional to $2B\tau f \times \frac{1}{3}B\tau$. For Fig. B, the corresponding change of flux linkages is $B \times 0 \cdot 075\tau$ in $0 \cdot 0375/f$ seconds, so that the rate of change of flux linkages is again $2B\tau f$; and the energy lost is proportional to $2B\tau f \times 0 \cdot 075B\tau$. Consequently

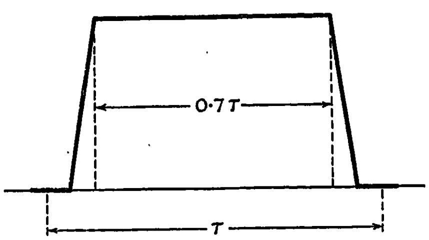

FIG. B.

the ratio of the eddy losses of Figs. A and B during the interval taken by a coil-side to pass from zero to maximum field strength is $0 \cdot 667/0 \cdot 15$, i.e. 4·45. On the other hand, when the eddy currents due to transformer action in the teeth are considered—the paths of these currents being at right angles to those of the eddies set up by rotation—the value of 1/4·4 derived by Dr. Clayton is obtained for the ratio of these eddy losses for Figs. A and B. These results show that it is essential to consider quite separately the eddy losses due to rotation and to transformer action; and this is the purpose of Equations (1) and (2) on page 45 of the paper.

DISCUSSION ON "THE USE OF SINGLE-CORE LEAD-COVERED AND ARMOURED CABLES FOR ALTERNATING CURRENTS." *

Mr. B. S. Hornby (*communicated*): I have read with interest the results of the tests described in the paper by Messrs. Harvey and Busby (see pages 368–378) and also the conclusions reached by Prof. Cramp (pages 379–383). The losses predicted in the case of extra-high-tension cables by Prof. Cramp are lower than one would anticipate, and I suggest that they should be confirmed by similar tests made on long lengths of cable laid underground. These tests could be carried out by bunching the three cores of existing

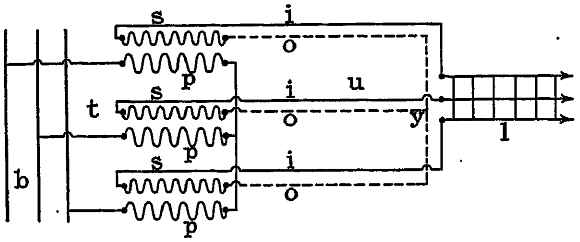

FIG. A.

e.h.t. duplicate mains, and, as the results would be of considerable practical value, no doubt a supply undertaking would allow their mains to be used for such tests at times of light load, when they could temporarily dispense with such mains. Similar tests made on cables protected by double steel-tape armour would also be of interest. I have also considered the problem of transmitting three-phase current through separate cables for each phase, but have worked on it in another direction, namely, by the use of a lightly-insulated

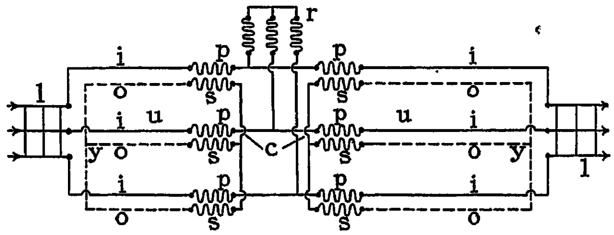

FIG. B.

outer concentric conductor arranged to carry a current equal to but opposite in direction to that in the main inner conductor. This arrangement eliminates all hysteresis and eddy-current losses in the armour and sheath, but doubles the copper loss. This loss is, however, of no serious consequence when the power is transmitted the greater part of the distance by overhead wires. The equalizing current is obtained by (1) moving the star-points at the transmitting and receiving ends to the cable ends, and (2) the use of current transformers on intermediate lengths of underground cable as shown in Figs. A and B, in which "i" and "o" indicate the inner and outer conductors of the concentric cables "u"; "p" and "s" the primary and secondary windings of the step-up or step-down transformers "t" or current transformers "c"; "l" the overhead lines; "y" the star-points; and "b" the busbars at the transmitting station.

* Paper by Prof. W. Cramp (see page 379).

Mr. D. M. Simons (*communicated*): I have been interested in the two recent cable papers by Prof. Cramp, the first by him and Miss Calderwood on single-core lead-covered cables, and the present paper covering in addition the effects of armour. Prof. Cramp's work should be of great interest to all cable engineers, and I think that his calculations of the open-circuit loss in the sheaths of cables and his work on armoured cables should be of particular importance. When the former paper first appeared, I noted that the author's formula for the simplest case of all, the case of short-circuited sheaths, to which he undoubtedly gave less consideration than to the other more difficult cases, was not in agreement with the work of other investigators. Considering the case of a single-phase circuit of two parallel single-core lead-covered cables, the distance between whose axes is D and the mean radius of whose sheaths is r, Prof. Cramp takes $K = r/D$. His formulæ contain the term $\log[(1 - K)/K]$, while, using the same symbols, most other writers have a term $\log(1/K)$. The difference between the two terms is fundamentally a difference in limits of integration; Prof. Cramp integrates the flux out of the sheath of the distant cable, while the more usual method is to integrate to its centre or axis. I myself believe that the integration should probably be carried to the axis of the second cable, as is done in the calculation of the inductance of parallel wires, for reasons so clearly stated by Nesbit.* In particular, Fisher,† Atkinson,‡ Clark and Shanklin,§ Capdeville,|| Sacchetto,¶ and Melsom and Beer ** all agree in effect upon the use of the term $\log(1/K)$. I rather hesitate to raise the question, in view of my appreciation of the value of these two papers, but the matter is one of practical importance, since the difference between the two formulæ is by no means negligible. Dwight,†† in his article on this subject, in which he developed practically a rigid formula for the sheath-circuit eddy loss which takes into consideration the proximity effect and holds even if the sheaths are tangent, mentions the earlier paper by Prof. Cramp and Miss Calderwood and calculates that the sheath loss is 37 per cent of the conductor loss instead of the 16 per cent given by them in one of the tables, the entire

†† *Electric Journal*, 1924, vol. 21, p. 62.

difference being in the logarithmic term. When, however, the same term was included in the present paper also, it seemed to me that the point should be settled one way or the other in the interest of all cable engineers. In view of the general agreement on one form of equation and, in particular, of Dwight's direct statement in regard to this term, I should like to ask Prof. Cramp his reason for using his form of the logarithmic term, or if there is any way of reconciling the two points of view. All the various formulæ should undoubtedly give approximately the same numerical answer, in order that the calculated value of induced sheath loss may not be a variable depending upon which particular formula is used.

Prof. W. Cramp (*in reply*): I do not think that there is any reason to suppose that long lengths of cable laid underground would give results substantially different from those upon which my analysis has been based. Everything depends, of course, upon the dimensions of the cable and the armouring, and if I could find a municipality willing to place some long lengths at my disposal, as suggested by Mr. Hornby, I should certainly be willing to take a confirmatory test. The difficulties, however, are considerable. The distribution of the magnetic field about three cores in parallel is not the same as about one central core, and the losses will certainly be greater in the former case. It is also difficult to get underground cables upon whose spacing and straightness reliability can be placed. Tests on double steel-tape armour are not, in my opinion, of much value, as such cables are generally avoided. Mr. Hornby's system of avoiding losses by moving the star-point of the system is very interesting, but, I think, would only be adopted for comparatively short lengths; indeed, the object of his device seems to be to connect short breaks in long overhead lines. For considerable distances the extra expense of the sheath copper, and the extra loss entailed, render the use of his system doubtful.

I fully expected that the question raised by Mr. Simons would occur in connection with the term $\log[(1 - K)/K]$, and it was with this expectation that I carefully guarded myself by inserting the last paragraph on page 481 of Volume 61 of the *Journal*. The difference between the above expression and the usual term $\log(1/K)$ is, as Mr. Simons points out, introduced by the limits of integration. Now there is no doubt that where the circuit consists of a pair of small parallel cylinders the limits adopted by the writers quoted by Mr. Simons are correct, but where these cylinders are enclosed in other conducting cylinders, of much larger diameter and forming no part of the original circuit, the case is, I think, quite different. For, under the former conditions, any magnetizing force arising from cylinder A and passing beyond the centre of cylinder B is exactly counteracted by an equal force due to cylinder B. This is the fundamental reason underlying the limits usually adopted, which are commonly used for the inductance of a pair of parallel wires. We are not here concerned, however, with the inductance of the original cores, but only with the induced currents in the sheaths that surround them, which are themselves low-resistance conductors. It is clear, therefore, that while there will be between the sheaths an uninterrupted path for the magnetic flux, the mere presence of a portion of either sheath will tend to deflect or damp out any alternating flux beyond this region by reason of the eddy currents induced in the portion of the sheath that intercepts the flux. The effect, then, of the presence of the sheath will be to increase the density between the sheaths slightly, and to reduce very effectually any magnetic flux that would otherwise exist between the sheath and the core of the conductor B due to the current in conductor A. I hope that this will explain to Mr. Simons why I have adopted the limits which he questions, and also why I inserted the paragraph on page 481 referred to above.

CHARTS FOR REGULATION OF TRANSFORMERS.*

By ARTHUR A. BOELSTERLI, Associate Member.

(*Paper first received 20th October, 1924, and in final form 31st January, 1925.*)

SUMMARY.

To ascertain the regulation—an essential characteristic of a transformer—when the ohmic and reactive drops respectively are given involves a good deal of calculation.

In the first part of the paper, charts are presented, from which the results can easily be read.

In the seond part a simple "chord diagram" is developed, which is well suited for approximate estimates.

Both methods are based upon the formula recommended by the American Institute of Electrical Engineers and permit a clear visualization of the relations implied.

1. REGULATION CHART.

In clause 6053 of the "Standards of the American Institute of Electrical Engineers" the regulation of a constant-potential transformer is defined as the difference between the no-load and rated-load values of the secondary terminal voltage at the specified power factor, such difference being expressed as a percentage of the rated-load secondary voltage.

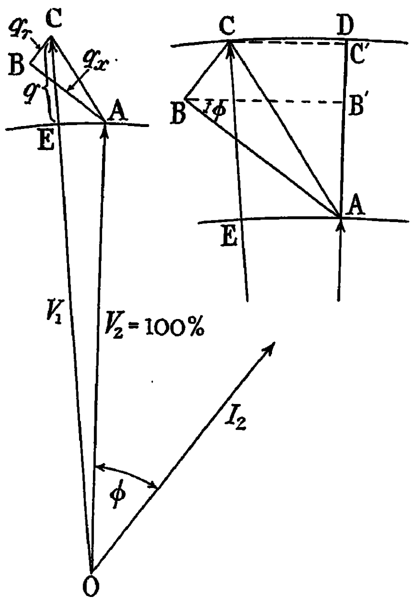

FIG. 1.

Fig. 1 represents the vector diagram, under load conditions, with the ohmic and reactive drops not separated into primary and secondary portions, but considered as total drops for the transformer. In making the vector of the secondary terminal voltage equal to 100 units of length, regulation as defined above is directly represented in the diagram. Although this paper specifically deals with transformers, attention is called to the fact that in the above form the diagram of vectors is identical with the diagram of a transmission line when electrostatic capacity is neglected and assuming concentrated resistance and inductance. Hence the methods developed below are equally applicable to a transmission line.

Reverting to the case of the transformer, it is assumed that either by tests or by computation from design data the ohmic and reactive drops are available. Thus the task is confined to the determination of the regulation from the configuration of vectors as shown in Fig. 1.

Regulation figures are usually required for several power factors. Various methods have in the course of time been developed for readily obtaining these figures. Among the graphical solutions the diagram of Kapp is well known. The Mershon diagram, which is merely an ingenious generalization of the diagram shown in Fig. 1, although applied almost exclusively to transmission lines, lends itself to the case of the transformer. Both methods mentioned, however, possess, owing to the relative smallness of the voltage-drops, the disadvantage of requiring to be drawn to a large scale in order to obtain results of acceptable accuracy. Analysis of the vector diagram, on the other hand, yields varied expressions for the determination of regulation. In its specific recommendation the American Institute has been fortunate in selecting a formula of excellent practical value (see clause 6391 of the Standards). It is this formula which is here made the basis of a novel graphical representation on the alignment principle. The charts developed afford a means of rapidly ascertaining regulation and it is hoped will be found useful, especially for routine work.

A second graphical solution of the formula will subsequently be shown in the shape of a simple circle diagram, which is thus well suited to the needs of those who but occasionally encounter the problem.

Let q_r = percentage ohmic drop;
q_x = percentage reactive drop;
$m = \cos\phi$ = power factor;
$n = \sin\phi$ = reactive factor;
q' = percentage regulation, uncorrected;
q = percentage regulation, corrected.

The formula referred to can be written as follows:

$$q = q' + \delta \quad . \quad . \quad . \quad . \quad (1)$$

where
$$q' = mq_r + nq_x \quad . \quad . \quad . \quad (2)$$

and
$$\delta = \frac{(mq_x - nq_r)^2}{200} \quad . \quad . \quad . \quad (3)$$

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

The quantity denoted by Equation (2) is evidently represented by AD in Fig. 2 and thus constitutes a first approximation. δ is a correction term, which, added to q', marks a near approach towards the true value. In Fig. 2, δ is represented by AD. Equation (3) is easily derived from the diagram with the aid of an expansion, omitting terms of higher order. The accuracy attained is such as to bring the theoretical error within the limits of the errors of measurements.*

Equations (2) and (3) contain the same four variables (m and n obviously count only as one, as they are merely the cosine and sine of the same quantity). Owing to their construction both formulæ lend themselves to development into alignment charts. Equation (2) is developed in Fig. 3. Here all the divisions on vertical lines are uniform. This makes the plotting of the chart extremely simple. The procedure on an empirical basis can be summarized as follows: Lay off arbitrarily two uniformly graduated scales for q_r and q_x; calculate from Equation (2) for each power factor to be represented in the chart two or (better) three pairs of values of q_r and q_x corresponding to one and the same value of q.

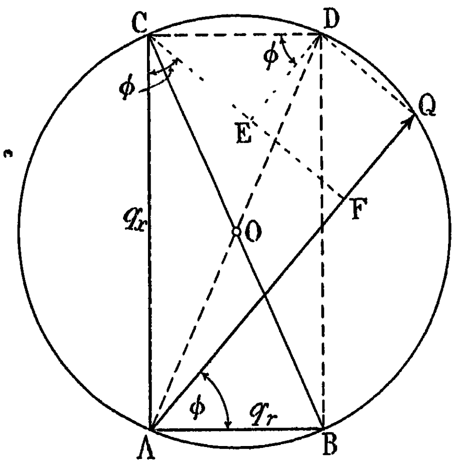

FIG. 2.

The straight lines joining corresponding values of q_r and q_x then intersect in points through which the respective power-factor lines can be drawn parallel to the q_r and q_x scales. Moreover, the unit of gradation is for any power-factor line the $1/q$th part of the distance of the aforementioned point of intersection from the zero point on that power-factor line. The zero points are all on the line joining the zero points of the q_r and q_x axes. By connecting the points on the scales that correspond to equal values of q the curves of constant regulation are obtained.

Fig. 4 represents Equation (3). The vertical gradations are here far from uniform and are obtained by methods for which the reader must be referred to textbooks on Nomography.

It will be noted that both Figs. 3 and 4 are arranged for lagging power factor only, in accordance with Equations (2) and (3), which hold good for lagging power factor only. The range of this formula can, however, be extended to cover the case of leading power factor by attributing in this case the negative sign to the reactive factor, and changing the signs accordingly. Similar charts to those presented could be drawn for the new conditions.

* See P. G. AGNEW and F. B. SILSBEE: "Accuracy of the Formulas for the Ratio, Regulation and Phase Angle of Transformers." Scientific Papers, Bureau of Standards, S. 211.

The use of the charts shown in Figs. 3 and 4 is best understood from a few typical examples.

Example 1.—For a transformer of 3 600 kVA the copper losses are given as 32 400 watts and the reactance as 8·5 per cent; it is required to determine the regulation figures for power factors of 1·0, 0·9, 0·8, and 0·7.

The ohmic drop q_r is in general obtained by dividing the copper losses in watts by 10 times the kVA output. In the above case this results in $q_r = 0\cdot90$ per cent. q_x is directly given as 8·5 per cent. Marking these values on the respective scales in Fig. 3 and laying a straight-edge across, we read the following figures for the regulation, representing a first approximation:

Power factor ..	1·0	0·9	0·8	0·7
Regulation.. ..	0·90 %	4·50 %	5·80 %	6·70 %

From Fig. 4 we read by the same procedure:

Correction	0·36 %	0·27 %	0·20 %	0·15 %

The correction always being directly additive, we obtain by addition the exact figures for regulation as follows:

Power factor ..	1·0	0·9	0·8	0·7
Regulation.. ..	1·25 %	4·75 %	6·0 %	6·85 %

The figures are rounded off to one-twentieth of 1 per cent, which corresponds approximately to the accuracy the charts afford.

Example 2.—From measurements on a transformer in operation the following figures on regulation are known:

Regulation at 0·85 power factor .. .. 4·5 %
,, at 75 % load and 0·70 power factor 4·1 %

What are the percentage copper losses and the reactance of the transformer?

This is the converse of the problem in Example (1). It is first necessary to refer the second regulation figure to full load, assuming proportionality between load and regulation. We thus obtain the regulation at 0·70 power factor to be 5·5 per cent. Plotting now in the regulation chart the two points corresponding to the two pairs of values of power factor and regulation, and laying a straight-edge through them, we read on the q_r and q_x axes:

$$q_r = 1\cdot26; \quad q_x = 6\cdot5.$$

q_r is approximately equal to the percentage copper loss; q_x is the reactance in the first approximation. It is now possible to obtain from the chart correction terms corresponding to the regulation figures given. Deducting these and using the corrected values again in the regulation chart we obtain figures of greater accuracy. For $q_r = 1\cdot26$ and $q_x = 6\cdot5$ we read the corrections:—

Power factor	0·85	0·70
Correction	0·12 %	0·07 %
The latter figures deducted from ..	4·5 %	5·5 %
Give	4·28 %	5·43 %

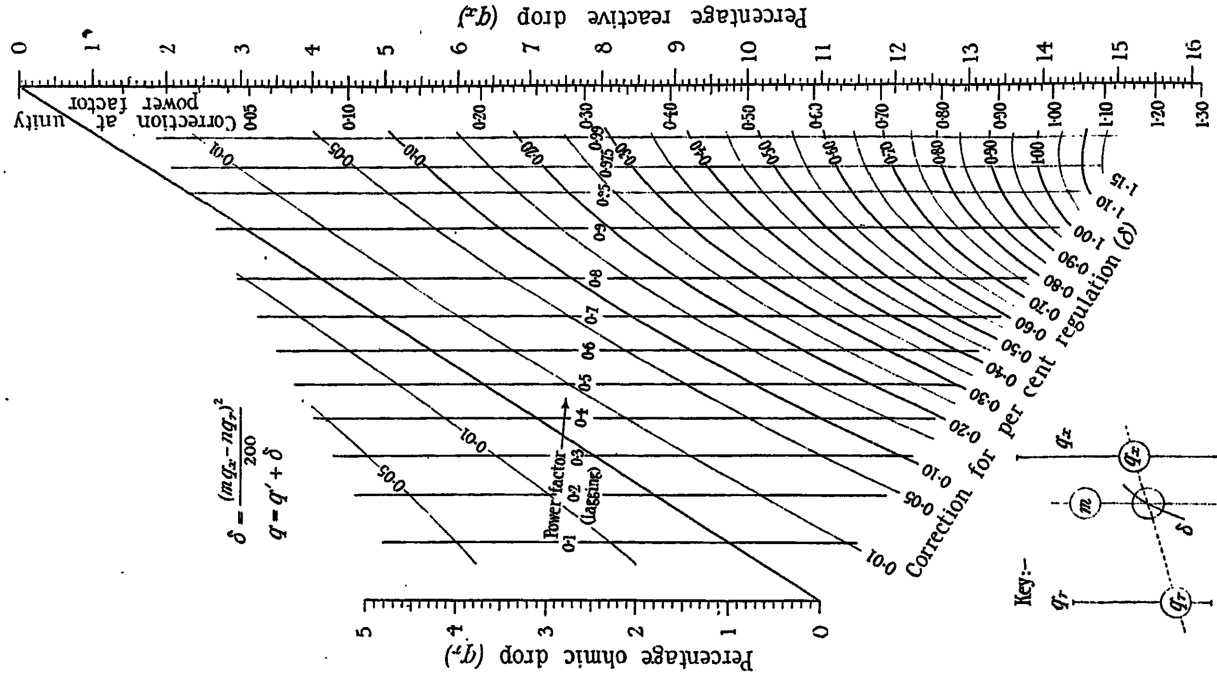

FIG. 4.—Chart for determination of correction term.

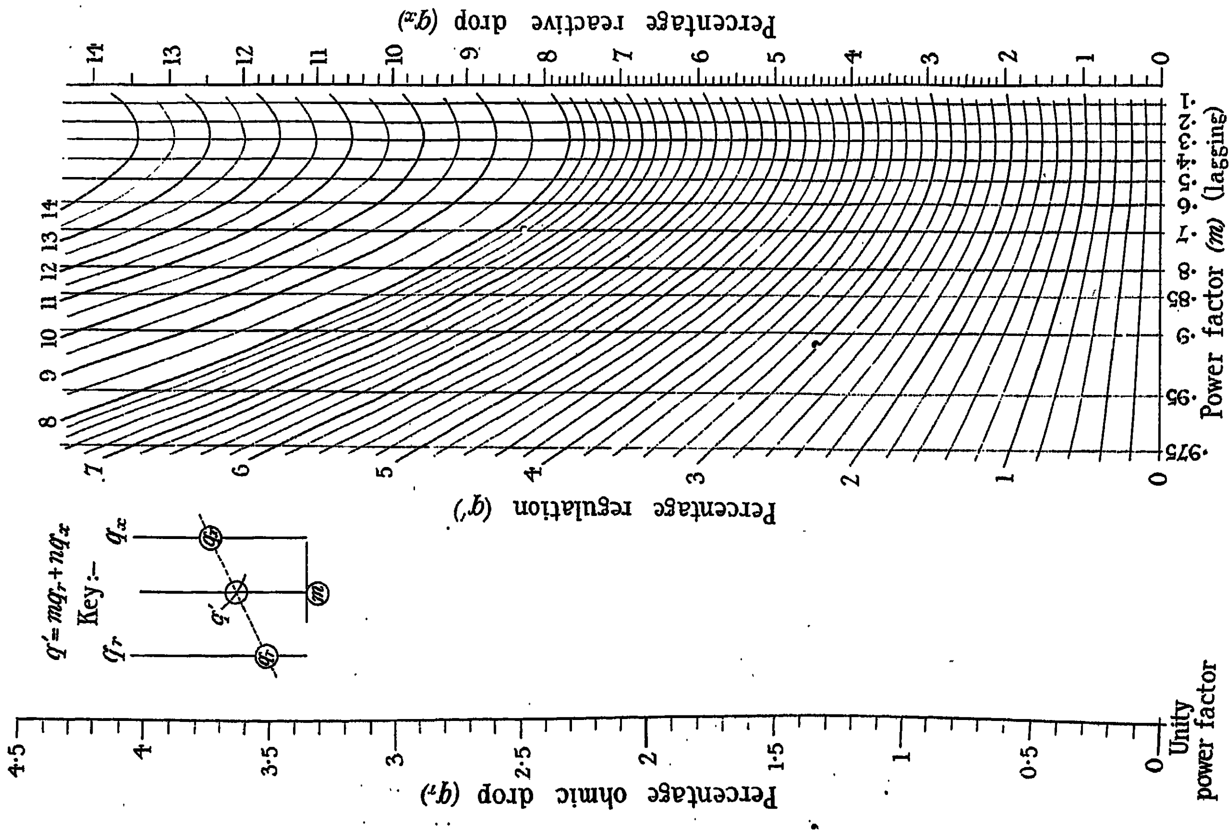

FIG. 3.—Alignment chart for determination of regulation of transformers.

Using these last values in Fig. 4 we find

$$q_r = 0{\cdot}83\ \%\,; \quad q_x = 6{\cdot}8\ \%$$

where q_r is the percentage copper loss, and q_x the reactance.

It will be seen that, in general, for comparatively low reactance the correction can be neglected without affecting the result beyond the limits of error commonly tolerated in calculations of this kind.

Example 3.—Regulation figures are required for a transmission line for which the ohmic drop and the reactance have been found to be 4·5 and 8 per cent respectively. The power factors are 1·0; 0·95; 0·9; 0·85; 0·8 and 0·7.

With $q_r = 4{\cdot}5$ per cent and $q_x = 8$ per cent we read from Fig. 3:

Power factor					
1·0	0·95	0·9	0·85	0·8	0·7
Regulation (approx.)					
4·5 %	6·75 %	7·5 %	8·0 %	8·4 %	8·8 %

From Fig. 4 we obtain the following corrections (rounded off):—

0·3 % 0·2 % 0·1 % 0·1 % 0·05 % 0·05 %

Adding these to the values above, the following figures result:—

Regulation (corrected)					
4·8 %	6·95 %	7·6 %	8·1 %	8·5 %	8·8 %

To make Fig. 3, which is primarily designed to cope with the case of the transformer, generally suitable for the case of the transmission line the range of both the q_r and q_x scales would have to be extended.

Depending on the user's ability to interpolate, the accuracy of the corrected readings is from 1/10 to 1/20 per cent. This compares well with commercial tolerances, which are not infrequently claimed to be as high as ± 20 per cent of the values put forward.

2. The Chord Diagram of Regulation.

In conclusion, mention should be made of a circle diagram that picturizes in a most simple and practical manner the relation as condensed in the American Institute formula, in any specific case of q_r and q_x. It has long been known, though rarely mentioned in textbooks, that in making q_r and q_x the sides of a right-angled triangle through the corners of which a circumscribed circle is drawn, the regulation as defined by Equation (2) is represented by the chord that is drawn through the vertex at an angle ϕ to q_r, where the power factor = cos ϕ. This is shown in Fig. 2, which serves to verify the relation:—

$$q' = AQ = AF + FQ$$
$$AF = q_x \sin\phi$$
$$FQ = ED = CD\cos\phi = AB\cos\phi = q_r\cos\phi$$

Thus $$q' = q_r\cos\phi + q_x\sin\phi$$

or $$q' = mq_r + nq_x \quad \text{(Equation (2)}$$

While this relation is well established, it is scarcely known that the correction term also, as in Equation (3), can in its essentials be represented in the simple diagram

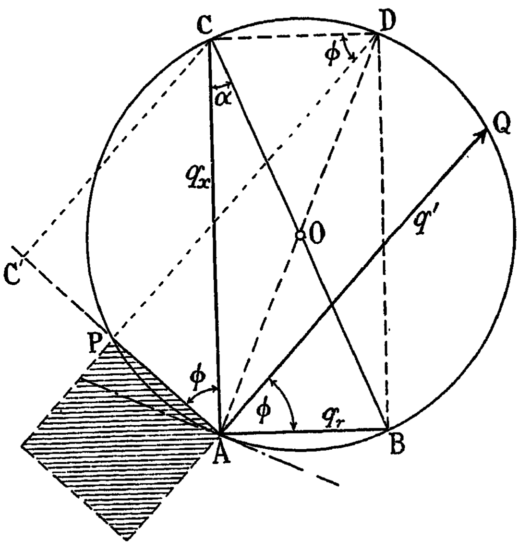

Fig. 5.

described; to this latter we propose to refer here as the "chord diagram of regulation," all quantities being represented by chords. It is only necessary to draw

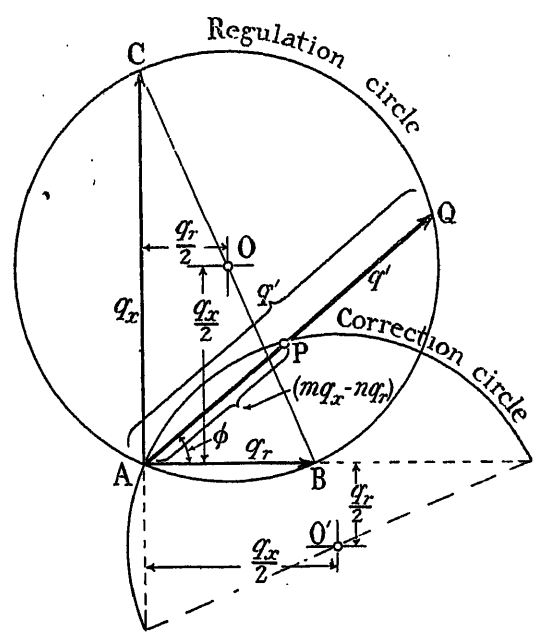

Fig. 6.

(Fig. 5) the chord that passes through the vertex A and is perpendicular to the regulation AQ to obtain from its length, when referred to the same scale to

which q_r and q_x are drawn, the basis of the correction term, that is

$$AP = mq_x - nq_r \quad . \quad . \quad . \quad (4)$$

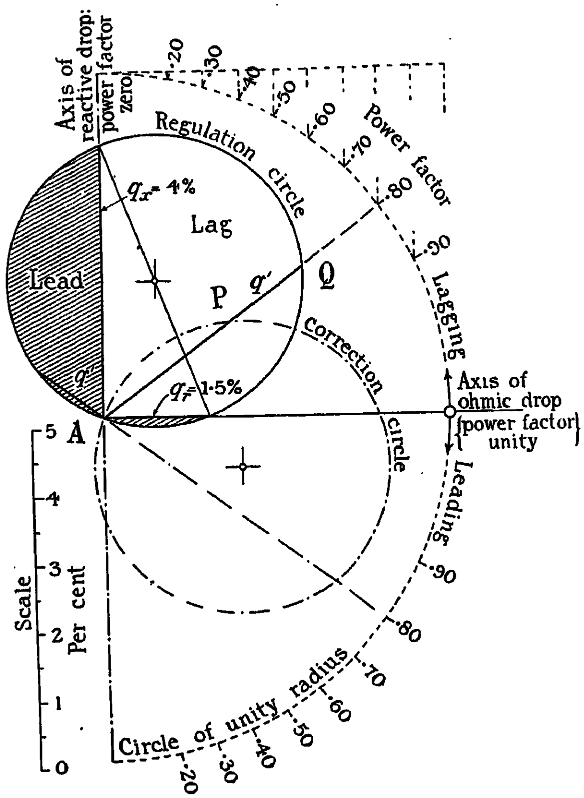

FIG. 7.

With this read off from the diagram, the correction term proper is obtained by raising to the second power the value read off and dividing the result by 200, as follows from the comparison of Equations (3) and (4).

Equation (4) is derived from Fig. 5 as follows:

$$\begin{aligned} AP &= AC' - C'P \\ AC' &= q_x \cos\phi \\ C'P &= CD \sin\phi = q_r \sin\phi \\ AP &= q_x \cos\phi - q_r \sin\phi \end{aligned}$$

or $$AP = mq_x - nq_r$$

When a second circle of the same radius is drawn, but with its centre displaced by 90° relative to the vertex A, the correction basis appears as the chord AP on the regulation chord itself, as shown in Fig. 6.

In Fig. 7 the complete chord diagram is drawn for $q_r = 1 \cdot 5$ per cent and $q_x = 4 \cdot 0$ per cent. On the unity circle the power factors (lagging and leading) are marked. A clear picture is obtained of the variation of the regulation q' and the correction factor as a function of the power factor. The hatched part of the circle corresponds to a leading power factor, and of this the segment to the left of the chord q_x refers to a voltage-rise.

In the particular case considered, we obtain the following figures for the regulation at a power factor of 0·80, lagging and leading respectively:

Power factor	0·80 lagging	0·80 leading
From Fig. 7, q'	3·60 %	1·2 %
Correction basis (AP) ..	2·25	4·15
Correction term $(AP)^2/200$	0·025 %	0·086 %
Regulation, corrected (and rounded off)	3·7 %	1·3 %

THE LEAFIELD COUPLED ARC.

By Major A. G. LEE, M.C., B.Sc., and A. J. GILL, B.Sc. (Eng.), Members.

(*Paper first received* 13*th January, and in final form* 25*th February*, 1925; *read before the* WIRELESS SECTION 1*st April*, 1925.)

SUMMARY.

The reasons for the introduction of coupled-circuit working are set forth, with some account of the preliminary experiments at Stonehaven and Northolt. The action of the coupled circuit in reducing harmonics and "mush" is explained.

Details of the design of the various portions of the circuit are given, together with an explanation of the tuning properties of the circuit.

The coupled circuit is found to give very constant frequency, and the factors contributing to this are dealt with in detail.

The reduction of harmonics and mush by the coupled circuit is very large, but the steps taken to reduce the residuum to still smaller proportions are described.

Section 1.

INTRODUCTION.

It is a matter of common knowledge that the Poulsen arc, if directly connected to an antenna, produces a great deal of disturbance to other wireless users on wave-lengths far removed from that of the arc. This disturbance is of two kinds, (1) the emission of harmonics, i.e. emissions which are definitely tunable and which can be heterodyned to a musical note, and (2) the emission of what has been called "mush." The latter manifests itself as a hissing sound and is usually found most strongly in the neighbourhood of the harmonic positions.

The cause of harmonics is to be found in the slight departure from sinusoidal form of the current in the oscillating circuit. Suitable design of the arc and the aerial circuit may reduce the strength of the harmonics below what is normally obtained from a valve oscillator of similar power on plain aerial, but in practice the harmonics, and more especially the mush, are still strong enough to give trouble.

The cause of mush is a little more obscure but is probably associated with the irregular frequency of the fundamental wave. The arc is an ionic contrivance and on a plain aerial connection has a frequency which, in the nature of the ionic action inside the arc chamber, cannot be expected to be very constant. Carson * has shown that if a sine wave has its frequency changed at a sinusoidal rate, or in other words undergoes frequency modulation, an infinite series of harmonics of the sum and difference of the fundamental and modulating frequencies is obtained.

When any one harmonic of this series happens to fit in with an harmonic resonant point of the antenna system, it gives rise to radiation on that frequency. With the arc, the fundamental frequency is undergoing frequent discontinuous changes and it is to be expected that the "harmonics" due to these irregular changes will form a continuous spectrum of disturbance, which is ready to emerge at any harmonic resonant point of the antenna.

In 1921, before the advent of broadcasting, the chief sufferer from the mush of the arc at Leafield was the Post Office station at Devizes. It was therefore decided to commence experiments on the introduction of a coupled circuit, with a view to the reduction of trouble.

From the theory outlined above it was to be expected that the provision of a primary oscillating circuit for the arc, in which both the capacity and inductance were concentrated, would tend to prevent the harmonic E.M.F.'s giving rise to currents of sufficient order to cause disturbance. The antenna system, with its distributed capacity and inductance, of necessity has harmonic resonance positions, so that the introduction of the primary circuit should cut down the harmonics before they get into the antenna system.

It was known that coupled circuits had been used in the early days of the Poulsen arc, but that their use had been discontinued, apparently on account of trouble with variable frequency. It was therefore decided to commence the experiments on a small scale on the 25-kW arc at Stonehaven. These experiments were completed in March 1922 and indicated that successful working of the coupled-circuit arc was possible and that the reduction of mush and harmonics was very considerable. Attention was next paid to the 30-kW arc at Northolt which was installed in July 1922, and the coupled circuit here proved equally successful.

It was then decided to embark on the provision of a coupled circuit for the arc at Leafield, which was completed and brought into commercial use in March 1924. The provision of this circuit involved radical changes in the layout of the plant and, as the station was in almost continuous commercial use, the operation of installation was necessarily a lengthy one.

Section 2.

DETAILS OF DESIGN OF THE LEAFIELD COUPLED CIRCUIT.

A diagram of the circuit as designed is given in Fig. 1. The values of inductance and capacity are those used on a transmitting wave of 12 350 m. The circuit can, however, be operated at wave-lengths from 8 500 m to 15 000 m.

In settling the electrical dimensions of the various parts of the circuit it was recognized that practical

* J. R. CARSON: "Frequency Modulation," *Proceedings of the Institute o Radio Engineers*, 1922, vol. 10, p. 57.

limitations would prevent the circuit being designed to give the maximum theoretical efficiency. The arc generators installed were known to operate satisfactorily with a value of $\sqrt{(L/C)}$ of about 150 to 270. This factor was given considerable weight in the choice of circuit constants.

It is known from theoretical principles that the efficiency of a coupled circuit is greater as the ratio

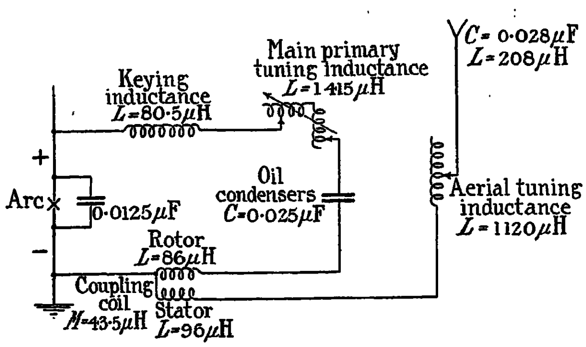

FIG. 1.—Diagram of circuit.

of C_2/C_1 increases. The value of C_2 is determined by the aerial, but the value of C_1 is to some extent a matter of choice.

There are limits, however, to the permissible reduction in capacity of the primary circuit, since the smaller condenser must operate at a higher voltage and this involves greater losses from leakage and corona, while the inductance value must be large, necessitating a large coil with greater losses.

The Poulsen arc functions most satisfactorily as a high-frequency generator when the ratio of direct current input to alternating output is $\sqrt{2} : 1$. When this ratio has values other than this there are large harmonic components present in the generated frequency. It has been found that in order to approximate to this ratio the value of $\sqrt{(L/C)}$ should not be less than about 100. For example, at a frequency of 25 000 cycles per second $LC = 40{\cdot}529 \times 10^{-12}$ and if $\sqrt{(L/C)} = 100$ then $L = 636\ \mu H$ and $C = 63\ 660\ \mu\mu F$.

Primary condenser.—In determining the most suitable value of condenser a table was prepared giving values of condenser voltage E, and values of $\sqrt{(L/C)}$ for a primary current of 250 amperes for various values of primary capacity and frequency, and is reproduced here as Table 1.

An examination of these figures led to the conclusion that the most suitable value of the primary condenser was 25 000 $\mu\mu F$ and that it should be suitable for a working pressure of 80 000 volts (R.M.S.).

There are three kinds of dielectric suitable for high-frequency condensers, namely air, mineral oil and mica. Investigation showed that air was out of the question, as its low dielectric strength and low permittivity would have made such a condenser impossibly large. The issue then lay between the oil and mica. The mica condenser is more compact and can be housed in smaller space; on the other hand the mica condenser is more expensive than an oil condenser of equivalent rating and cannot be overloaded with impunity, an event which might occur if the aerial became disconnected. It was therefore decided to adopt oil as the dielectric and to arrange the condenser in four units of 6 250 $\mu\mu F$ capacity.

Experiments were carried out to determine the suitability of commercial transformer oil as a dielectric medium at high frequencies. It is well known that the dielectric strength of such oil is improved when the oil is cleaned and dehydrated. The preliminary step was to determine whether the power factor was likewise improved by such treatment. Various methods of treatment were compared.

The oil selected was a light-grade non-sludging oil having the characteristics laid down in British Standard Specification No. 148 for insulating oils for use in transformers and oil switches.

The oil was not of the non-freezing variety and during installation it was exposed to heavy frost, which produced a semi-solid constituent. Tests were then made to determine whether the presence of this constituent had any influence on the power factor of the oil. It was recognized that the most convenient method of treating the oil would be by means of a centrifuge, and a De Laval dehydrator was obtained and tests carried out to determine whether such treatment was as effective in lowering the power factor as other methods of drying. Tests were also carried out to determine

the effect of washing by contact with live steam on the oil prior to dehydration.

Most of the measurements of power factor and dielectric strength on samples of oil were carried out by the National Physical Laboratory and the summarized results of tests are as follows. The power factor measurements were made at a frequency of 25 000 cycles and the dielectric strength measurements were carried out at a frequency of 50 cycles per sec.

(1) Centrifugal dehydration is a satisfactory method of improving the power factor of oil, and by this means a normal power factor of 0·0003 in commercial oil can be lowered to 0·00005.

(2) The presence of a freezing constituent had no appreciable effect on power factor.

(3) Oil subjected to live steam and afterwards dehydrated was found to be unimproved. This appeared to be due to the presence of water particles in an extremely finely divided state. If such oil is subsequently heated for some time at 130° C. the high dielectric strength and low power factor appear.

(4) Heating the oil after plain dehydration gave an improvement in dielectric strength of 10 000 volts, i.e. from 52 000 volts to 62 000 volts in the standard gap of ½ in. dia. balls spaced 0·15 in. apart.

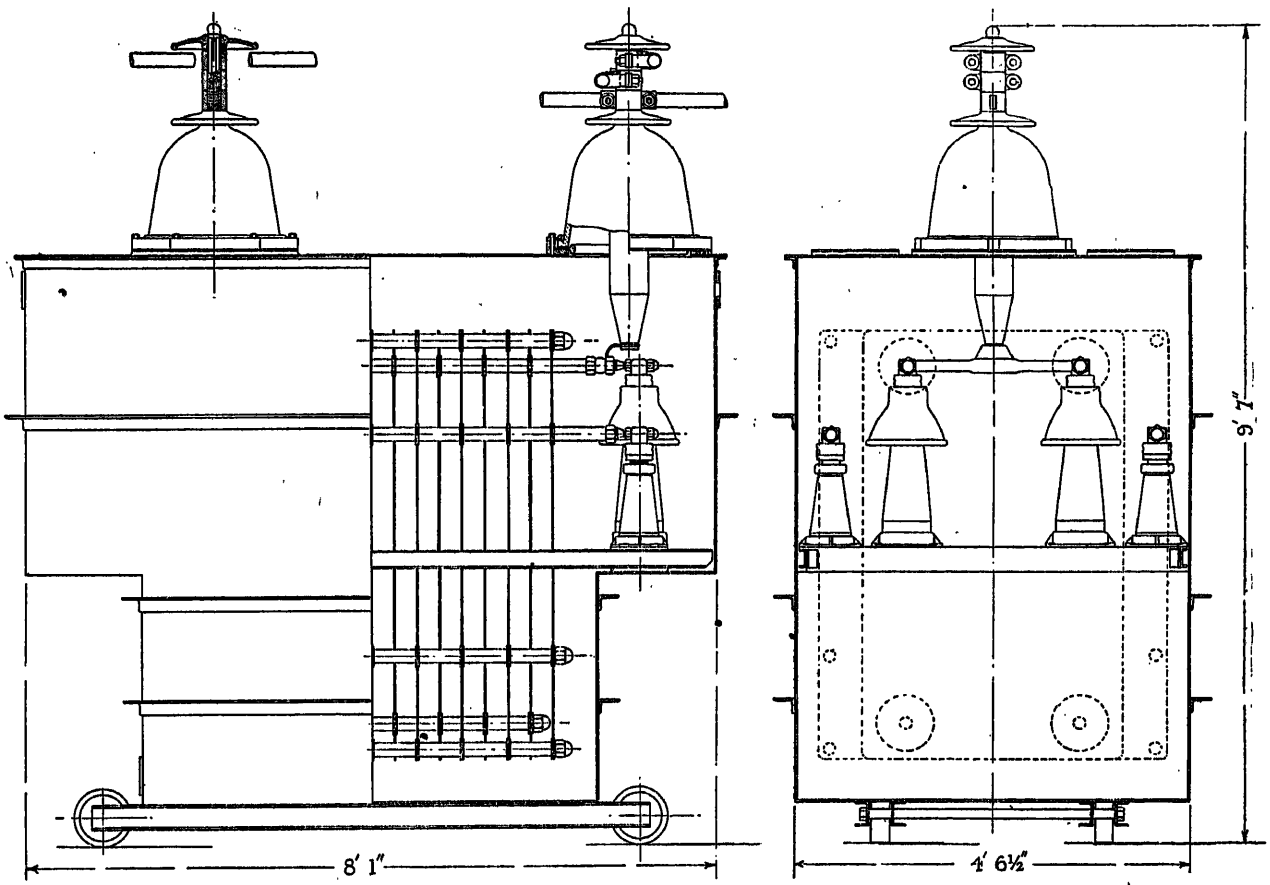

Fig. 2.—Arrangement of oil condenser. Capacity 6 250 $\mu\mu$F with oil of permittivity 2·2; working pressure 80 000 volts (R.M.S.).

The remaining point for investigation was the safe working stress for oil at high frequencies. There is an absence of published information on this subject. Peek * quotes comparative figures of the dielectric strength of a sample of oil between flat discs 2·5 cm diameter and 0·25 cm apart as 17 000 volts (max.) per mm at 60 cycles per sec. and 6 700 volts (max.) per mm at 90 000 cycles per sec. Here the oil subjected to the high-frequency voltage has only 37 per cent of its dielectric strength at low frequencies. Rough experiments were carried out to check these results and it was found that untreated transformer oil having a strength of 35 000 volts (R.M.S.) at 50 cycles on the standard gap when tested between flat plates ¾ in. apart at 55 000 cycles per sec. broke down at 35 000 volts (R.M.S.). Using dehydrated oil between plates having edges rounded to $\frac{3}{32}$ in. radius spaced 1 in. apart, a

* F. W. Peek, Jun.: "Dielectric Phenomena in High-Voltage Engineering," p. 165.

working pressure of 40 000 volts (R.M.S.) at 25 000 cycles per sec. could be safely used.

The strength of oil does not increase proportionately to the spacing between electrodes, and from these results it was estimated that in order to provide for a fair margin of safety at a working pressure of 80 000 volts (R.M.S.) at 25 000 cycles per sec. a spacing of 3 in. between electrodes should be maintained. Further experience indicates that this is on the liberal side and if it were possible to seal the tanks hermetically this spacing could be reduced.

During these experiments a small experimental oil condenser was built of 5 000 $\mu\mu$F total capacity in two units of 2 500 $\mu\mu$F each. The plates were spaced $1\frac{1}{2}$ in. apart and were of zinc $\frac{1}{16}$ in. thick. This condenser was in regular use at Northolt radio station as a coupled-circuit condenser operating at between 35 000 and 40 000 volts at 55 000 cycles. The only difficulty experienced was in obtaining suitable stock insulators to support the plates, and eventually the trouble was cured by making these of ebonite. The oil used in this case was not dehydrated.

In the condensers at Leafield (Fig. 2) the supporting insulators for both high-tension and low-tension plates are hollow porcelain columns arranged vertically. The merit of the vertical arrangement is that the insulators are in simple compression, and the dust particles cannot line up along the top surface of the insulator as they do in the case of horizontal insulators. Provision is made for the circulation of oil up through the centre of the columns. Vertical plates were adopted in preference to horizontal plates to avoid the risk of bubbles being trapped on the under surfaces. The horizontal rods carrying the plates rest on spherical shaped seatings on top of the insulators so that no bending moment can be communicated to the insulator; moreover, one end only of each rod is rigidly fixed, the other end having a small permissible travel to allow for differences of expansion. The spacing between all parts of h.t. and l.t. conductors is nowhere less than 3 in.

The design of lead-out insulator presented an interesting problem. The ordinary type of transformer or oil-switch bushing is unsuitable owing to the heavy capacity current passed by such bushings at high frequencies. In the experimental condenser referred to above, chemical bell jars of glass had been used, standing over holes in the tank cover through which the conductor passed. These had proved satisfactory and had been suggested by similar shaped insulators used on Admiralty condensers of lower voltage.

A similar type of bushing was adopted for the large condensers, using porcelain bell jars. This type of bushing (Fig. 3) has the advantage that its main insulation is air, while the porcelain provides mechanical support and excludes dust but carries a relatively small dielectric current. The distribution of potential between a line conductor and a plate having a circular hole through which the conductor passes has been investigated by Clerk Maxwell and others * both mathematically and by means of electrolytic cells having electrodes of analogous shapes.

* C. W. Rice: "Electrostatic Problems," *Transactions of the American Institute of Electrical Engineers*, 1917, vol. 36, p. 905.

It has been established in the limiting case, where the plate is plane and the conductor a line and where the dielectric is of uniform permittivity, that the equipotential surfaces are confocal hyperboloids of one surface, the focal point being the edge of the hole and the axis of revolution the conductor. The distribution of potential between such a plate and line is shown in Fig. 4 by equipotential surfaces and in Fig. 5 as a

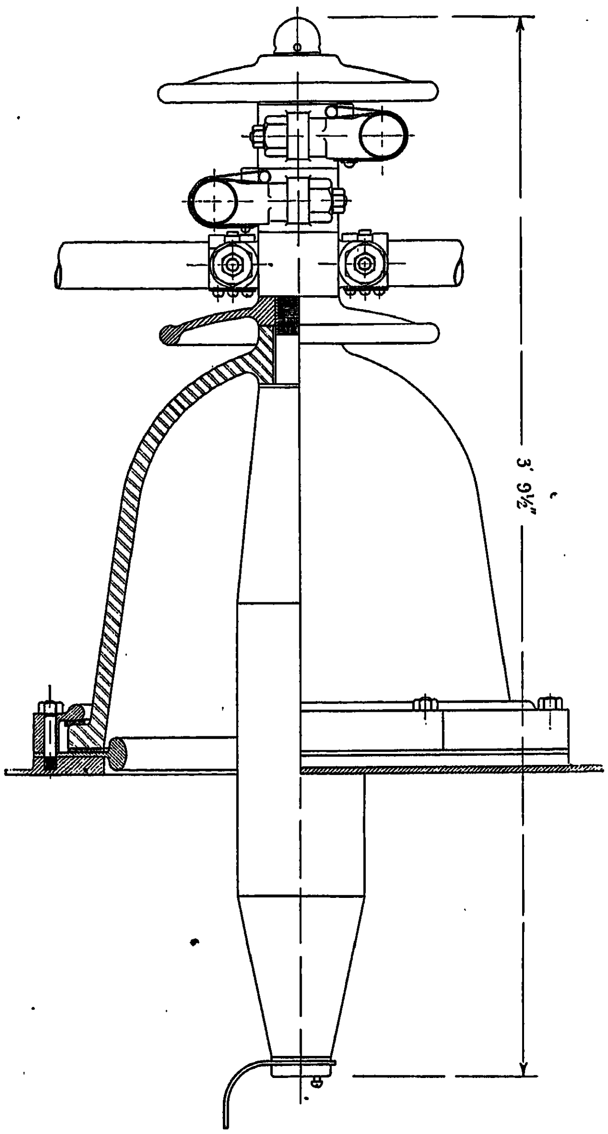

Fig. 3.—Bushing of oil condenser.

graph. The slope of this latter curve indicates voltage gradient. The gradient becomes infinity at the plane and at the line. In practice if we make the inner and outer conductors take the shape of confocal hyperboloids the distribution of potential between them will be unchanged and can be readily determined. From the shape of the potential curve it is clear that the potential gradient changes very rapidly near the edge of the hole and little or no advantage arises in making the

radius of the outer hyperboloid less than about 95 per cent of the focal radius C. If a tangent to the potential curve be drawn at this point it is seen that another different diameters of inner conductors. If the radius of the inner conductor is less than about $0 \cdot 33\ C$ the maximum gradient occurs at the surface of this con-

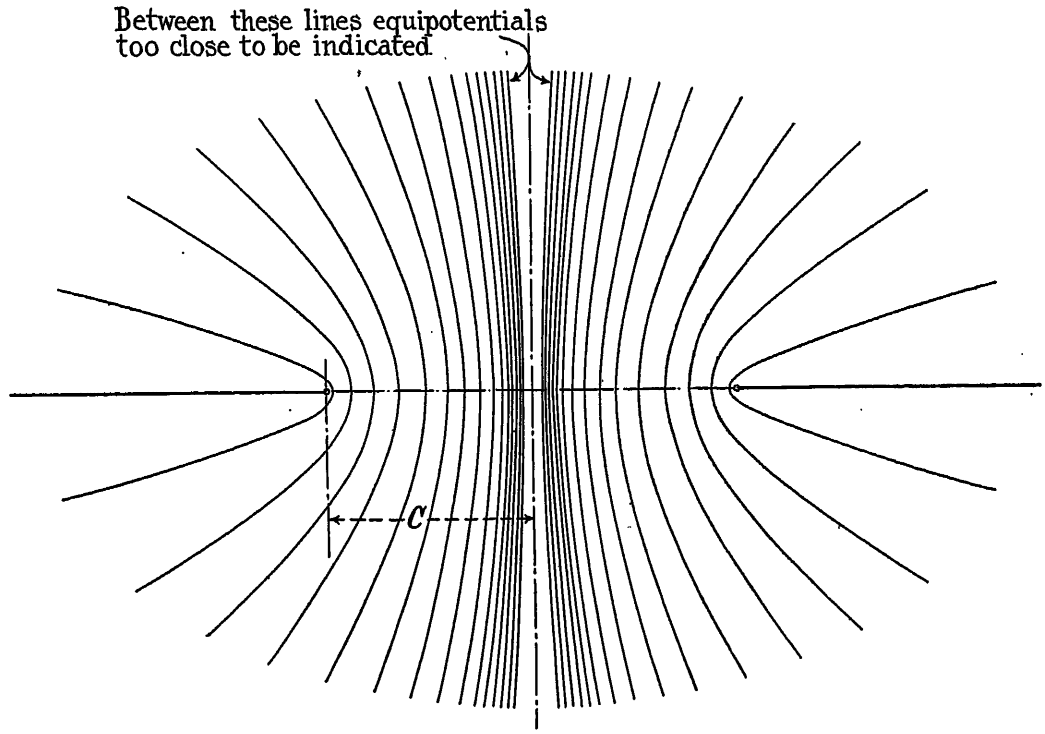

FIG. 4.—Equipotential surfaces between line and hole in plane. Radius of hole = C.

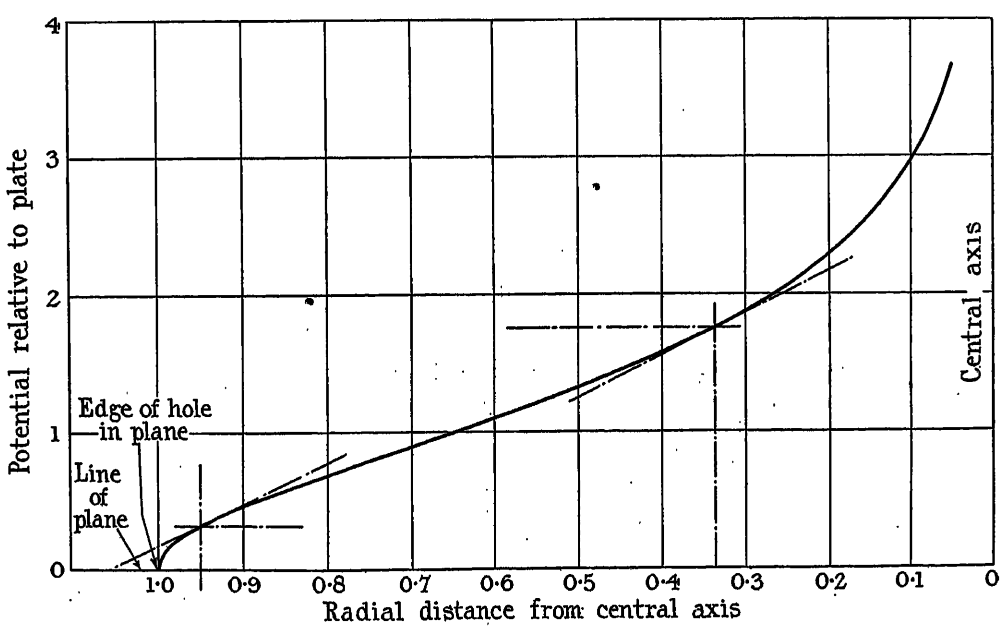

FIG. 5.—Distribution of potential between line and hole in plane.

similar tangent to the curve can be drawn at a radius of about $0 \cdot 33\ C$. This is more clearly shown in Fig. 6, where the radius of the outer conductor has been assumed to be $0 \cdot 95\ C$ and the maximum gradient plotted for ductor. On the other hand if the radius of the inner conductor is greater than $0 \cdot 33\ C$ then the maximum gradient occurs at the surface of the outer conductor.

The focal radius in the present case was taken as

20 cm and the inner conductor 7 cm radius. Taking the ultimate dielectric strength of air as 21 000 volts (R.M.S.) the voltage at which corona will appear will be $21\,000 \times 20/2{\cdot}4 = 176\,000$ volts (R.M.S.). The bushing should of course be worked well below this value to allow for the distortion of flux due to the outer conductor not conforming to a true hyperboloid.

The condenser has worked satisfactorily without sign of breakdown. The losses are extremely small and cannot be determined by temperature measurements as the surrounding air increases in temperature more rapidly than the condenser when the station is working.

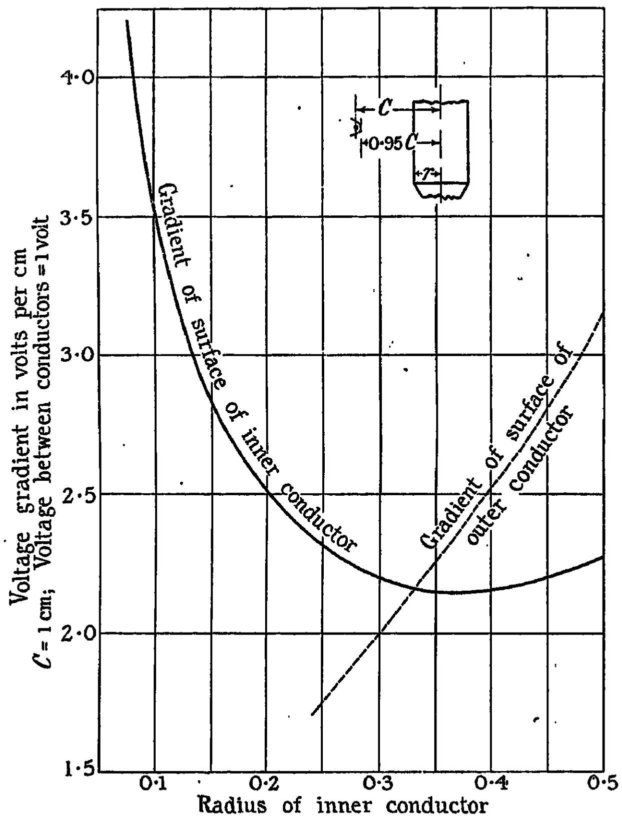

FIG. 6.—Maximum potential gradient with various sizes of central conductor.

Primary inductance.—At the time when this circuit was designed it was desired to obtain practical data of the performance of strip copper inductances in comparison with tubular and divided-wire types. As the strip pattern has great advantages from the points of view of cheapness and ease of manufacture it was decided to adopt this pattern at Leafield, as a divided-wire inductance was already installed there and direct comparison could be made.

Some type of variometer was required in the primary circuit, and in order to minimize the circuit resistance it was decided to combine this with the primary inductance. The inductance consisted of eight spiral coils, each coil consisting of seven turns of copper strip 4 in. wide × $\frac{1}{8}$ in. thick, the turns having a pitch of $3\frac{1}{2}$ in. and a mean diameter of 76 in. The coils were mounted with their axes vertical, the four lower coils being fitted on a moving carriage which ran on rollers and passed under the four upper coils, which were fixed in position. The vertical pitch of the coils was 10 in., this giving 6 in. clearance between the layers.

In subsequent experiments three coils were removed and the inductance now consists of three moving and two fixed coils. The whole is carried on a wooden

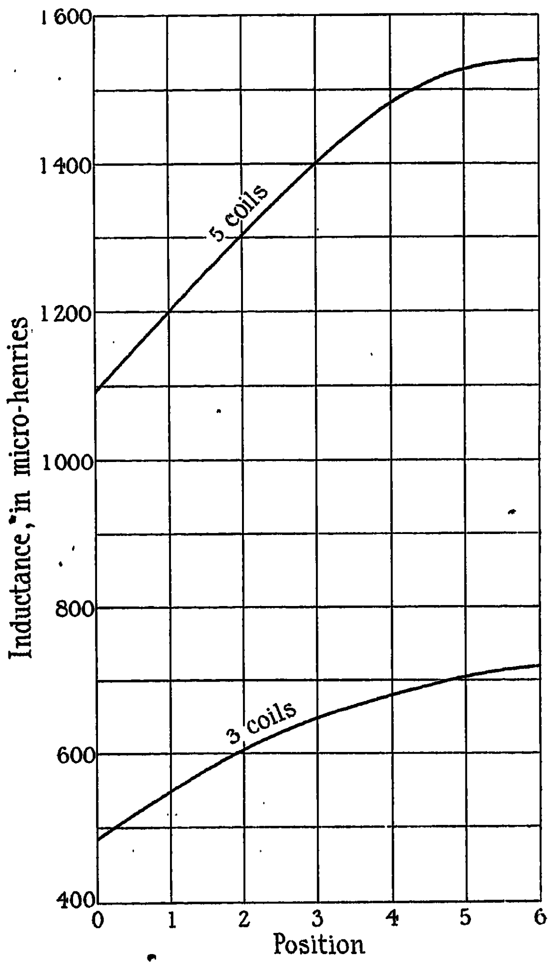

FIG. 7.—Position of variometer.

table 6 ft. above the floor, as it had been found that proximity to a concrete floor may appreciably increase the losses in a coil. The moving carriage is operated from the control platform by means of a handwheel and gears. It is thus possible to vary the wave-length of the primary circuit while the arc is running.

The variation of inductance by this means is quite satisfactory and is indicated in the case of three and five working coils in Fig. 7. The conductors are mounted directly on the wooden framework without the use of other insulation, as it had been found that thoroughly dry wood had better insulating properties at high frequency than most other materials. The wood used was mostly ash, but it was found that with this material prolonged drying by high-frequency currents was essential before its full dielectric properties

were developed. While under construction it was found that American whitewood had greatly superior qualities and this was substituted where possible. For some days before bringing the circuit into use and while the station was being operated on plain aerial the new primary circuit consisting of inductance and condensers was brought near resonance with the spacing wave so that a circulating current, which was gradually increased up to 150 amperes, was induced therein. At first the woodwork increased in temperature by about 60 deg. F., but after a few days this fell to normal. At one or two points charring occurred due to imperfect contact between the copper and wood causing corona. In one place only the ash supporting arm charred internally and had to be replaced by American whitewood.

Comparative measurements of resistance were made between this coil and the previously installed divided-wire inductance. This inductance is a single-layer solenoid of 22 coils of cable consisting of 1 600 insulated strands. These measurements show that the divided-wire type is decidedly superior ; this superiority becomes more pronounced at the shorter wave-lengths.

Coupling transformer.—It was decided to adopt separate inductive coupling as affording the readiest means of variable coupling between the primary and secondary circuits capable of adjustment while running. The coupling transformer consists of four coils, two of which are fixed and are in series in the aerial circuit. The remaining two coils are in series in the primary circuit and are rotatable inside the stationary coils.

The coils are built up of flat strip copper 4 in. × $\frac{1}{8}$ in. and pitched 1 in. apart between turns. The mean diameter of the fixed coils is 51 in. and each consists of four turns. The mean diameter of the rotatable coils is 37 in. and each consists of five turns. The copper is mounted on the wood framework, which in this case is of teak.

For reasons explained later, the losses in the coupling unit depend upon the tuning adjustment at which the circuit is worked and are found to be higher than desirable. It has therefore been decided to substitute the strip copper coupling unit by a divided-wire type.

The magnitude of M, the mutual inductance of the coupling coil, can be calculated for a resistance load in the secondary, if a current ratio I_2/I_1 is assumed. This, for the Leafield circuit, would be something slightly less than 10 μH. In practice, however, the secondary current has a reactive component which increases its impedance, and it is necessary to add something to the calculation made in this way in order to ensure that the power gets across. The coupling unit was therefore made variable up to about 90 μH, the best value (found by trial) being 43 μH. It was observed that the amount of coupling was not critical in its effect on the current obtained, and the value was finally decided by its effect on the constancy of frequency—too small a value making the arc less stable as it reduced to some extent the flywheel effect of the secondary circuit, and too large a value having the effect of making the aerial-swing relatively more important while the aerial current was not increased beyond the value which could be obtained on relatively smaller couplings. Under these circumstances the coefficient of coupling is approximately 3 per cent.

Costs.—Costs of some of the chief items of plant are given in Table 2.

TABLE 2.

Approximate Cost, including Erection and Overhead Charges.

	£
Condenser bank, including pipework, dehydrator, tanks and pumps	2 800
Primary inductance, including wooden framework, copper, operating gear and tools ..	480
Coupler, including woodwork, copper, insulators and metal fittings	160
High-tension busbars and supports	150
Miscellaneous items, meters, switches, screens, etc.	250

Section 3.

TUNING OPERATIONS ON THE COUPLED CIRCUIT.

Apart from the fact that the Poulsen arc has a somewhat unique cycle of operations, the ordinary theory of the oscillation of coupled circuits may be applied to elucidate the operation of tuning. Many papers have been written on the discontinuous frequency-changes which occur in the operation of valve transmitters with coupled circuits, of which one of the earliest was by Townsend.* Townsend described a graphical method of explaining the discontinuous frequency-changes. His description of the actions which take place may be applied to coupled-circuit arc working, but as his diagrams are in terms of the square of the wave-lengths it is thought that the following method of explaining the action is perhaps somewhat simpler. The diagrams and theory are of course elementary but are a necessary preliminary to the particular action of the arc on coupled circuits.

Fig. 8 shows the changes of the several reactances in the primary circuit as the frequency generated is altered. The primary circuit reactance $\omega L_1 - (1/\omega C_1)$ over the portion of the frequency range considered is almost a straight line. It can be shown that the effect of the current in the secondary circuit is to impress an E.M.F. in the primary, the reactive component of which, $(-\omega^2 M^2/Z_2^2)X_2$, may be regarded as an additional inductance or capacity in the primary circuit depending upon the phase of X_2. The sum of these two reactances forms the net reactance of the primary circuit. It is well known in this case that the frequency generated will be such that the net impedance of the primary circuit is zero. In other words, for the particular diagram given (in which the primary and secondary circuits are both tuned to the same frequency f_0), the arc will oscillate at the points f_1 or f_2, where

$$\left(\omega L_1 - \frac{1}{\omega C_1}\right) - \frac{\omega^2 M^2}{Z_2^2} X_2 = 0$$

* J. S. TOWNSEND: "Oscillations obtained by coupling a secondary circuit with a continuous-wave valve oscillator," *Radio Review*, 1919–20, vol. 1, p. 369. Since the paper was written the authors' attention has been called to an earlier article on the subject by HUMBY and SCHONLAND: "Wave-lengths radiated from oscillating valve circuits," *Electrician*, 1919, vol. 83, p. 443.

These frequencies are given for the isochronous case by the ordinary theory of coupled circuits, viz.

$$\omega_1 = \frac{\omega_0}{\sqrt{(1+k)}}; \quad \omega_2 = \frac{\omega_0}{\sqrt{(1-k)}}$$

where $\omega_1/(2\pi)$, $\omega_0/(2\pi)$ and $\omega_2/(2\pi)$ are the frequencies f_1, f_0 and f_2 respectively, and k is the coefficient of coupling.

Tuning of the circuit may be effected by keeping the secondary circuit constant and altering the inductance of the primary. This is the method employed at Leafield. Further lines such as those shown dotted may be drawn on the diagram to represent this tuning by alteration of inductance, and the interception of these lines with the curve of reactance due to the secondary circuit gives new oscillation points such as f_3 and f_4.

the line still further to the right, it ceases to cut the negative secondary reactance curve, and the oscillations therefore suddenly jump to a much higher frequency represented by f_5, where both reactances have changed sign and we have again the equality $\omega L_1 - (1/\omega C_1) = (\omega^2 M^2/Z_2^2)X_2$. These effects are depicted in Fig. 9, in which the dotted lines represent the frequencies obtained graphically in this way.

On retracing our steps by moving the line $\omega L_1 - (1/\omega C_1)$ from right to left, it is now the high-frequency oscillation which has taken possession of the arc and we have frequencies given by the intersection of this line with the positive values of $(\omega^2 M^2/Z_2^2)X_2$. On passing beyond the positive maximum of reactance due to the secondary, the frequency generated again makes a sudden jump, this time to the low side.

In this discussion we have neglected the effect of resistance in order to make the matter more clear. It

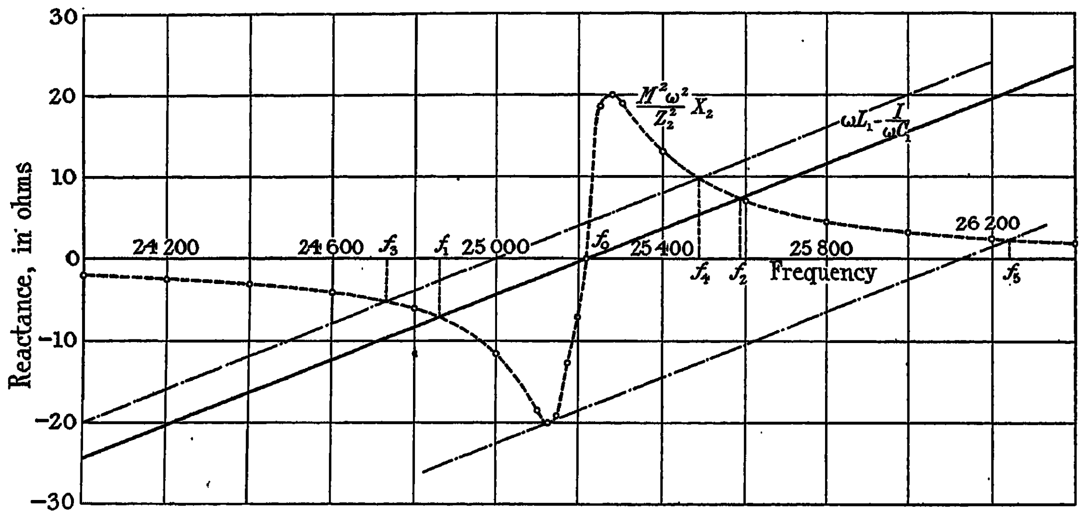

FIG. 8.—Variation of effective reactance of the primary circuit.

Now, in general, the arc will only oscillate on one frequency at a time if it has a choice of two frequencies which are not harmonically related. This is because the extinction period of the arc forms a discontinuity which can only fit one cycle of operations.

With a coupled circuit such a cycle of operation is normally stable unless certain limits are exceeded, because a change from one mode of oscillation, say f_1, to the other, f_2, entails an almost complete reversal of phase in the secondary circuit, a process which can only be carried out by the expenditure of a certain amount of energy.

We will now trace out the effects which occur as the primary inductance is altered from a low-frequency resonance value to a high frequency. As the line $\omega L_1 - (1/\omega C_1)$ is moved parallel to itself from left to right of the diagram, oscillations commence at a low frequency, gradually rising in frequency as the line is moved to the right. It will be seen that near the negative maximum of the curve representing reactance from the secondary circuit, the frequency-change for a given movement of the line becomes smaller. Moving

is obvious, however, that as we approach the isochronous frequency from either side the effective resistance introduced by the secondary into the primary circuit will increase. For instance in the Leafield case, if it were possible to reach the isochronous frequency the effective resistance introduced by the secondary into the primary would be over 40 ohms.

We shall therefore approach a point when the total effective resistance of the primary circuit is too great for the negative resistance developed by the arc to handle and the oscillations will stop, starting again immediately at the new frequency position determined by the tune of the primary circuit in relation to the reactance from the secondary, as already described. The area enclosed by this oscillation hysteresis effect will, therefore, be smaller than that shown by the dotted lines in Fig. 9. The heavy lines in Fig. 9 indicate the actual frequencies obtained as the tuning of the primary circuit of the arc at Leafield was altered. The arrows on both the dotted and heavy curves indicate the direction in which the tuning was effected. The points of interest in these latter curves are:

(1) The hysteresis area is much smaller than that calculated, in which no allowance was made for a limit to the negative resistance effect of the arc.
(2) The hysteresis is not symmetrical about the isochronous position, a fact which is reflected in the current ratios given later.
(3) The frequency-change is very flat as we approach the positions of frequency discontinuity.
(4) A further point of interest is the difference in the calculated and observed frequencies, part of which is due to minor inductances and capacities, e.g. leads which were not allowed for in the calculation, and a further part which is due to the well-known property of an arc giving a frequency lower than that due to the LC values of the circuit, on account of the extinction period forming part of the total cycle. It has been calculated that the extinction period of the arc at Leafield is of the order of 1 per cent of the total period.

The difference between the two frequencies f_1 and f_2 is in agreement with the coupled-circuit formulæ already given for the isochronous position, viz.

$$\omega_1 = \frac{\omega_0}{\sqrt{(1+k)}}\,;\quad \omega_2 = \frac{\omega_0}{\sqrt{(1-k)}}$$

except that the absolute value is affected by the extinction period as above stated.

The arc at Leafield is operated with both marking and spacing waves. It will be seen, therefore, that provided both these waves are kept sufficiently far away from the frequency discontinuity position, the arc can be operated in a quite stable manner.* In practice, operation on the low-frequency side is found to be more stable than on the high-frequency side, and in addition this side gives a larger secondary current. The actual operating tuning point is very slightly beyond the isochronous position, which in practice is far enough away from the discontinuity position to be perfectly stable. It will be realized that, if operation on the low-frequency side is decided upon, the secondary circuit has to be set at such a value as to enable the frequency required to be attained.

Fig. 10 shows the ratio of secondary to primary current as the tuning of the primary circuit is altered. It will be seen that tuning the primary circuit from the low-frequency side gives the larger current ratio. No explanation has been found for the early break on the high-frequency side, but it may possibly be associated with stray capacity couplings.

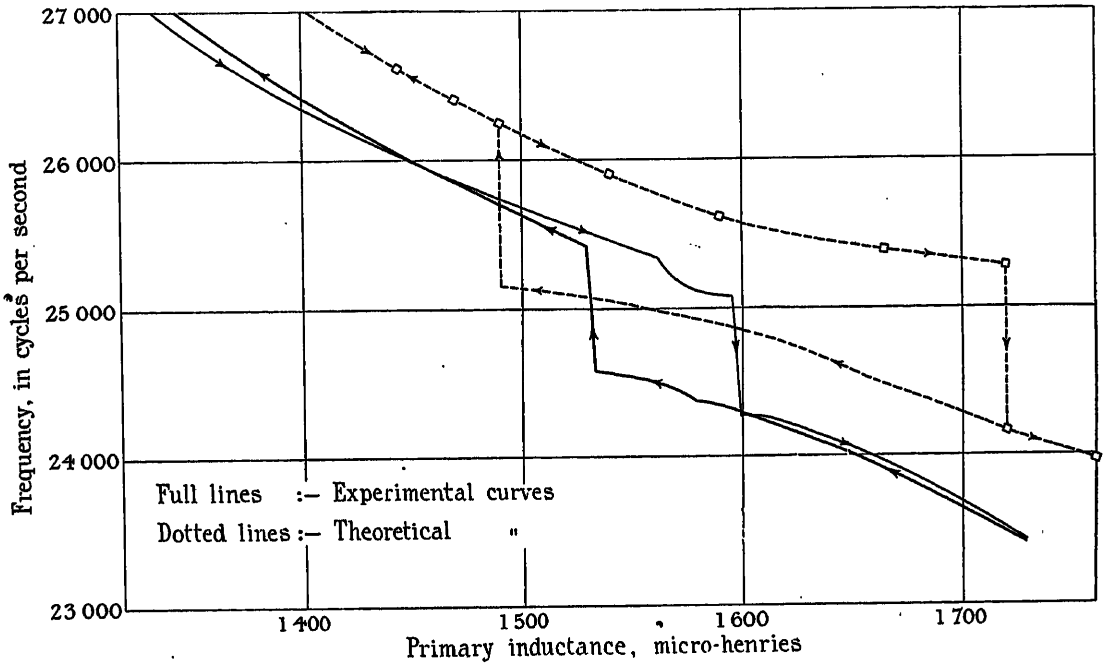

FIG. 9.—Variation of frequency generated as tuning of primary circuit is altered.

The point where the two curves cross is, as nearly as can be estimated, at the isochronous position. It will be seen that a larger current ratio is obtained beyond the isochronous position, a phenomenon which has been given the name of "Ziehen" by German writers.

The distinction between the isochronous tuning position and the isochronous frequency may perhaps be emphasized here. When the circuits are tuned to the same frequency, or are isochronous, the frequency generated on the "low side" is lower than the isochronous frequency by 370 cycles per sec. The current in the secondary circuit is therefore out of phase with the voltage, and the circuit presents reactance to the current.

* This has already been reported by PESSION: "Funzionamento dell' Arco Poulsen ou circuiti accoppiati," *L'Elettrotecnica*, 1923, vol. 10, p. 890, and it was also a feature of the experiments at Stonehaven and Northolt in 1922.

It is obvious that as we pass the isochronous position we shall get nearer the frequency at which the secondary circuit is resonant, and hence I_2/I_1 will increase. In actual working with the arc, however, the secondary current only increases a short way beyond the iso- in the primary circuit compared with that in the secondary, the less power is wasted in the primary coil and condenser and, what is more important, in the arc itself. It is this possibility of getting a ratio I_2/I_1 greater than unity which permits of the coupled arc

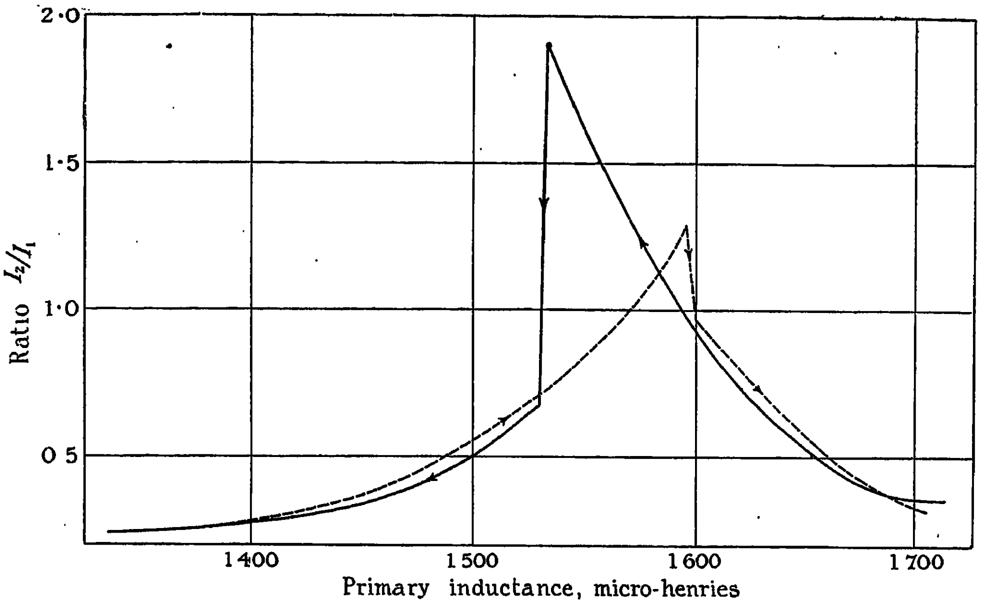

FIG. 10.—Ratio of secondary to primary current as tuning of primary is varied.

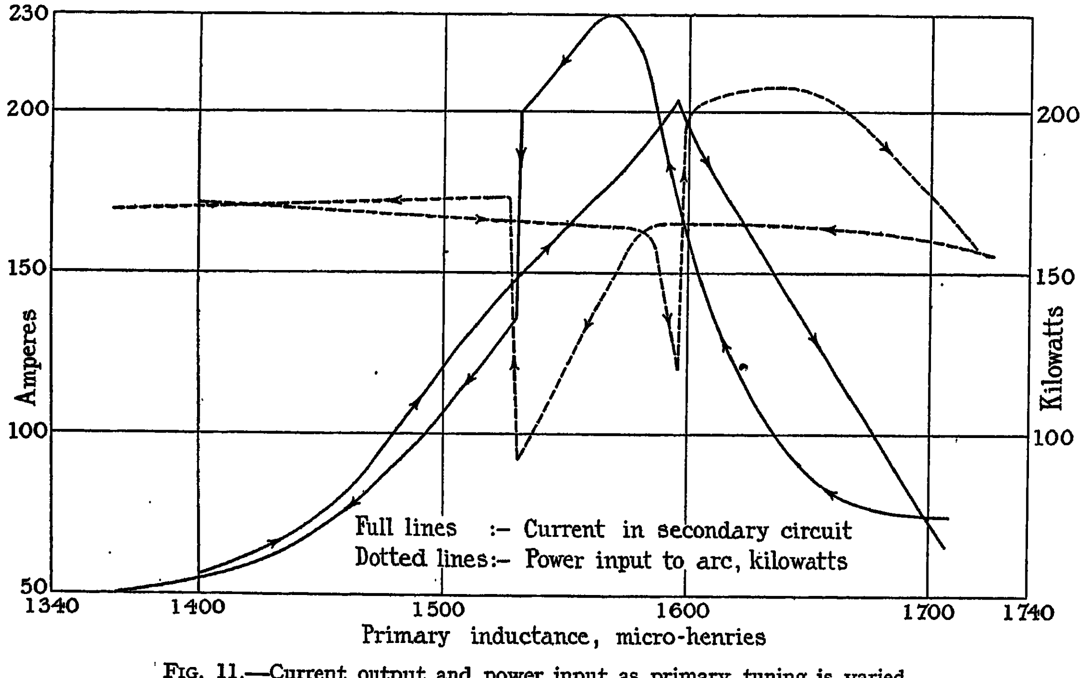

FIG. 11.—Current output and power input as primary tuning is varied.

chronous position, on account of the various limitations on output involved in the design of the particular arc, although the ratio of currents and also the efficiency continue to increase. With regard to the latter point, it is obvious that the smaller we can make the current being operated at an efficiency equal to or greater than that obtained in plain aerial working.

Fig. 11 shows a curve representing the actual currents obtained on various tuning adjustments of the arc at Leafield, from which the ratios in Fig. 10 were calculated.

This curve was obtained by keeping the d.c. voltage approximately constant. The power input is also plotted, from which it may be seen that the efficiency rises considerably as the isochronous position is passed.

Section 4.

Other Forms of Coupling.

The inductive type of coupling has been used in all the experiments at Stonehaven, Northolt and Leafield because it is relatively cheaper than condenser coupling and can be made continuously variable. The Northolt circuit has an auto-transformer coupling, while the Stonehaven and Leafield circuits are transformer-coupled.

The object of fitting a coupled circuit is, however, the reduction of harmonics and mush and, theoretically, it is fairly obvious that a capacity coupling offers advantages in this direction inasmuch as the harmonic voltage impressed on the secondary circuit is much reduced by employing a capacitative in lieu of an inductive coupling, the voltages in the two cases being $I_1/(pC_m)$ and pMI_1 respectively, $p/(2\pi)$ being the frequency of the harmonic and I_1 the harmonic current in the primary. It will be seen that the voltage decreases with the frequency in the case of the capacitative coupling, while it increases with the frequency with inductive coupling.

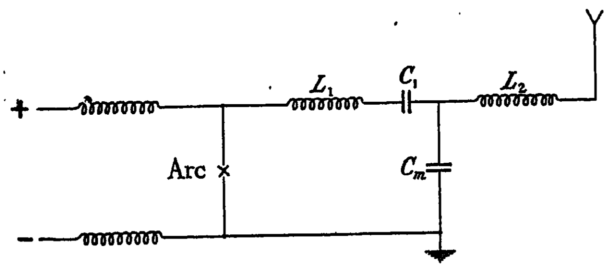

Fig. 12.—Capacity coupling.

Fig. 12 gives the circuit diagram in the capacity case. This circuit has been tried out on the arc at Northolt. On the first attempt the tuning was found to be critical and the arc unstable. A second attempt was, however, more successful but the following experimental facts emerged. With weak coupling and the circuits in approximately the isochronous position, the low-frequency oscillation f_1 was unstable, but the high-frequency f_2 was stable. With tighter coupling it was found that the low-frequency oscillation f_1 was stable but the f_2 frequency unstable. With couplings in between these two values both f_1 and f_2 were stable but the tuning could not be carried far beyond the isochronous position on account of the closeness of the frequency discontinuity. The value of the coefficient of coupling in these tests was of the same order as in the inductive tests. The results indicate that, while stability can be obtained, there is some inherent instability in the capacitative case in the arrangements at Northolt. The efficiency is also low because the tuning cannot be carried beyond the isochronous position.

Listening tests were made for harmonics around 400 m at Dollis Hill, about 6 miles from Northolt, where it was found that the higher harmonics were reduced but the lower harmonics were unaffected. The results are complicated by the possibility of direct radiation from the primary circuit, and at this distance it cannot be entirely excluded from our reckoning. These experiments have only recently been carried out and some more work requires to be done to remove, if possible, the causes of instability and low efficiency.

An interesting feature of the tests is the relatively very small current in the coupling condenser C_m during the f_1 oscillation, and the relatively large current, approximately equal to $2I$, during the f_2 oscillation. These are, of course, to be expected from the theory of coupled-circuit oscillations. The same phenomenon is, of course, present in the inductive types of couplings. In the transformer type of coupling, however, the field in the coupling coil during the f_1 oscillation is approximately double that due to I_1 or I_2, as the currents assist. In the f_2 oscillation, on the other hand, the currents are opposite in phase and the net field is small. The losses in the coupling coil are therefore larger in the f_1 than in the f_2 type of oscillation.

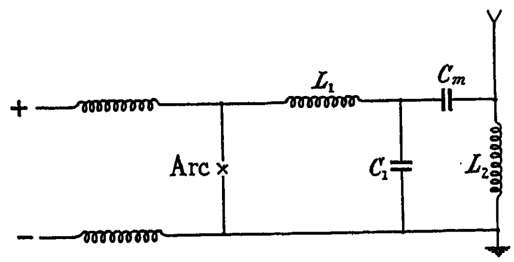

Fig. 13.—Capacity coupling.

Another type of condenser coupling which has been recommended is a small condenser connecting the high-voltage points of the two inductances L_1 and L_2 (see Fig. 13). Calculations which have been made for this circuit indicate a very small voltage across the coupling condenser during one type of oscillation, and an excessively large voltage during the other type. The latter possibility has discouraged any trial of this type of coupling.

Section 5.

Constancy of Frequency.

It is well known that an arc on plain aerial excitation is liable to unsteady frequency variations, and one of the pleasing features of the coupled-circuit working at Leafield is the remarkable steadiness of the frequency and the purity of the note.

The modern demand for high selectivity in the receiver requires very great steadiness in the transmitted frequency. As time goes on, the crowding together of wireless services will demand that more and more attention be paid to this point. Some inquiry has therefore been made in regard to this feature of coupled-arc working.

An instrument was designed for the purpose of

observing these small changes of frequency of the order of a few cycles per second. It consists of a heterodyne oscillator beating with the signal to give a beat note of approximately 1 000 cycles per sec. The output of a second low-frequency oscillator, tunable to 1 000 cycles per sec., is placed in series with the telephones and the beats between the two 1 000-cycle notes are reduced to zero. Any variation in the signal of even a fraction of 1 cycle per second is then immediately audible as a slow beat between the two notes. The tuning condenser on the 1 000-cycle oscillator is calibrated in terms of cycles per second, so that frequency variations can be read off directly. Precautions have to be taken that the instrument itself does not vary its frequency. Over short intervals of time this is easily attained, but over long intervals of time its absolute frequency is checked by highly accurate wave-meter measurements. In what follows, the instrument will be referred to as a "frequency meter" for shortness.

The following are some of the observations made on the Northolt arc, which normally is less steady than that at Leafield, and it was thought that this might be a function of the higher frequency at which the former arc is worked.

(1) *Arc with a resistance load of 2 ohms in the primary circuit and the aerial circuit disconnected.*—It was found that the variation of mean frequency was not great, but that the beat note on the frequency meter was ill-defined, indicating that the variation was too rapid to allow a musical beat note to be obtained. No quantitative idea of the magnitude of the variation was obtainable.

(2) *Similar conditions of circuit, but with a large condenser shunted across the arc.*—The frequency variations were the same as in case (1).

(3) *Arc with normal circuit coupled to aerial with auto-transformer coupling.*—The beat note was now found to be clear and musical. The mean variation on the frequency meter was of the order of 2 to 3 cycles per sec. Weather calm.

(4) *Conditions of* (3) *repeated but with a large condenser shunted across the arc.*—The beat note became even clearer and more musical than in (3) with the same order of mean variation.

These tests indicate that the arc itself is unstable, but that the coupled circuit exercises a stabilizing tendency and that the addition of a condenser in shunt across the arc improves the stabilizing properties of the circuit. The instability of frequency of the Northolt arc set was found not to be due to the high frequency but to aerial variations.

Similar results to these have been obtained at Leafield, except that in the case of coupled circuit without the shunt condenser across the arc the beat note on the frequency meter is definitely not good.

What may perhaps be called the steady "instantaneous frequency" obtained with coupled-circuit working is partly the explanation of the enormous reduction of mush which is observed. As explained at the commencement of the paper, mush is thought to be due to the very rapid, though possibly small, changes of fundamental frequency.

The property of a coupled circuit of reducing permanent or prolonged frequency-changes is, of course, obvious from a reference to Fig. 8. If, for instance, the arc is oscillating at a point such as f_1, and the frequency tends to increase, due, say, to some irregularity in the extinction period, such as a short period of excess ionization causing earlier ignition, then the secondary circuit will put back into the primary circuit a larger value of $(\omega^2 M^2/Z_2^2)X_2$. In this particular mode of oscillation, f_1, this quantity acts as an effective inductance in the primary circuit, and its increase tends to slow down the oscillation and to some extent to compensate for the change of frequency. The order of compensation for small changes of this kind has been calculated for various portions of the curve, and in general it may be stated that the magnitude of the variations is halved. This reduction is not large and would not be sufficient to explain the remarkable difference in purity and steadiness of note between plain aerial and coupled-circuit working.

A change of frequency of the current in the secondary circuit, however small, cannot take place instantaneously. This, in itself, would be sufficient to explain the purity of note, due to the suppression of rapid variations, when the signals are heard at a considerable distance. The same phenomenon of purity of note is, however, evident at the station itself, where of course the current in the primary circuit is heard strongly. The stabilizing effect of the condenser shunted across the arc also appears to be of some importance.

There seems to be a possibility that the secondary current has some action upon the irregularities liable to occur in the arc cycle, more particularly those in the extinction period. Unfortunately the efforts made to get experimental evidence of this by oscillograph records have failed, due to the enormous stray magnetic and electric fields at the wireless station clouding the phenomena which it was desired to observe.

Such oscillograph observations as were made, however, indicated that with the shunt condenser across the arc the extinction voltage was slightly higher than the d.c. voltage across the arc. It is fairly obvious that the particular shunt condenser employed ($0 \cdot 0125\ \mu F$) is large enough to absorb the surplus current when the arc is finally blown out, thus preventing the rise of voltage which normally occurs at extinction. In the normal arc circuit the arc becomes unstable when the current is reduced to a certain small quantity, and at this point the magnetic field blows out the arc suddenly, causing a rush of current into the external circuit. This in turn produces a rise of voltage, due to the inductance of the circuit. The rise in voltage tends to maintain the arc and delay the blow-out slightly, and the arc is stretched out farther before it finally goes out. With the shunt condenser, however, the surplus current is absorbed without producing much rise of voltage, and the arc should therefore go out at a shorter length than in the normal case.

If it may be assumed that the ionization in the gap between the electrodes is dependent to some extent upon the final distance of the arc from this gap, then

the longer arc will leave less ionization in the gap than the shorter arc given by the shunt condenser condition. Further, the low extinction voltage and short final arc of the shunt condenser condition are more favourable to action by a small external E.M.F., such as that acting from the secondary circuit. If this E.M.F. is increased from any cause, the suggestion is that the final arc length is increased and the ionization in the gap lowered. This in turn will delay the re-ignition and cause a lower frequency to be generated. Now if the primary circuit tends to get out of step with the secondary, due, say, to excess ionization causing early ignition, the secondary current will not change instantaneously and hence the phase of the two currents will change. The normal phase relations at the f_1 oscillation point are such that the secondary current is about 10 degrees behind the primary current. The magnitude of the E.M.F. in the primary, due to the secondary current, is therefore of the order of 330 volts at the moment of extinction. The rate of change of this E.M.F. at this point is approximately 33 volts per degree shift of phase. An increase of the phase difference between primary and secondary will therefore produce a larger reaction voltage which, it is suggested, tends to compensate by reducing the ionization in the gap.

The voltage at ignition will also be affected by the secondary reaction voltage, but as the actual ignition voltage is in the neighbourhood of 3 400 volts it is unlikely that the reaction voltage will have much direct effect on the ignition, except, as suggested, through the medium of the ionization.

Some confirmation of this suggestion is given by the following experiments.

(1) Using the coupled circuit in both cases, the frequency generated was found to be higher by 40 cycles per sec. when no shunt condenser was employed than with the shunt condenser. Making allowance for the normal compensating effect of the coupled circuit, this is equivalent to a change of 80 cycles per sec. in the primary frequency, which is further equivalent to a reduction of the extinction period to two-thirds of that in the shunt condenser case. Making the usual assumption that, during the extinction period, the condensers are charged at constant current, the charging rate for the shunt condenser case is two-thirds of the without-shunt-condenser condition. Therefore the reduction of the extinction period is given both by calculation and experiment.

The peak value of the ignition voltage was measured in both cases and was found to be nearly the same, viz. 3 200 volts in the without-shunt-condenser case, against 3 400 volts with shunt condenser.

It follows, therefore, that if with the 50 per cent longer time interval of extinction the ionization, as indicated by the ignition voltage, is nearly of the same order as in the without-shunt-condenser case, then the ionization must have started at approximately a 40 per cent higher level, which agrees moderately well with the known smaller extinction voltage in the shunt condenser condition.

(2) The stabilizing tendency of the shunt condenser should only apply to the low-frequency mode of oscillation, f_1. In the f_2 mode of oscillation the phase relationships of the currents in the two circuits are reversed and, moreover, the reaction E.M.F. is now acting in a reversed direction, the net result being a tendency to increase instability for rapid fluctuations.

Actual listening tests show the mush to be more pronounced when oscillating on the high-frequency than on the low-frequency side.

(3) A resistance of 5 ohms was inserted in the shunt condenser circuit. The effect of this would be to reduce seriously the current-absorbing properties of the shunt condenser. Actual listening tests at the station showed the mush to be much worse with this arrangement.

The above discussion refers to the instantaneous irregularities of frequency and we will now turn our attention to the larger and slower variations which are liable to occur.

Some of the most probable of the causes of such variations are as follows :—

(*a*) Changes of d.c. voltage across the arc.
(*b*) Changes in ionization, due to variation in quantity of methylated spirit fed to the arc.
(*c*) Change in the capacity of the primary condenser, due to alteration of temperature.
(*d*) Swing of aerial affecting capacity or inductance.
(*e*) Rain or mist affecting leakage or electrostatic capacity of aerial.

As already stated, the coupled circuit only halves the variation due to a permanent or semi-permanent cause, and it is therefore of importance to reduce these effects as much as possible by correct design or management.

These items were dealt with individually, with the following results.

(*a*) No variation in frequency due to changing the d.c. supply within the limits ordinarily used could be traced.

(*b*) Starving the arc of methylated spirit produces a change of 10 cycles in the frequency; and flooding the arc with the spirit produces a similar change. These are, however, extreme conditions rarely met with in practice.

(*c*) After a prolonged run the temperature of the air in the circuit room rises, and this causes a small, slow change in the frequency, through alteration of the capacity of the condenser; on the marking wave this is compensated by a carbon resistance in the keying circuit, which has an opposite effect on the frequency as the temperature rises.

(*d*) The top, flat portion of the aerial at Leafield consists of 16 parallel wires strung up tightly, 30 ft. apart, and these do not appear to contribute anything appreciable to the frequency variation. The down-lead consists of extensions of these 16 wires coming down in fan-shaped formation to two points near the leading-in insulator, the height of the latter above ground being about 20 ft.

The experiment was performed of exciting the aerial with a small valve oscillator and observing the variations of frequency on a windy day by means of the frequency meter and at the same time observing the movements

of the aerial. The maximum variation of frequency observed was 16 cycles per sec. (which on coupled circuit working would be reduced to 8 cycles) and this was definitely correlated with the movements of the wires in the bottom portion of the fan-shaped down-lead, where the wires were in close proximity. Calculation shows that changes in capacity and inductance of a multiple antenna are greatest when the wires are close together, and that if there were no external loading these changes would tend to compensate each other in their effect on frequency. The effect of the aerial tuning inductance is, however, to render of small effect any change in the inductance of the antenna, and the capacity changes predominate. Arrangements are therefore being made to modify the down-lead with a view to reducing this swinging effect of the separate wires. The variation of frequency in normal weather is only 2 to 4 cycles per sec. and in certain windy weather, particularly with S.W. winds, the variation is of the order of 6 to 8 cycles. It is hoped that this latter variation will be reduced by the alterations contemplated.

(*e*) It might be expected that the dielectric constant of the air under the antenna would be increased by the presence of moisture, but there appears to be no material alteration of the aerial constants from this cause. Leakage might also be expected to change the frequency generated in the case of coupled-circuit working, but there does not appear to be any appreciable effect due to this cause. No difficulty exists in starting up on a wet day and it is probable than any leakage dries out quickly.

Section 6.

Elimination of Harmonics.

The lower-frequency harmonics which had formerly troubled Devizes and other wireless stations were found to have been eliminated by the coupled circuit, but no improvement was observable on the broadcasting band of wave-lengths which were still interfered with by some of the higher harmonics of Leafield.

Attention was therefore paid to tracing the source of these harmonics at the station itself and suppressing them by various expedients.

The apparatus used for this purpose was of two kinds:

(1) A small frame coil tunable to the broadcasting range and with a small 2-volt lamp as indicator.
(2) A portable heterodyne oscillator covering the broadcasting range.

Of the two kinds, the latter proved more generally useful, as it could be carried about outside the station and would still pick up the harmonics at a comfortable strength.

It will be remembered that in Section 4 the relative merits of condenser and inductive coupling were discussed and it was shown that inductive coupling tended to pass the higher harmonics. At Leafield, however, the primary circuit condenser has a capacity to earth of 0·002 μF which, as will be seen from the diagram in Fig. 14, acts as a shunt across the coupling coil for these higher harmonics. Owing, however, to the somewhat congested layout of the circuit at Leafield, there is fairly close proximity between portions of the primary and secondary circuits, with a possibility of stray coupling between these points.

The keying coils, on account of their proximity to the aerial coil, probably transferred the harmonics directly to the aerial coil without passing through the shunted coupling. The steps taken to reduce this effect were to shunt the keying coils by placing a condenser of 0·01 μF across them and by connecting this condenser to earth through a condenser of 0·001 μF, the object of which was to keep the harmonic potential of the keying coils as low as possible. A small resistance was also placed in the key side of the coils for damping purposes.

The condenser shunted across the arc was next found to be a source of harmonics, as was proved by the great reduction of the series of harmonics when the condenser was removed. This condenser, however, performs too important a function in stabilizing the frequency and in increasing the current output to allow it to be removed. Various experiments in the nature of adding damping to this circuit were made and were found to

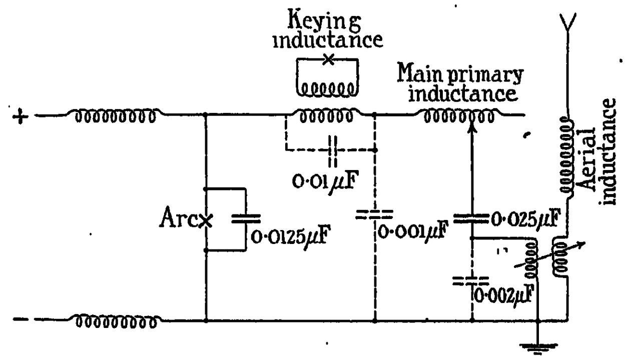

Fig. 14.—Diagram giving position of condensers (shown dotted) for shunting harmonics.

reduce the harmonics considerably, but these have not been adopted on account of the increase of mush. At Northolt, the extinction period being very short, the shunt condenser has only a small effect in stabilizing the frequency, and the damped-shunt condenser circuit is in use.

Damping circuits across the d.c. choke coils were also tried, but produced no improvement.

It was now thought that direct radiation from the primary circuit was the cause of disturbance in the immediate vicinity of the station, and steps were taken to screen the building. This was found to cause a considerable improvement locally.

By this time the only place which complained of disturbance on the broadcasting band was a town about 6 miles from Leafield, although places not so far away were immune. The telephone circuit from this town to the station was suspected and it was found that the heterodyne oscillator before mentioned, when held 2 ft. away from the switchboard in the telephone exchange at the town, could pick up the harmonics from Leafield. Steps were taken to place air-core choke coils of 2 000 μH inductance and 8 $\mu\mu$F self-capacity in the telephone and telegraph wires, and this

operation has quite removed the trouble in the town concerned, which is now quite clear of harmonics on the broadcasting band of wave-lengths.

It is rather curious how these high harmonics could get on to the telephone wires, because the circuits are in an underground cable for about a mile from the station. The cable sheath apparently carried harmonics, as the track of the cable across the field could be traced by walking across the route carrying the heterodyne oscillator. The choke coils were placed in the wires where they emerged from the cable and also at the point where they entered the adjacent town.

Section 7.

Keying of the Coupled Arc.

This is performed, as indicated in Fig. 14, by keying in the primary circuit only. The difference in frequency between spacing and marking is only 80 cycles per sec., so that the amplitude of secondary current is nearly the same in both cases. This constancy of amplitude avoids the considerable disturbance in the neighbourhood of the fundamental frequency which is present on systems employing a suppressed wave during spacing.

The authors have not attempted to give a complete bibliography covering the subject, as fairly extensive lists have already been given by Pedersen * and Elwell.†

They desire to thank Colonel Purves, the Engineer-in-Chief of the Post Office, for permission to publish the results of the experiments. They would also like to acknowledge the cordial co-operation and assistance of Mr. R. G. de Wardt, the engineer-in-charge of the Leafield station, who carried out many of the experimental tests and, in addition, specially devoted himself to the suppression of the residual harmonics.

* P. O. Pedersen: "The Poulsen Arc and its Theory," *Proceedings of the Institute of Radio Engineers*, 1917, vol. 5, p. 255.
† C. F. Elwell: "The Poulsen Arc Generator."

Discussion before the Wireless Section, 1 April, 1925.

Mr. C. F. Elwell: I am gratified to hear that the divided-wire inductance has been so successful and that the authors contemplate using divided wire in the variometer. It is interesting to know that a cheap form of insulation can be obtained by using ordinary dry whitewood, though I question whether this would be useful where divided wire is employed, as the corona effect from the small wires would probably cause burning to start. The apparatus for observing the frequency is ingenious, and the results obtained are very interesting. I do not think it is at all surprising that the condensers tend to stabilize the arc; that was the original object of putting a plain shunt condenser across the arc. The changes of frequency due to a variation in the quantity of methylated spirit fed to the arc are interesting. They rather point to the necessity for research along these lines. I should like the Post Office to try pure hydrogen, as it has many advantages.

Mr. R. V. Hansford: The average wireless engineer is apt to think that the arc is obsolete on account of the two great disadvantages which it possesses, viz. the emission of "mush" and the variation of frequency. By fitting a coupled circuit to the arc at Leafield and, by so doing, overcoming, to a very great extent, both those disadvantages, the authors have demonstrated quite successfully that the arc has been rescued from immediate obsolescence. I say "immediate" because I believe that ultimately the valve must take the first place. I do not think that there is much scope for the arc even now, except for aerial powers greater than 100 kW. I was responsible, in association with Mr. Faulkner, for the experiments at Stonehaven and the installation of the coupled arc at Northolt to which the authors refer. An experience such as that enables one to appreciate to the full the nature of the success at Leafield, and it is a source of satisfaction to know that the conclusions arrived at from our small efforts on small- and medium-power arcs have been confirmed in the repetition on a larger and more difficult scale at the high-power station at Leafield. The coupled arc at Northolt was not put in as a preliminary to Leafield, but as an absolute necessity. When the installation was started up for the contractor's acceptance tests it created such a stir amongst receivers in London that it was necessary to put a coupled circuit in before it could be used commercially. Messrs. Dubilier kindly supplied a temporary high-power condenser at very short notice, and the coupled circuit was in use commercially within a very few weeks. It seems to me that on two occasions in the paper the basis of the theory is given as an accepted fundamental principle which the average reader would not willingly accept without some explanation. In the early part of Section 2 the authors state: "It is known from theoretical principles that the efficiency of a coupled circuit is greater as the ratio of C_2/C_1 increases." I do not know that I could accept such a generalization as it stands. Theoretical considerations have led me to believe that as regards the use of a coupled circuit with a valve transmitter, the efficiency under ideal conditions is independent of the ratio of C_2/C_1; in practice, of course, the smaller the condenser the larger is the inductance and the larger the corresponding resistance losses and also, as the authors point out, the larger the voltage on the condenser; so that, in practice at any rate, there is a tendency to make C_2/C_1 as small as is reasonably possible, rather than large as suggested by the authors for an arc circuit. I can only conclude, therefore, that this expression in regard to efficiency applies to the arc in particular, and I think that point is worthy of a little more elaboration and justification. In the early part of Section 3 the authors state: "It is well known in this case that the frequency generated will be such that the net impedance of the primary circuit is zero." As a statement of principle I think that needs a little justification. Immediately afterwards the authors equate the reactance to zero, and, although they say on the next page that they have neglected resistance, I am not sure if they intended the sentence to read "net reactance" or "net impedance." Personally I

do not think that either statement would be strictly accurate.

Commander F. G. Loring: Although I have had nothing to do with the design of the Leafield station, I have had much to do with the results obtained, and they show, as I know from reports received, that an immense advance has been made during the past few years. Engineers in all parts of the world are interested in this Leafield experiment. I have been greatly struck by the amount of work involved in obtaining these results, not only as regards the maintenance of constant frequency in long-distance communication but also as regards the elimination of "mush" and harmonics. On the broadcasting band we used to receive a very large number of complaints. The complaints have not ceased, because a considerable body of listeners-in still blame Leafield and Northolt for any trouble that occurs in the broadcasting band. I am convinced, however, that those complaints are not now justified.

Mr. R. E. H. Carpenter: I should like to ask the authors their opinion as to the possible usefulness of a

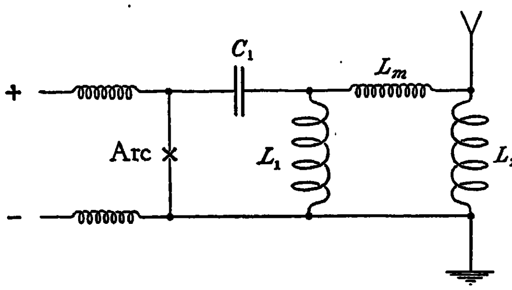

FIG. A.

method of coupling which is not referred to in the paper, and which I can explain more readily in diagrammatic form (see Fig. A). If a choke L_m of small self-capacity and high reactance were connected in the manner shown, it should give the desired advantage as regards the passage to the aerial circuit of the fundamental frequency, with increasing impedance for the harmonics. It is conceivable that that might form a cheap and convenient way of effecting the desired type of coupling. The three coils could be conveniently at right angles.

Mr. A. C. Warren: I should like to identify myself with Mr. Hansford's remarks on the efficiency of coupled circuits. I presume that in their statement on page 698 the authors intended to refer to the overall efficiency of the coupled arc, in which case the evidence is experimental rather than theoretical. Experiments at Northolt showed that the efficiency increased with the ratio C_2/C_1, as indicated in Table A.

TABLE A.

Method of working	C_2/C_1	Efficiency
		per cent
Coupled circuit	0·7	25
Coupled circuit	1·4	28
Coupled circuit	2·65	39
Plain aerial	—	34

In Section 5 the authors state that the frequency-changes due to circuit variations are halved by the use of the coupled circuit. At Leafield, under the working conditions the primary and secondary currents and circuit constants are approximately equal. Further, the second term in the equation for determining the frequency (page 703) may be rewritten $(I_2^2/I_1^2)X_2$; thus it seems to me that the compensation which occurs actually balances the variation, since I_2/I_1 is approximately unity for small circuit variations. This would account for the exceptional constancy of frequency obtained at Leafield.

Dr. W. H. Eccles: It would be very interesting if the authors would explain, briefly and in simple language, why an arc will maintain a coupled circuit in only one frequency. A coupled circuit has two natural frequencies and will, when sparked, give two wave-lengths simultaneously. If, however, it is put on an arc circuit, it will be excited in only one of these frequencies. Why is only one frequency excited by an arc at a time, and why does the arc sometimes prefer the shorter and sometimes the longer of the two wave-lengths? The mathematical explanations have, of course, been published; what I should like to hear is a physical one.

Mr. R. G. de Wardt (*communicated*): The coupled circuit at Leafield has now been in use for over 12 months, and testimony to the excellence of the design is given by the fact that although Leafield transmits on an average for 18 to 20 hours a day, on only one occasion has it been necessary to revert to plain aerial working. This was a few days after the coupled circuit had been brought into use and before the intricacies of tuning had been fully mastered, and was then only necessary to avoid delay in a transmission. The condenser design is the most novel feature of the circuit, and it will be of interest to members of this Institution to know that during tuning tests three of these condensers were operated at a potential of 90 000 volts at a frequency of 25 000 cycles per sec. for over an hour without any difficulty being experienced. A point which the authors do not mention is the sharpness of the emitted wave. I have received correspondence from all over the world relative to Leafield's transmissions, and the majority of the writers comment on the sharpness of the tuning. Leafield's 12 350-m wave is perhaps unfortunately situated in that it is close to the wave-lengths of several of the American high-power stations, together with Nauen and Stavanger, so that sharpness of the emitted wave is of importance. A correspondingly high degree of selectivity on the part of the receivers used to receive Leafield's signals is of course necessary if full advantage of this feature is to be taken. The constancy of the wave-length is, as the authors point out, a very important point, and an interesting commentary on this was furnished by the engineer in charge of the American station with which Leafield works traffic. He stated that the note of our signals gradually changed during a long transmission. Careful checks failed to find any drift in the frequency of the emitted wave, and this change in note appears to be due to the variation in heterodyne note of the receiver due to variation in

filament brilliancy. With regard to the elimination of mush on the broadcasting band in the near vicinity of the station, the screen over the building containing the arc transmitter and the primary and secondary circuits has, without doubt, been the most effective method of prevention. This screen only affected local listeners and had no effect on the mush in London, for example. Before this was adopted, the experiment of earthing the aerial at the lead-in, and energizing the primary circuit with full normal current, was tried. No difference in mush could be noticed at a distance of 2 miles. Fears were expressed that such a screen would cause heavy losses, but no appreciable difference can be noticed. Care was taken when erecting the screen in so selecting the earthing points that no one wire carried an abnormal current. This screen, which has now been up for some months, appears to be less effective than when first erected, probably owing to the fact that only dry joints were used, the screen being of an experimental nature. It is now being replaced by a permanent arrangement in which all joints will be soldered.

Major A. G. Lee and **Mr. A. J. Gill** (*in reply*): Mr. Elwell raises the question of the use of American whitewood as insulation for coils composed of divided wire. We have so far observed no trouble from corona, but in any case steps are ordinarily taken to design the coil to run below the corona limit. We agree with Mr. Elwell on the advantages of the use of pure hydrogen, and it is proposed to try it when a suitable opportunity occurs.

Mr. Hansford and Mr. Warren both suggest that the statement in regard to the dependence of the efficiency upon the ratio C_2/C_1 is not based on theoretical principles. They may perhaps be referred to the paper by Chaffee * on the amplitude relations in coupled circuits. He found that the ratio of I_2/I_1, for both higher and lower frequency oscillations, was proportional to $\sqrt{(C_2/C_1)}$, and we have verified this relationship to hold for the undamped free oscillations of the arc circuit. This amplitude ratio is unaffected by the resistance of the circuits unless the resistance is very large. The maximum circuit efficiency, apart from other considerations, is obtained by increasing the ratio of I_2/I_1 as much as possible, because resistance losses in the primary represent pure waste. As has been pointed out in the paper, voltage limitation in the condenser design is the principal determining factor in this direction. Mr. Warren's experimental results are of interest in corroborating the theoretical relationship.

Mr. Hansford also suggests a confusion between the terms "impedance" and "reactance" in connection with the remarks on the frequencies generated by the coupled circuit, and disputes the axiomatic nature of the principle that "the frequency generated will be such that the net impedance of the primary circuit is zero." This is such an old well-accepted principle that it is somewhat surprising to find it challenged at this date. The theorem has been well expounded by Kennelly † in a very interesting paper published in 1916, though, as was pointed out in the discussion on Kennelly's paper, the theorem was in use by Heaviside and Perry. From a physical point of view the statement is fairly obvious, because there is no physical alternating E.M.F. to drive the oscillating current which actually exists. As the sum of the alternating voltages round the circuit is zero, the net impedance must also be zero. The angular velocity of the oscillation will be such as to bring about this condition. It should be mentioned that the discontinuity in the arc cycle introduces an unknown factor into the question of frequency, which cannot be taken into account mathematically. The use of reactances, instead of impedances, in the equations in the paper is the usual approximate method of determining the frequency, and inasmuch as the negative resistance of the arc balances the positive resistance of the circuit, when taken over a complete cycle, the result is sufficiently accurate. The discontinuity in the arc cycle prevents the complete mathematical expression of the resistances (including negative resistance) in the circuit.

Mr. Carpenter's suggested coupling is interesting, and it is thought that the choke feed to the secondary circuit would be effective in reducing the transmission of harmonics. Without an actual trial it would be difficult to say whether it would work smoothly. In the f_1 type of oscillation the choke would carry only a few amperes, whilst in the f_2 oscillation it would have the full antenna current flowing through it, which would give rise to peculiar effects in regard to the tune of the circuit.

Mr. Warren suggests an explanation for the constancy of frequency at Leafield. As was pointed out above, I_2/I_1 is proportional to $\sqrt{(C_2/C_1)}$, hence it follows that the current ratio cannot remain constant for small circuit variations as suggested.

Mr. de Wardt's remarks on the screening of the building emphasize the necessity for preventing the primary circuit from emitting disturbances which will affect points in the near vicinity of the wireless station. It may be of interest to mention that recently at Northolt the same problem has been met in another way. The primary coil had a large number of spare turns which have been short-circuited by a condenser which tunes them to a point above the broadcasting band. Any harmonic current in the primary on the broadcasting band will then induce in the short-circuited turns harmonic current which is 180° out of phase with the harmonic current in the primary, thus producing a counter magnetic field, which for points outside the station cancels out the main field due to the primary. The condition for cancellation is that the harmonic ampere-turns in the short-circuit coil must equal the harmonic ampere-turns in the primary coil.

The question raised by Dr. Eccles is a difficult one to answer satisfactorily, because the answer is not capable of convincing proof. In the first place, as already suggested in the paper, the coupled arc appears to be capable of performing on only one frequency at a time, because of the effect of the discontinuity in the arc cycle. It is, perhaps, not generally realized that a system of two ordinary coupled circuits can be made to oscillate on only one frequency, by suitable arrange-

* E. L. Chaffee: "Amplitude Relations in Coupled Circuits," *Proceedings of the Institute of Radio Engineers*, 1916, vol. 4, p. 283.

† A. E. Kennelly: "The Impedances, Angular Velocities and Frequencies of Oscillating Current Circuits," *Proceedings of the Institute of Radio Engineers*, 1916, vol. 4, p. 47.

ments of the initial charges in the circuit (the experiment is easily demonstrated with two coupled pendulums). Such a system of oscillation is perfectly stable in the absence of any disturbing force. It would, however, be expected that such disturbing forces might be present in an arc circuit, but this is where the effect of the discontinuity in the arc cycle is felt. If we assume one type of oscillation to have been built up and then we introduce a disturbance which tends to set up the other type of oscillation, it is thought that the gap in the arc cycle—during which there is no current through the arc—would tend to choke out the building-up process of the second type of oscillation. A similar phenomenon is present in coupled-valve oscillation circuits, in which a heavy negative bias on the grid prevents more than one type of oscillation being maintained, the oscillation with the lower amplitude under the particular circuit conditions being eliminated. At the isochronous position it is found that the arc invariably comes up on the lower-frequency side. When the tuning is carried beyond the isochronous position, in the high-frequency direction, but below the point where the frequency discontinuity appears, and the arc is started up, the lower frequency is generated in about 75 per cent of the times, while in 25 per cent the arc comes up on the higher-frequency oscillation, which frequently reverts to the low side after running for a short time. These facts are difficult to explain; they seem to hold only for the inductive type of coupling and may even be individual to the particular circuit layout employed.

Mr. Hansford refers to the arc as having been rescued from immediate obsolescence. This is, however, a question of economics. The arc and valve are now on a par in regard to technical performance, except for the lower power efficiency of the arc. The future will therefore decide upon the relative running costs of the valve station, with its expensive maintenance, and the arc station with its low maintenance charges but higher power costs.

DISCUSSION ON "SOME ACOUSTIC EXPERIMENTS WITH TELEPHONE RECEIVERS." *

Mr. M. D. Hart (*communicated*): I should like to express my appreciation of the authors' method, given in Part I of the paper, for determining the natural frequency of a telephone diaphragm, but I wish to join issue with them on the subject of their measurement of "overall acoustical-electrical efficiency." From the figures given in Table 10 it would appear that the energy flux of the sounds which were used was as great as $22 \cdot 48$ ergs per cm^2 per second, and the measurement of these figures is based on the validity of the adiabatic law at the amplitudes encountered. I would point out that Rayleigh's figure for the amplitude of a just-audible sound of frequency 256 periods per sec. is $1 \cdot 27 \times 10^{-7}$ cm,† and from this figure the corresponding energy flux may be calculated as $8 \cdot 5 \times 10^{-7}$ ergs per cm^2 per second, using the expression $\frac{1}{2}\rho n^2 a^2 c$ for the energy flux.‡ Thus it seems that the energy flux of the sounds dealt with in the paper were of the order of tens of millions of times as great as that of the minimum audible sound, and the application of the adiabatic law, on the assumption of the correctness of which the authors' calculations are based, to such amplitudes is very improbable. Further, it has been shown § that, in the case of sounds of frequency 100, an energy flux of about 15×10^{-4} ergs per cm^2 per second involves quite an appreciable value of what is called the "degradation coefficient," showing that even for these amplitudes, which correspond to a fairly loud sound, the divergence from the adiabatic law may not be neglected. Moreover, it is shown in the last-mentioned paper that, when the values of the degradation coefficient are of the order of those investigated therein, a large fraction of the sound energy emitted from the source is degraded into heat in the atmosphere through which the sound passes, so that a measurement of efficiency based upon energy readings taken at an arbitrary distance from the source does not represent the true "acoustical-electrical" efficiency of the latter. To sum up: the values for the energy flux quoted in the paper are so enormous that the validity of the adiabatic law on which their calculation is based is very questionable and, even if they be correct, the figure given for the efficiency of the receiver does not truly represent that quantity and should be qualified by the distance from it at which the observations were taken in any particular case.

Dr. E. T. Paris (*communicated*): Experiments of the kind described in the paper are of great interest and importance to those concerned with acoustical measurements, and it is satisfactory to learn that a direct measurement of the acoustical-electrical efficiency of a telephone receiver can be made with, apparently, so little difficulty. In connection with these efficiency measurements, however, there is one point to which I think more attention should be paid. The method of measuring the acoustical energy flux described in the paper depends on the correctness of the equation given on page 512 for the particle velocity in a spherical sound-wave, and the experimental verification of this equation might well be extended in view of the fact that recent experiments have led us to expect an appreciable degradation of sound-energy in the neighbourhood of sources of quite moderate output. In view of my own experience with sound-absorbing materials, I was at first rather surprised to see that the 4 inches of cotton waste used by the authors to line the sound-chamber in which the experiments were performed was so effective as "to prevent any trouble from reflected waves." We have, at the Signals Experimental Establishment, Woolwich, apparatus by means of which the sound absorption-coefficient of any material can be readily measured, and it was thought that some observations on a 4-inch layer of loosely packed cotton waste, as used in the experiments, might be of interest to the authors. The result showed that this substance has a very high absorption coefficient, two measurements with sound of frequency 512 vibrations per second giving the values $0 \cdot 92$ and $0 \cdot 91$ respectively, the layer of cotton waste being backed by three layers of five-ply wood glued together. This means that over 90 per cent of the incident sound-energy is "absorbed" (i.e. not reflected), so that a surface which is covered with this material approximates to one which is acoustically "black." The method employed for measuring the absorption-coefficient was the "stationary-wave" method, in which use is made of the interference phenomena occurring between the incident sound-wave and that reflected from the specimen under test. Although over 90 per cent of the incident sound-energy was absorbed by the cotton waste, these interference phenomena were still quite well marked, and gave rise to positions of maximum and minimum pressure-variation in front of the specimen, such that the amplitude at a maximum was about $1 \cdot 8$ times that at a minimum. The experiments showing the effect of an air cavity on the frequency of a telephone diaphragm are especially interesting. It seems that it might be possible to employ the observed change in the fundamental frequency of a diaphragm due to an air cavity of known volume for the purpose of calculating the equivalent mass of the diaphragm. If the diaphragm is supposed to be replaced by a simple piston-like vibrator of mass m controlled by a mass-less spring of stiffness S, the calculation of the additional stiffness S' in terms of the volume of the air cavity and the area and mass of the piston does not appear to present any

* Paper by Prof. E. Mallett and Dr. G. F. Dutton (see page 502).
† Cf. Lord RAYLEIGH: "Theory of Sound," 1896, vol. 2, p. 439.
‡ Cf. HORACE LAMB: "The Dynamical Theory of Sound," 1910, p. 167.
§ M. D. HART: "On the Degradation of Acoustical Energy," *Proceedings of the Royal Society*, A, 1924, vol. 105, p. 82.

special difficulty, and it would be interesting to see how the equivalent mass determined in this way compares with that found by other means, such as loading the diaphragm, or the alternative method described by Kennelly in "Electrical Vibration Instruments," Chapter 10. The double-resonance phenomena observed when the air cavity is extended into a long tube (Table 5 and Fig. 12, p. 510) recall the effects observed with certain acoustical double resonators, the theory of which has been dealt with by the writer.* By an extension of the method employed in the papers referred to, an equation can be derived from which the resonance frequencies of a simple tube and diaphragm combination could be worked out, provided that we know the equivalent mass and area of the diaphragm. For a tube of length L and cross-sectional area σ_1, closed at one end by a rigid plate and at the other by a diaphragm of equivalent mass m and area σ_2, the resonance frequencies are those values of f which satisfy the equation

$$\cot \frac{2\pi f L}{a} = \frac{2\pi\sigma_1 m}{a\sigma_2^2\rho} f_0\left(\frac{f}{f_0} - \frac{f_0}{f}\right)$$

where f_0 is the resonance frequency of the diaphragm, a is the velocity of sound, and ρ is the density of air. This equation should be applicable, provided σ_2 is equal to or less than σ_1. In the actual experiment described by the authors, the cross-sectional area of the tube was considerably less than the area of the diaphragm, i.e. $\sigma_2 > \sigma_1$. In this case there is of necessity a widening of the tube at the diaphragm end and the matter is not so simple. I do not think that the combination can then be treated as a coupled system with only two components. The extra volume of air in the wider part of the tube will give rise to a third component, equivalent to a Helmholtz resonator interposed between the straight tube and the diaphragm. The combination is then straight tube—Helmholtz resonator—diaphragm, the end of the straight tube forming the neck, and the diaphragm part of the wall, of the Helmholtz resonator. If the combination is treated as a system with two components only (tube and diaphragm), and four times the length of the tube is taken as the wave-length appropriate to the tube component, we get the rather curious result that one of the resonance frequencies of the coupled system sometimes lies between the frequencies of the two components (see Table 5, p. 510, tube lengths 14·7 and 19·9 cm). The resonator and telephone combination shown in Fig. 14 should also show double-resonance phenomena. The arrangement is analogous to the "Boys resonator," the theory of which has been developed by the writer in the papers quoted above. The Boys resonator consists of a tube open at one end and leading at the other through a short neck into a Helmholtz resonator. The resonance frequencies of the Boys resonator are given by values of f which satisfy the equation

$$\tan \frac{2\pi f L}{a} = -\frac{2\pi\sigma_1}{ac} f_0\left(\frac{f}{f_0} - \frac{f_0}{f}\right)$$

L being the length and σ_1 the cross-sectional area of the tube, while c is the hydrodynamical conductance of the neck of the Helmholtz resonator and f_0 is its frequency. The Helmholtz resonator is equivalent to a simple vibrator of mass m, approximately equal to the mass of air in the neck. If the cross-sectional area of the neck is σ_2 and its length is l, this mass is $\rho\sigma_2 l$. Also, since the conductance c is approximately equal to σ_2/l, we have $c = \sigma_2/l = \rho\sigma_2^2/m$. Substituting this value of c in the frequency equation, we obtain

$$\tan \frac{2\pi f L}{a} = -\frac{2\pi\sigma_1 m}{a\sigma_2^2\rho} f_0\left(\frac{f}{f_0} - \frac{f_0}{f}\right)$$

and this will be the equation for determining the resonance frequencies of a double resonator made from a tube of length L and cross-sectional area σ_1, closed at one end by a diaphragm of equivalent mass m, area σ_2 and frequency f_0. This equation can, of course, be obtained quite independently of the theory of the Boys resonator, but the process is longer.

Prof. E. Mallett and Dr. G. F. Dutton (*in reply*): With regard to the "degradation of acoustical energy" and the applicability of the usual theory involving the adiabatic law, the authors' experiments do not confirm the results arrived at by Mr. Hart in his paper. The energy fluxes used in their experiments were very much greater than those used by Mr. Hart, and yet there was no indication of any "degradation." Table 7, for instance, shows that the variation of sound pressure and particle velocity at a frequency of 694 with radial distance from the equivalent source to be very closely in agreement with the usual theory, and Figs. 18 and 18 (*a*) give a similar result for a frequency of 439. These are not isolated results. Many other determinations agreed equally well. Two, at frequencies of 960 and 590, are illustrated in Fig. A. In all these cases the relation between

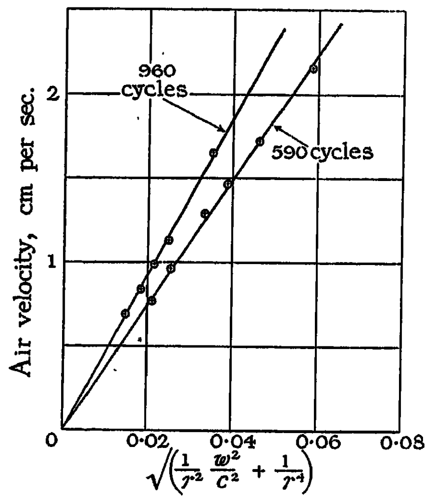

FIG. A.

$$\sqrt{\left(\frac{1}{r^2}\cdot\frac{\omega^2}{c^2} + \frac{1}{r^4}\right)}$$

and the particle velocity is seen to be represented by a straight line passing through the origin; whereas if

* *Proceedings of the Royal Society*, 1922, vol. 101, p. 301, and *Philosophical Magazine*, 1924, vol. 48, p. 769.

there were "degradation" of the order found by Mr. Hart the curves would be quite noticeably concave towards the abscissa. Again, Fig. 15 shows the relation between the exciting current of the telephone in the resonating tube and the particle velocity a few centimetres in front of the mouth. The fact that this is a straight line also indicates that up to a particle velocity of 4 cm per sec. at any rate there is no "degradation." For if any appreciable loss—increasing with amplitude—were taking place, either in the stationary wave within the tube or in the progressive wave outside, the rate of increase of particle velocity with exciting current would decrease as the latter was increased, and the curve would be concave towards the abscissa. Further, the various resonance curves of the telephone diaphragm taken by the Rayleigh disc would all have shown a flattening had marked losses been taking place in the

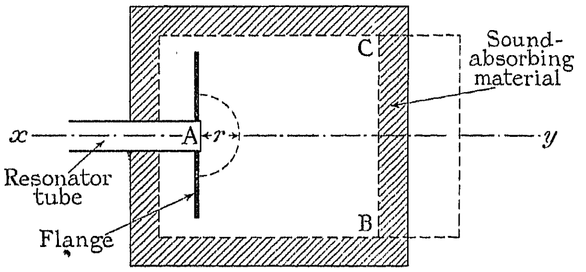

FIG. B.

sound wave, and such distortion would have been brought to light by the circle and straight-line construction. It appears, therefore, that at fluxes considerably greater than those used in the receiver efficiency determinations, and very considerably greater than those used by Mr. Hart, any "degradation" effect is negligibly small.

The measurements made by Dr. Paris on the sound-absorbing properties of cotton waste are very interesting and justify the authors' choice of this material for a lining for their sound chambers. The statement that no trouble was experienced from reflected waves refers of course to the measurements made, all within, say, 10 cm from the source of sound. In Fig. B, A represents the source of sound, xy the axis along which measurements were taken and CB the end wall of the box. Assume that the whole of the energy falls on CB, area 10 000 cm^2, and is reflected as a plane wave, and that measurements are being made 10 cm from A. Then taking Dr. Paris's figure of 91 per cent absorption the ratio of the reflected energy flux per cm^2 at A to the direct energy flux is $(2\pi r^2/10\,000) \times 0{\cdot}09$, or less than 0·6 per cent. When the distance from the source is 4 cm, as in the efficiency measurements, the ratio is 0·1 per cent. Actually, of course, the whole of the wave is not reflected direct from the end wall, but much of it strikes the other walls before reaching the area where measurements are being made, and at each reflection a further 91 per cent of the remaining energy is lost. The whole effect of reflection can therefore be neglected in the absence of resonance effects and standing waves, which at particular frequencies may give a little trouble. But even this may be avoided by a suitable choice of the positions of the apparatus within the box.

The authors did attempt to use the alteration of resonant frequency with alteration of cavity volume as a means of finding the equivalent mass. The problem reduces itself to finding the constant A in the equation $f_0^2 = \frac{1}{4\pi^2}\left\{\frac{S}{m} + \frac{A}{vm}\right\}$ at the top of page 508. For the slope of the curve of Fig. 9 is $A/(4\pi^2 m)$ and, if A is known, the equivalent mass m is found at once. Doubtless A could be determined mathematically, but then it would be necessary to assume that the diaphragm was vibrating according to the Bessel function theory. Or it might be determined from a static test, from measurements of the deflection at the centre with a given air pressure, but this would not be so simple as Kennelly's method of measuring the vibration amplitude at the centre at resonance.

Dr. Paris's remarks regarding the double-resonance curves are very interesting, and should help considerably towards a complete understanding of this complicated phenomenon. One of the objects of this series of experiments was to show that a diaphragm vibrating in any other mode than the fundamental was not coupled with the tube, and this was successfully demonstrated. That there actually are three members of the system, viz. diaphragm, cavity and tube, is clear, but the cavity is so far from its resonance that it can possibly be taken as merely modifying either or both of the other members, reducing the system in effect to one of two components.

PROCEEDINGS OF THE INSTITUTION.

43RD MEETING OF THE WIRELESS SECTION, 4 FEBRUARY, 1925.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 7th January, 1925, were taken as read and were confirmed and signed.

A paper by Messrs. L. B. Turner, Member, and F. P. Best, Student, entitled "The Optimum Damping in the Auditive Reception of Wireless Telegraph Signals" (see page 493), was read and discussed.

On the motion of the Chairman a hearty vote of thanks was accorded to the authors, and the meeting terminated at 7.22 p.m.

725TH ORDINARY MEETING, 5 FEBRUARY, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m., and announced that since the last meeting the Institution had lost two distinguished members, Mr. C. H. Wordingham, C.B.E., Past-President, and Mr. Oliver Heaviside, F.R.S., Honorary Member and Faraday Medallist. Votes of condolence with the families of the deceased were carried, the members standing in silence.

The minutes of the Ordinary Meeting of the 22nd January, 1925, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see page 237) was also taken as read and the thanks of the meeting were accorded to the donors.

The President announced the presentation by Colonel R. K. Morcom of a statuette of the late Sir Joseph Wilson Swan, President of the Institution in 1898, and asked Dr. Ferranti to make a few remarks regarding the work of Sir Joseph Swan in connection with the development of electricity.

Dr. S. Z. de Ferranti: There are not so many now who were personally acquainted with Sir Joseph Swan. I had the privilege of discussing with him many things which interested him particularly, and especially the question of electric lighting, and I think that perhaps it is owing to this acquaintanceship—indeed, this friendship—that I have been asked to speak. I cannot, however, say anything adequate to the occasion, because to give in a few minutes a description of the work done by this great inventor would be out of the question. I should, however, like to remind the members that it is owing to him that we have electric lighting as we know it, and upon his work the present electrical industry has been built up, because the first of these heavy electrical engineering sections was electric lighting. Electric power, tramways, heating, and electro-metallurgy, have all followed on the electric light work which, as I say, commenced this great new development. Swan was seeking a means of producing electric light other than the arc lamp, and eventually succeeded in making the incandescent electric lamp very much as we know it to-day. The inventions of Edison have often been mentioned in this connection, but it is clear that Swan, quite independently, invented for all practical purposes the incandescent electric lamp, maybe at the same time as, or maybe sooner than, Edison. He was a wonderful inventor. He gathered together all known information on a subject and laboriously worked at it until he had got the idea into a shape in which it was useful. His idea of squirting incandescent lamp filaments was really the basis of what is becoming an important industry—the making of artificial silk. He did not pursue it to its full length of application to the silk industry, but nevertheless his original work made this further development possible. The statuette which has been offered to the Institution by Colonel Morcom is the work of Sir Joseph Swan's daughter, Mrs. Morcom, and I feel that if only Sir Joseph could have seen what has eventuated he would have been very delighted.

After some brief remarks by **Colonel R. K. Morcom,** the statuette was formally accepted by the President on behalf of the Institution.

Dr. J. H. Jeans, M.A., LL.D., Secretary of the Royal Society, then delivered the Sixteenth Kelvin Lecture entitled "Electrical Forces and Quanta" (see page 483).

Sir Oliver Lodge: Before proposing a vote of thanks to Mr. Jeans for his interesting lecture, I should like to take this opportunity of thanking the Council for the signal honour that they have done me this year in electing me an Honorary Member of the Institution. I appreciate it very much, because I have no claim to be called an engineer. I do not know that Mr. Jeans has been as revolutionary as I half expected him to be. He seems to disbelieve in an ether; but if he only means that he disbelieves in two ethers I agree with him. I say that we must have one; he is satisfied with none because he is a mathematician and can proceed and calculate without reference to it. I venture to say that the theories of relativity and of quanta do not explain—and do not really pretend to

explain—but they express the facts of nature in a wonderful manner, and I fully accept them as methods. When Mr. Jeans objects to the ether, he means, I venture to say, the old dynamic ether—the ether of Lord Kelvin. He, and Fitzgerald and others of the last century, were always trying to make a model of the ether, or, in other words, to explain or express the ether in terms of matter; and I think with Mr. Jeans that it cannot be done. We need not be surprised at this, for of the two things, ether and matter, ether is the more fundamental. One cannot explain the more fundamental in terms of the derived; and we know that matter is a derived thing. It is made up of electric charges, and therefore—doubtless, I say—made up of ether. Very well, one must explain electricity and matter in terms of ether, and start fundamentally; but we know too little about it. I hope, myself, that the ether will finally be explained hydro-dynamically—by some particular kind of circulatory motion. Such an explanation may be called dynamical in a sense, but one cannot exactly apply the ordinary methods. Meanwhile, for mathematical purposes, the ether can be ignored. Ignoring a thing does not put it out of existence. Those equations on the board—the whole of the relativity theory—never mention the ether at all; and they need not do so, of course. But when proceeding from equations to things themselves, to reality—whatever people mean by reality, it is a difficult term to define—then the ether—*an* ether—is necessary. I believe Einstein thinks so; and Eddington has told me that he thinks so. I am not at all sure what Mr. Jeans thinks, but he has a very great right to any opinion that he forms, because I yield to no one in admiration of his extraordinary mathematical powers. What he told us in the first part of the lecture was a masterly exposition of the essential points; his identification of Lord Kelvin's two overshadowing "clouds" is most interesting, and all he has said is instructive. The permanence of the universe, and the fact that it has lasted more than a millionth of a second, or a million seconds, does seem to depend on the facts which the theory of quanta strives to express. The connection between radiation energy and frequency is a great discovery, and a surprising one to me. It is not at all surprising that frequency remains constant;—we are familiar with that in the case of sound; sound travels from a concert room through wood or any sort of material, the wave-length changes enormously, but the pitch is preserved and the concert is just as good;—but that the electron-expelling energy is preserved is wonderful. Apparent continuity arising out of discontinuity is common: the pressure of the air appears to be quite continuous—the barometer shows this—but it is really due to a bombardment of separate particles. Our senses do not appreciate minutiæ, atomic minutiæ; and now that we are penetrating into the interior of the atom, we find things that we had not expected. We find the quantum active in the connection between ether and matter, and there is still a great deal to discover about that. I beg to propose that a hearty vote of thanks be accorded to Mr. Jeans for his extremely interesting lecture.

The resolution, after being seconded by **Dr. A. Russell, F.R.S.,** was put to the meeting by the President and carried unanimously.

The meeting terminated at 7.30 p.m.

726TH ORDINARY MEETING, 19 FEBRUARY, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 5th February, 1925, were taken as read and were confirmed and signed.

Messrs. J. N. Robertson and H. Tomlinson Lee were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows:—

Elections.

Associate Members.

Crivelli, Rene Gabriel, M.E.E.
Dunham, David, B.Sc. (Eng.)
Loveridge, Claude Warren, B.A.
Sparkes, Thomas.

Graduates.

Barkwith, Joseph William B.
Barry, Gerald Noel F.
Berry, Edgar.
Cullinan, Reginald.
Everett, Reginald Edgar.
Gardner, Ernest John.
Henn, Stanley Thomas.
Hortop, Cecil Lawrence.
Ince, Thomas Henry.

Graduates—continued.

Macdonald, James Wright.
Murphy, John.
Rao, N. Srinivas.
Troup, George.
Tubb, Burton Henry J.
Watson, Gerald Victor.
Webster, Harold.

Students.

Aitken, Thomas Archibald, B.Sc.
Allaway, Lionel George.
Bancroft, George Denton.
Baveja, Pran Nath.
Bayne, Alec Edward.
Bennett, James.
Black, Richard Henry.
Bone, Ronald Scoble.
Brown, James Duncan, B.A.
Buckingham, Donald.
Carlton, Cyril Gordon.
Chaplin, Stephen.
Chilton, George William.
Clarke, Harold.
Cobbold, Robert James.
Cocks, Sidney Herbert.
Crombleholme, Frederick.
Cunningham, Alastair Andrew.
Desai, Maganbhai Vaghjibhai.
Donegan, Jeremiah.
Dowsett, Harry Lyttleton.
Drummond, John Fleming.
Dunn, Philip Ryland.
Evans, Moses.

Students—continued.

Farmer, Frank.
Fouracre, Victor William M.
Ganly, Richard Ernest.
Gardner, Frank Joseph.
Glenn, Hugh.
Gray, John.
Guthrie, James Robert.
Haggart, Andrew.
Harris, Richard Norman.
Hockney, Thomas Reginald.
Hodge, Archibald Greig.
Holder, John Eric D.
Hoskin, Frank.
Hutchison, Eustace Neville.
Johnson, Kenneth Corbridge.
Kellas, James Macnicol.
Landale, Stenard Ernest A.
Lawrence, Walter Francis C.
Lawrence, Cecil Frederick.
Lyons, Douglas Arthur.
McGreevy, Thomas.
Mackay, Victor Peterson.
Marryat, John.
Meeke, James Denis.
Mepsted, Maurice Eustace.
Millward, Gerald Richard.
Myers, Clifford.
Myers, Leonard Morris.
Murdoch, Matthew Weir H.
Nunn, Richard Trevett.
Padwick, Henry Francis J.
Parsonage, John Frank.
Patmore, Sydney John.
Peel, George Neville.
Pike, Ralph Charles.
Reed, Edward James.
Rennie, Douglas Ogilvie.
Roebuck, Ronald.
Sandy, Vivian John S.
Simpson, Alexander Victor.
Smyth, Vere Stainer W.
Stewart, Charles Eric.
Stewart, Donald Arnott.
Stirrup, Reginald Brade C.
Swift, Edgar.
Tanner, Ernest Basil T.
Taylor, Arthur Harold.
Thomas, Eugene Royston.
Tracey, William Thomas.
Upton, Robert Hildyard.
Viant, John Robert.

TRANSFERS.

Associate Member to Member.

Amberton, Richard.
Collins, Albert, B.Sc.(Eng.).
East, Alan Neville.
James, William Henry N.
Lee, John Andrew.
Maxwell, Kenneth Graeme, Lieut.-Col., M.C.
Phillips, Charles Francis.

Graduate to Associate Member.

Brierley, Herbert.
Jamieson, James, B.Sc.

Student to Graduate.

Allsop, George, M.Eng.
Barrand, Percy Christian.
Base, George Cecil.
Bridgeman, Wilfrid Robert O.
Brough, Leonard George.
Cohen, Isaac Judah, B.Sc.(Eng.).
Cooper, George.
Cuffley, Walter.
Dunn, Charles Trevor, B.Sc.(Eng.).
Everett, Arthur G.
Graham, Alexander.
Harley, Lawrence Shepheard, B.Sc.(Eng.).
Harlow, Harold George, B.Sc.
Holman, Horace.
Howard, Arthur.
Jones, Ernest Thomas L.
Lash, Alfred Reeves.
McCulloch, Reginald Andrew.
Sinclair, William.
White, Albert Ernest.

A paper by Major E. Ivor David, Member, entitled "Electricity in Mines" (see page 521), was read and discussed. On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.50 p.m.

44TH MEETING OF THE WIRELESS SECTION, 4 MARCH, 1925.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 4th February, 1925, were taken as read and were confirmed and signed.

A paper by Mr. D. W. Dye, B.Sc., Associate Member, entitled "Current-Transformer Methods of Producing Small, Known Voltages and Currents at Radio Frequencies for Calibrating Purposes" (see page 597), and a paper by Lieut.-Colonel K. E. Edgeworth, D.S.O., M.C., and Mr. G. W. N. Cobbold, M.A., Associate Member, entitled "The Measurement of Frequency and Allied Quantities in Wireless Telegraphy," were read and discussed.

Mr. G. W. N. Cobbold also demonstrated "A Direct Method of Setting an Undamped Radio Oscillator to any Desired Frequency Within an Accuracy Approaching 1 in 10 000," and this was discussed.

On the motion of the Chairman votes of thanks to the authors for their papers and to Mr. Cobbold for his demonstration were carried with acclamation, and the meeting terminated at 7.55 p.m.

727TH ORDINARY MEETING, 5 MARCH, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 19th February, 1925, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see page 334) was taken as read and the thanks of the meeting were accorded to the donors.

A paper by Colonel T. F. Purves, O.B.E., Member, entitled "The Post Office and Automatic Telephones" (see page 617), was read and discussed. On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.55 p.m.

INSTITUTION NOTES.

Nominations for Election to the Council.

In addition to those members nominated by the Council (see page 613) the following have been nominated for the vacancies which will occur on the 30th September next:—

Ordinary Members of Council (Members):

C. Rodgers, O.B.E., B.Sc. (*Nominated by* Messrs. A. R. Everest, A. B. Field, M.A., B.Sc., A. P. M. Fleming, C.B.E., M.Sc., F. C. Gibbons, F. Hird, B.A., E. S. New, M. J. Railing, W. O. Smith, F. Wallis and A. P. Wood).

J. N. Waite (*Nominated by* Messrs. J. Anderson, L. H. A. Carr, M.Sc.Tech., J. F. Crowley, D.Sc., E. Fawssett, R. Johnson, A. H. W. Marshall, W. M. Selvey, C. Vernier, E. B. Wedmore and J. Wright).

Ordinary Member of Council (Associate Member):

J. H. Parker (*Nominated by* Messrs. W. F. Andrews, E. B. Barnett, B. B. Heaviside, W. J. Jeffery, A. L. Lunn, A. P. MacAlister, T. A. G. Margary, W. J. Oswald, L. Owen and W. Young).

Associate Membership Examination Results.

April 1925, Supplementary List.*

Passed.

Hallé, C. R. (South Africa).
Larkin, C. N. (South Africa).

Students' Premiums.

The following premiums, each of the value of £10, have been awarded by the Council for papers read before the Students' Sections during the past session:—

Author	*Title of Paper*	*Students' Section*
P. G. Ashley, B.Sc.	"Fuses and Fusible Cut-outs"	North-Eastern
D. I. Dawbarn	"Variable-Speed Three-Phase Commutator Motors"	North-Eastern
E. Gallizia	"Some Problems of the Turbo-Alternator"	South Midland
J. H. Reyner	"The Direction-finding Equipment at Niton and Cullercoats"	London
W. R. T. Skinner, B.Sc., and G. E. Barrett, B.Sc.Tech.	"High-Pressure and High-Temperature Steam"	North Midland
A. Tustin, M.Sc.	"Economics and Industrial Electrification"	North-Western

* See page 614.

Model Form of General Conditions of Contract (Export).

The two following additional sets of Model Conditions of Contract have been approved by the Council:—

B1. Export Contracts (delivery f.o.b.; excluding cables).

B2. Export Contracts (including complete erection or supervision of erection; excluding cables).

Copies of each may be obtained from the Secretary of the Institution, Savoy Place, Victoria Embankment, London, W.C. 2., or from the publishers, Messrs. E. and F. N. Spon, Ltd., 57, Haymarket, London, S.W. 1, at one shilling per copy, post free.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 May–25 June, 1925:—

	£	s.	d.
Adcock, F. W. D. (Leigh-on-Sea)		5	0
Allan, C. T. T. (Cardiff)	2	2	0
Aylott, H. J. (Ilford)		10	0*
Barclay, W. R. (Birmingham)		5	0*
Barnes, C. W. (London)		5	0
Beale, H. R. (Wellington, N.Z.)		8	6
Beck, J. W. (Seven Kings)		5	0
Bellamy, L. C. F. (Hong-Kong)	1	1	0
Cameron, D. L. (Toronto)		16	0
Campbell, R. G. (Liverpool)		10	0
Cleaver, R. L. (London)		15	0
Clinch, W. N. C. (Brimsdown)		5	0
Coe, G. D. (Wrexham)		10	6
Colborn, C. (Swansea)		8	6
Collins, W. (Bristol)	1	1	0
Coventon, G. L. (Chepstow)		5	0
Crocker, E. (Birmingham)		5	0*
Damsell, R. F. (Rugby)		5	0*

PERMANENT MAGNETS IN THEORY AND PRACTICE.

(SECOND PAPER.)*

By S. EVERSHED, Member.

(*Paper received 4th February, and read before* THE INSTITUTION *19th March,* 1925.)

PREFACE.

The present paper follows one on the same subject read before the Institution on the 13th May, 1920. It was originally intended that modern practice in magnet-making should be described in a second paper, with enough metallurgical explanation to render the various processes intelligible. This simple plan was soon abandoned when it was discovered that current metallurgical science had nothing to say about those matters which are of most consequence to the magnet maker. His perplexities begin with the steel itself as it comes from the steelworks. Why should magnets made from one batch of steel differ so widely in their magnetic power? What is the source of the magnetic potency of steel? And what causes the strength of a permanent magnet to fall off with age? To answer such questions as these, the present writer found it necessary to enter an almost untrodden metallurgical field; to study spoiled magnet steel and its restoration; to determine the relation between the carbon content and the coercive force of hardened tungsten steel; to investigate the harmful magnetic effect of ultra-heating; and, lastly, to measure the slow decay of hardened steel.

The outcome of prolonged research on these and other kindred subjects is included in the following paper in Part III, which treats the metallurgy of magnet steel as a material for permanent magnets, and is founded on the hypothesis that the potency of steel arises from the molecular pattern created by the solution of carbon compounds in magnetic iron. A strictly logical sequence in so intricate a subject is out of the question, but for greater ease of reading the various matters to be dealt with are presented, so far as possible, in their natural order. No attempt has been made to adhere to conventional metallurgical ideas or phraseology. The metallurgical reader, should there chance to be one, may possibly feel lost without his pearlite, his austenite, and his phase rule, but a little fresh air does no one any harm.

Part IV opens with a general account of the manufacture of permanent magnets, beginning with the making of the steel. The different stages of manufacture are then dealt with, one after the other, attention being mainly directed to points of difficulty and matters in which common practice stands in need of amendment. It is shown that the most favourable composition for magnet steel can be determined once for all from measurements of available magnetic energy, the optimum composition of tungsten magnet steel having already been ascertained by that means.

The section in Part IV under the heading "Cast Magnets" contains an account of a research conducted by the British Scientific Instrument Research Association, and completed some three years since. It was found possible to cast permanent magnets in either tungsten steel or cobalt steel, and the cast magnets, while presenting many advantages over the customary magnets of rolled steel, were in no way inferior to them in magnetic power.

Throughout the paper, and notably in bringing Part IV to a conclusion, the author has freely introduced ideas of a speculative kind. This has been done rather in the hope that trains of thought may be set going in other minds in altogether novel directions. Where these will end no one can tell. Perhaps nowhere; but in any case it is good to make occasional excursions from our accustomed groove.

In the earlier stages of research the want of suitable apparatus made it difficult to proceed without metallurgical help. This was invariably forthcoming, and at the very beginning the author was able, by kind permission, to make certain preliminary experiments in the works of the Birmingham Small Arms Co. Thanks are also due to the directors of Messrs. W. H. Allen and Son of Bedford for permission to use the "inverse rate curve" apparatus installed in their metallurgical laboratory, and to Mr. R. Rolfe, who very kindly undertook the task of determining inverse rate curves from samples of tungsten magnet steel supplied by the author's firm.

The numerous samples of tungsten steel with graded carbon content, required for the determination of the carbon-coercive-force curve, were all specially cast and presented to the author by Messrs. Thos. Firth and Sons, and his warmest thanks are due to the directors of the firm for this most generous help, as also to Dr. W. H. Hatfield, the director of the Brown-Firth Research Laboratory, under whose supervision the samples were prepared.

All the chemical analyses given in the paper were made for the author's firm by Messrs. Riley, Harbord and Law, and the writer is indebted both to Mr. Harbord and to Mr. Law for helpful advice on many occasions. Thanks are specially due to Mr. Law for the microphotographs of tungsten magnet steel referred to in the introduction to Part III.

Nearly all the experimental work recorded in the paper was done by Mr. Finnis, ably assisted by

* See *Journal I.E.E.*, 1920, vol. 58, p. 780.

Mr. Baker. It has been the author's pleasure on more than one occasion in past years to acknowledge his indebtedness to Mr. Finnis. On the present occasion the two graphs given in Figs. 2 and 3 will serve better than any words as testimony of the skill and precision with which the experimental work was done. In plotting these curves for reproduction the author has purposely included every observational point just as it stands in the original record of the experiments, each plotted point standing for the simultaneous readings of temperature and magnetic intensity by two observers.

Finally, a word as to standards of measurement. Temperatures have almost invariably been measured by platinum-rhodium-platinum thermo-couples made in the laboratory from wires supplied by Messrs. Johnson and Mathey, the couples being subsequently verified by the National Physical Laboratory. Occasional use has been made of a Leeds and Northrup colour-comparison pyrometer in cases where it was impracticable to insert a thermo-couple inside the steel test-piece. The author's astatic moving-coil magnetometer has been used throughout for the magnetic tests. The instrument is standardized by comparison with standard inductance coils which have been verified by the National Physical Laboratory.

Except where another source is indicated, the experimental work recorded in the diagrams and tables in this paper was done at Acton Lane Works under the author's supervision.

Table of Contents.

PART III.

THE METALLURGY OF THE PERMANENT MAGNET.

(1) Introduction.

Natural phenomena being mostly beyond human comprehension, we often try to explain them to ourselves by analogy with something simpler. But simplification and explanation seldom go well together. There is frequently an illusive simplicity in the form in which Nature presents her puzzles, and then the first step in explanation is apt to land the inquirer in a maze of difficulty.

So it is with the steel of which a permanent magnet is made. Solid and hard, a rigid body with a definite shape, it presents no obvious difficulty to the mind and apparently nothing could very well be simpler. But metallurgy tells a very different tale. Steel is found to possess an extremely complicated structure and to be endowed with many strange properties. Magnetism tells much the same story of complexity, but in another language. Among the more mysterious attributes of steel is the property with which we are concerned in this paper, namely, the power of maintaining a magnetic field and acting as a permanent magnet. It might be supposed that somewhere in the long and intricate metallurgical story of steel, as told in many a textbook, this occult magnetic power would find a place if not an explanation. It is not so, however, and just in those places where it is natural to look for something relating to the properties of steel which give rise to the two factors of magnetic energy, we find gaps in the story. But both metallurgical structure and inherent magnetism go to the making of a permanent magnet, and in the present paper an attempt must be made to fill up the gaps as far as possible and present the story of magnetized steel as a whole. For reasons of space it can only be a story in outline, and on the metallurgical side it will naturally be confined to steels of the composition used for magnets.

The absence of metallurgical guidance in matters

concerning the magnetism of steel is natural enough. Steel is mainly employed for structural purposes where mechanical strength is the first consideration, and for that reason metallurgical research has been directed for the most part to the mechanical properties of the various kinds of steel; properties which are largely governed by chemical composition, thermal treatment and crystalline structure. Hence in the past the principal weapons of the metallurgist have been chemical analysis, the pyrometer, and the microscope, and it could hardly be expected that these would throw light on magnetic phenomena which appear to have their origin in the actions of individual atoms and molecules.

In a recent paper * Mr. Watson has sought to establish some connection between the gross structure seen in the microscope, and the magnetic properties of magnet steel. It is only natural that they should have something to do with each other, but the relation cannot be that of cause and effect. Anyone who makes a microscopic examination of the interior of a permanent magnet under a high magnifying power, can scarcely fail to be struck by the fact that the more powerful the magnet the less there is to be seen in the microscope. The harder the steel the fewer the signs of crystalline or other structure, and inside a magnet made of good homogeneous magnet steel in the completely hardened state there is scarcely a trace of visible structure.† The only possible conclusion to draw is that the development of the power of permanent magnetism in steel depends on the absence, and not on the presence, of visible structure. In looking for the origin of that power the microscope does not help us. The source is nowhere to be seen, and it must be sought by other means. It must be looked for among the molecules of iron, the molecules of carbon and other elements that enter into the composition of magnet steel.

Perhaps it is not only in the realm of permanent magnetism that the microscope fails to see the things that matter. In the past, micrographic study has greatly advanced metallurgical knowledge of the gross crystalline structure of metals and alloys, but to anyone who, like the present writer, is a mere intruder in the metallurgical field and therefore takes an outside view, it does not appear that the microscope, as a guide to the fundamentals of metallurgy, is likely to add appreciably to what it has already accomplished. Future progress seems to demand that optical vision should be replaced by mental vision, aided by some keener weapon than the microscope. Magnetism is such a weapon, but its application is limited at present to the magnetic elements. Another keen instrument of research, and one of more general application, is the X-ray spectrograph, which is already being widely used and bids fair to unravel many an obscure problem. Applied to metals, X-rays penetrate the molecular structure and reveal the arrangement of the atoms in the elementary crystal which forms the unit from which the gross structure seen in the microscope is built up.

It may be anticipated that before long the hypothetical molecular pattern, which Ewing's theory requires for the magnetic mechanism in iron and steel, will be put to the searching test of comparison with the pattern disclosed by X-rays. Whether the facts so revealed will fit in with an old and well-tried magnetic theory or whether that theory, like others before it, will have to give place to one in better agreement with newly discovered facts, no one can tell. But whatever the outcome of X-ray research may be, the discovery of the actual molecular pattern of the magnetic mechanism will be a forward step in magnetism second only in importance to the discovery of the planetary electrons.

Metallurgical knowledge and the facts of magnetism having been kept in reason-tight compartments (a metaphor we owe to Cuninghame Graham), the light to guide us in looking for the source of the magnetic power of the permanent magnet has mostly come from the magnetic phenomena themselves, phenomena which are now known to arise directly from the internal mechanism of the atom, the motion of the planetary electrons in their orbits constituting an electric current and endowing the atom or molecule with a powerful magnetomotive force. In the former paper an examination of the magnetic action of an assemblage of magnetic molecules enabled some sort of mental picture to be formed of the pattern in which the molecules would require to be arranged in order to give the whole mass the power of behaving like a permanent magnet. Now, steel containing carbon possesses that power in an eminent degree, and since the steel is known to be a solution of carbide molecules in iron, the inference must surely be that, in some way or other, the molecular pattern of solution constitutes the magnetic mechanism of the permanent magnet. It is easy to show by experiment with steels containing carbon, that the greater the development of the state of solution the more powerful the steel becomes as a permanent magnet. In this paper, therefore, the magnetic mechanism of Ewing's theory will be identified with the molecular pattern which is formed when carbon, in the form of carbide molecules of some kind, is dissolved in magnetic iron.

When embarking on the study of unfamiliar facts it never comes amiss to begin by acquiring a sense of the proportion of things, so that we may know beforehand whether we are to look for a mountain range or a speck of dust. The reader need not trouble about the mountain, for all the essential properties of the permanent magnet are to be found in a tiny fragment of steel, a mere invisible speck.

Turning to the microscope for the last time, what is the size of the smallest entity visible therein? How many molecules will it contain? To answer these questions the author has again availed himself of friendly help. When using a microscope with the high magnifying power of 3 000, Mr. Law found that the smallest entity which he could recognize with certainty as a metallic crystal grain, measured 105×10^{-6} cm

* E. A. Watson: "Permanent magnets and the relation of their properties to the constitution of magnet steels," *Journal I.E.E.*, 1923, vol. 61, p. 641.

† These statements are founded on an examination of microphotographs of tungsten magnet steel in different states of hardness. The samples were supplied by the author's firm in the form of cylindrical bar magnets and Mr. E. F. Law very kindly undertook the photographic work, for the purpose of this paper. The surface photographed was a transverse section near the middle of the length of each magnet. A magnifying power of 1 000 was used in taking the microphotographs.

in diameter. Assuming this tiny object to be a cube, it would contain $105^3 \times 10^{-18} \times 4 \cdot 2 \times 10^{22}$ molecules; in round numbers 50 000 million molecules. In the hardened steel of a permanent magnet a crystal grain, visible or invisible, is a homogeneous solution of carbide molecules in iron, and when considering a mass of steel as a solution the unit is the crystal grain. If the grain is large enough to contain 50 000 million molecules, we may just catch a glimpse of it in a powerful microscope as a minute structureless object of recognizable shape. More than that cannot be seen. The molecular pattern of solution is there in the tiny speck, the pattern which, in the view of the present writer, links metallurgical properties with permanent magnetism, but being a pattern of molecules it is, of course, far beyond the range of visibility in even the most powerful microscope. In short, apart from mental vision, nothing short of X-rays or magnetic phenomena can bring the molecular pattern of solution within our reach.

The iron-carbon solution, which constitutes the crystal grain in magnet steel, embodies also the magnetic machinery of the permanent magnet. But whereas the crystal grain may contain millions of molecules, a very small number will serve as a unit of magnetic action. With the aid of his celebrated working model of the magnetic mechanism, Ewing has shown that, so far as the magnetic phenomena of iron and steel are concerned, the whole secret of the magnetic machinery is contained in a group of a few dozen magnetic molecules. Looking on such a group as in some sense a unit portion of the magnetic machine, the crystal grain in its magnetic aspect is seen to be an assemblage of such units and quite likely to contain an immense number of them.

In the following pages, therefore, steel will present itself in two aspects, and when considering it as a solution the crystal grain must be borne in mind as the homogeneous unit. On the other hand, when looking at steel in its magnetic aspect, our attention will be directed to a tiny bunch of magnetic molecules, and not to the vast crowd of molecules which even the smallest visible crystal grain contains. But whether solution or magnetism happens to be foremost at the moment, our mental vision must be extended far beyond the gross appearances seen in the microscope, into a region where atoms and molecules are at work close to the very heart of things.

(2) The Theory of Magnetism in Iron.

Before considering the metallurgy of magnet steel, attention must be directed to one or two purely magnetic matters. The previous paper was founded on the combined theory built up by Ampère, Weber and Ewing, and in Part I it was shown that the power of a permanent magnet to maintain a magnetic field and resist demagnetizing forces depends on the ability of small groups of magnetic molecules to hold themselves together as local oriented systems, by means of their mutual induction. But in a mass composed of magnetic molecules of equal magnetomotive force, and uniformly distributed in space, local bonds of mutual induction, flux tubes threading small groups of molecules and binding them together by magnetic forces, are impossible, for lack of the necessary available spaces to contain them. Hence to set up the condition that gives rise to permanent magnetism there must be some kind of variformity in the distribution of magnetomotive forces, and since there is no reason to believe that the molecules of any magnetic element are unequal as regards their magnetomotive force, it follows that the required variformity must be a want of uniformity in the distribution of the magnetic molecules in space. It is more than likely that the want of uniformity is systematic; small groups of molecules being gathered together so as to leave vacant spaces available for the propagation of the mutual induction which, after magnetization, will serve as the magnetic bond between them. In the case of iron, which crystallizes in cubic order, it is natural to identify the gathered group with the eight molecules at the corners of a cube or primitive crystal; but this is rather a convenient mental picture than a hypothesis supported by facts. Evidently the variformity is a characteristic of the particular magnetic material, in a sense it is the structure of the material, and the greater the degree of variformity in any material used for making a permanent magnet, the greater the maintaining power of the magnet.

So much as a summary of the view of Ewing's theory put forward in the previous paper,* the basis being a molecule which is magnetic in virtue of the motion of its planetary electrons (Ampère's molecular current), and Weber's theory of magnetization as the orientation of a mass of magnetic molecules. Since the publication of that paper, Sir Alfred Ewing has suggested a modification of his original theory, his later view being that it is the planetary electron orbits only, and not molecules as a whole, that become oriented under the action of a magnetizing field; and that the power to retain the oriented state arises from the mutual induction between the several electron orbits of the individual atom or molecule. The fundamental principle of the original theory remains, but the origin of the retaining power has been transferred from the mutual induction of neighbouring molecules in a group, to the mutual induction of neighbouring electron orbits in an atom or molecule.† In this modified form the theory has not yet been developed to the point where it can replace the original theory as a guide in threading our way through the mazes of permanent magnetism, and in the present paper, as in the previous one, Ewing's theory in its original form will be assumed as a basis.

(3) Molecules: Magnetic and Non-Magnetic.

It is a strange fact that of all the known elements only three are magnetic at ordinary temperatures and under normal conditions. The magnetic elements are, of course, iron, nickel and cobalt, and in olden days when no one troubled about the inside of an atom these were the uncanny exceptions to the rule of no magnetism. But since it became known that every kind of atom contains electrons moving in orbits,

* "Permanent Magnets in theory and practice," Part I, *Journal I.E.E.*, 1920, vol. 58, p. 780.

† J. A. Ewing: *Proceedings of the Royal Society* A, 1922, vol. 100, p. 449; *Proceedings of the Royal Society of Edinburgh*, 1921–22, vol. 42, Part I, p. 97. *Philosophical Magazine*, 1922, vol. 43, p. 493.

and is therefore a potential source of magnetism, the difficulty has been to explain the absence of magnetic effects in the so-called non-magnetic elements. Iron, nickel and cobalt, with their powerful magnetism, are natural enough.

Weber saw the magnetic molecule as a little magnet. Ampère thought of its magnetism as arising from an electric current flowing in the molecule. It is now known that Ampère was right, the motion of the planetary electrons constituting the current. In the previous paper, when considering magnetization as an orientation of magnetic molecules, it was unnecessary to pay attention to individual electron orbits and, in order to provide a simple mental picture of the process of orientation, the several orbits of the molecule were all supposed to be lumped together, as it were, and regarded as equivalent in their effect to a single imaginary current ring behaving like a little coil carrying a permanent current.

We are, however, now going to look at the molecule of iron in its metallurgical aspect and, among other things, it will be necessary to take account of it as it exists when iron, being red-hot, ceases to be magnetic. We are therefore faced by the fact that iron can exist either in the magnetic or in the non-magnetic state, and the convenient image of the iron molecule as a single imaginary current ring behaving like a coil no longer serves. We must picture the iron molecule as equivalent to two equal current rings in order to have a system capable of changing from one magnetic state to another.

Iron loses its magnetism, apparently because each molecule loses its magnetic moment. What actually happens to the molecule is not known, but it is something equivalent in effect to a re-arrangement of the relative positions of the orbits of the planetary electrons. When the molecule is magnetic all the electrons belonging to it travel the same way round their orbits and endow the molecule with its magnetic moment and magnetomotive force. When the molecule is non-magnetic, the electrons must be travelling opposite ways in the different orbits, the numbers going one way and the other being such that the algebraic sum of the magnetic moments of the several orbits is zero. Hence the change from magnetic to non-magnetic, or vice versa, consists in a shifting of orbits from one arrangement to the other, a change that amounts to a reconstruction of the molecule.

For mental convenience we may suppose that there are only two orbits in the molecule of iron, each containing half the total number of planetary electrons belonging to the molecule. In this way we form a simple mental picture of the magnetic mechanism of the iron molecule as consisting of two imaginary current rings of equal and constant magnetic moment. If the currents in the rings go the same way so that their magnetomotive forces act in the same direction, then the system represents an iron molecule in the magnetic state. If the currents go opposite ways, then there will be no magnetic moment and no resultant magnetomotive force, and in that state the system represents the iron molecule in the non-magnetic state. To convert the system from one state to the other it is only necessary to turn one of the rings round, about a diameter, through half a revolution; and it is something equivalent in effect that takes place in the real iron molecule when the magnetic change occurs.

The energy required to convert a magnetic molecule into the non-magnetic state and the time occupied in effecting the magnetic change should be borne in mind when considering the metallurgical phenomena of iron and steel. To move two neighbouring coils relatively to each other, from positions in which their magnetomotive forces act in the same direction to positions in which they are opposed, requires the expenditure of force; energy must be supplied to effect the movement. If the coils are allowed to return to their original positions this energy will be released again. The same holds good for the simple model molecule composed of two current rings. Hence, assuming electron orbits behave like current rings and coils, any shifting of the orbits in an atom which has the effect of converting it from the magnetic to the non-magnetic state, will need a supply of energy to bring it about. This deduction from the known laws of electromagnetism is borne out by the facts, for there is a measurable absorption of energy when iron changes from the magnetic to the non-magnetic state, and the energy is released again when the iron returns to the magnetic condition.

Nothing is known from observation about the time occupied by an atom or molecule in effecting the magnetic change. However it is performed, it is an affair that concerns electrons and their orbits, and we may guess the time to be inconceivably short, more or less comparable perhaps with the periodic time of an electron travelling round its orbit. Now metallurgy has to do with various molecular transformations in iron and steel that progress quite slowly, occupying time measured by minutes or even hours, and sometimes, as we shall see in Section (16), stretching out into years. In comparison with even a single minute, the magnetic change of a molecule must be practically instantaneous, and it will be so regarded in the following pages.

(4) Coercive Force and Potency.

When magnets began to be made of steel it was soon recognized that besides the magnetism of the steel there was some other property, some hidden power, that went to the making of a permanent magnet. In iron this power was almost entirely absent. Steel, although less magnetic than iron, possessed far more power to act as a permanent magnet, and in hardened steel the power was present in the highest degree. To this mysterious property, latent in the steel before it was magnetized, the misleading name "Coercive Force" was given in very early days. Hard steel, for example, was said to possess a great coercive force; though what the steel was supposed to coerce it would be hard to say at this distance of time. However, there the property was, and coercive force it was called. To-day the property is still recognized as inherent in the steel, but the old name for it has long been transferred from the steel to a purely magnetic quantity

which happens to serve, in some degree, as a measure of the coercive force property.

This confusing transference of name was made some forty years ago by Hopkinson. Finding the term coercive force already in use, and perhaps hardly realizing the meaning it held for the maker of permanent magnets, he attached it to the demagnetizing force which serves to reduce the flux in iron or steel to zero. To speak in a parable, a certain man in authority transferred the name coal from the black lumps in a sack to the weights employed in weighing it; and to this day men call the weights "coal," much to their own mental confusion. Hopkinsonian coercive force is the weight. The property latent in the steel, the coercive force known to the magnet maker, is the coal.

At this time of day it would be futile to attempt to re-name the demagnetizing force that reduces the flux to zero. Coercive force it has been for all of us since Hopkinson's time, and coercive force it will doubtless remain. But it must not be forgotten that it is purely a magnetic quantity, one which affords a sort of measure of the ability of the magnetized mass to withstand the action of demagnetizing forces.

Knowing that iron possesses scarcely a trace of the power to withstand demagnetizing forces and that steel has it in a high degree; knowing, moreover, that steel differs from iron in composition, we are justified in believing that the withstanding power has its origin in some particular molecular arrangement, a molecular pattern, so to speak, highly developed in hard steel, almost non-existent in soft iron. Whether we are always clearly conscious of it or not, it is the power latent in the molecular pattern that we have in mind when we refer to the coercive force *of the steel.* To avoid confusion it is essential to realize that although we use magnetic means to detect it, the *coercive force of the steel* is not itself a magnetic property. It is there in the steel, as a molecular pattern, whether the steel is magnetized or not. It is the coal, and must not be confused with the Hopkinsonian weight.

In the following pages, in order to avoid circumlocutions when referring to the withstanding power latent in the molecular pattern, it will be called the "potency" of the steel, and Hopkinson's coercive force will be regarded as a convenient indicator of different degrees of potency in different kinds of steel.

According to the theory on which this paper is founded, potency must have its origin in some kind of systematic variformity in the distribution of the magnetic molecules, and hence in the light of that theory the molecular pattern is the variformity. But variformity implies the particular theory associated with the names Ampère, Weber and Ewing, and a word specifically adapted to a theory is always open to the objection that some day the theory may be replaced by a better one, and in that event the word becomes misleading. The terms molecular pattern and potency are free from this objection.

In a piece of pure iron the volume is occupied solely by magnetic molecules. Iron possesses hardly any potency and, to make it fit for a permanent magnet, potency must somehow be imported into it. So far as knowledge goes at present, this cannot be done on an adequate scale without introducing non-magnetic substances into the iron, and since the non-magnetic molecules replace some of the magnetic molecules, a piece of iron can only acquire potency at the sacrifice of some of the inherent magnetism. It is easy to make steel of great potency if the accompanying sacrifice of magnetic molecules is ignored, but the true art in making magnet steel consists in carefully balancing gain in potency against loss of magnetic molecules. This principle has often been overlooked by steelmakers.

In the following sections, the molecular pattern that gives rise to great potency will be identified with the arrangement of molecules in a solution. Knowledge of solutions is not yet sufficiently advanced to enable a clear mental picture of that arrangement to be formed, but, whatever may be the state of things in a solution, it certainly provides the kind of molecular pattern that gives potency.

(5) THE STATE OF SOLUTION.

The metallurgical aspect of steel as a solution has already been referred to. It is a strange kind of solution. Not so much because it happens to be in the solid state, as for other reasons that will unfold themselves as we go along.

For most of us a solution is a liquid with something dissolved in it, like salt in water. So familiar is the fact that salt dissolves in water, that no explanation seems called for until we begin to wonder what the molecules of salt are doing in the water. When we inquire of the learned what is the relationship between the salt and the water, the solute and the solvent, no very definite answer is forthcoming. Everything, or nearly everything, seems to be known about solution except what it is. It is easier to say what it is not. Solution is not a mere mixture in which the molecules of different kinds pay little or no attention to each other. On the other hand, solution is not chemical combination, for that is an affair of atoms and definite proportions, whereas the constituents of a solution can exist together in any proportions within limits.

When a solution is examined some little time after dissolving the solute substance in the solvent, it is found that the solute has become uniformly distributed throughout the liquid. To do this, the solute molecules must have been acted on by forces akin to those which cause the molecules of a gas, contained in a closed vessel, to distribute or disperse themselves uniformly. In the case of the gas the ultimate effect of the molecular dispersing forces is a pressure on the walls of the vessel and on the surface of any body inside the vessel. Similarly, in a solution, the solute molecules exert a pressure, and apparently gas pressure and solution pressure are of the same nature, if indeed they are not identical. In a solution the solvent seems to fulfil the function of the space inside the closed vessel, and just as the molecules of gas are confined within the vessel so the molecules of solute are confined within the volume of the solvent.

The mobility of solute molecules in a liquid or solid solution is naturally very much less than that of molecules in an otherwise empty space. A bunch of mole-

cules when put into an empty vessel would disperse with extreme rapidity and almost instantly become uniformly distributed. But a similar bunch of solute molecules in a liquid would find their movements hampered by the presence of surrounding molecules of solvent and, with diminished freedom to travel, the dispersal of the molecules would, of course, go on much more slowly. In a solid it must be even more difficult for molecules to travel from place to place. Nevertheless, when a solution is in the solid state, the solute molecules do manage to move about when the forces are there to set them in motion. But the greatly restricted molecular mobility in the solid naturally makes travelling exceedingly slow.

When the constituents of a solution have widely different properties, as in the case of salt and water, or when one constituent greatly exceeds the other in quantity, as in a dilute solution, it is useful to mark the difference by the words solute and solvent. But in metallic solutions, more generally known as alloys, it is impossible to distinguish between the constituents in that way and solution is then seen to be a mutual condition, each constituent being, as it were, dissolved in the other. But solutions of the completely mutual kind are very different from the one-sided solution with which we are concerned in this paper. When carbon, combined with some other element to form a solute molecule, is dissolved in iron, the two constituents play entirely different parts. Nothing can make the carbon do what the iron does, nor can anything make the iron act like carbon. For this reason it will be convenient to adhere to the terms solute and solvent, although nowadays these words have lost some of their distinctive meaning.

At any given temperature there is a limit to the quantity of solute which a given volume of solvent can hold in solution, and when the solution contains that limiting quantity it is described as a saturated solution. If the temperature of a saturated solution is lowered to some other point, a sufficient quantity of solute will pass out of solution to leave the solution in the saturated state which corresponds with the lower temperature. The surplus solute which comes out of solution in that way makes its appearance as a separate substance, and if the solute is naturally a crystalline substance the surplus will appear in the form of tiny crystals.

When a surplus quantity of solute passes out of solution and assumes the crystalline form, the solute molecules are required to travel from the positions they occupy as constituents of a solution to the positions they must take up as members of a crystal, a procedure somewhat analogous to what happens in a squad of soldiers on the order to form fours. Hence to pass from solution to crystal each solute molecule must make a journey; and journeys, however short, take time. The time taken on any particular molecular journey will depend on the propelling force acting on the molecule, and on the molecular mobility. In solid steel we must be prepared to find the solute constituents taking time measured by minutes or days, or even it may be years, to accomplish the passage from solution to crystal.

The solute molecules, the pressure of solution, the surplus solute, the molecular mobility, the journeys of the solute molecules on their way from solution to crystal, and the time occupied on the journey, are all matters intimately connected with steel as a solution, and for that reason attention has been drawn to them at the outset. It seemed all the more necessary to do so, because metallurgical textbooks, for the most part, bury the molecule and its doings under a tumulus composed of microphotographs, equilibrium diagrams, and the phase rule of Willard Gibbs.

(6) Steel as a Solution.

Every kind of steel is a solution, many of the elements, both alone and in combination, being soluble in iron. The solutes not only dissolve in molten iron, but remain in solution when the iron cools down and becomes solid. Moreover, certain elements will actually pass very slowly into solid iron and dissolve in it, taking many hours to do what is done in a few seconds in a liquid solvent. This brings us at once to the difference between a liquid solution and a solution which, like steel, is in the solid state. The difference is not fundamental. In the main principles underlying the behaviour of solutions, solid and liquid solutions are alike. It is in the element of time that they differ. In a solid the mobility is so small compared with that of a liquid like water, for example, that molecular journeys, such as those of the solute molecules on their passage from solution to crystal, occupy immensely longer times. On the lowering of the temperature of a liquid solution like salt water, the passage of the solute molecules from solution to crystal is so quick as to appear almost instantaneous; whereas in solid steel even when heated red-hot to give greater mobility, the same process is found to occupy several minutes, as we shall see in a later section. When the steel is cold (at room temperature) the mobility is so slight that in practice it is ignored and the cold steel is regarded as being in an unchangeable condition. Nevertheless, there is evidence that even when cold the mobility is not quite zero; the molecules can, and do, go on journeys, although with almost incredible slowness. Novel evidence of this will be given on a later page. On general grounds it seems probable that the mobility does not actually vanish until the temperature falls to the absolute zero.

Turning now to the solutes in steel, of the many elements that are commonly used at the present time we are only directly concerned with carbon, tungsten and chromium. Of these the first was accidentally introduced into iron in the Early Iron Age. The other two have been brought into use in more recent times as the result of efforts to increase the hardness of tool steel. Hardness and potency being both associated with the state of solution, steels which lent themselves by their hardness to the making of tools have sometimes proved to make good magnets.

It is an easy matter for the steelmaker to dissolve all manner of elementary substances in iron and describe the resulting product as steel. But to ascertain what happens to the various elements jumbled together in this way, whether they combine and if so

in what chemical forms, has been a task of the greatest difficulty, and it has needed much patient research by many metallurgical workers to determine the composition of the various solute molecules met with in steel. Naturally carbon was the first to be attacked. It has been conclusively demonstrated that under ordinary conditions carbon only dissolves indirectly in iron. It does so by combining with some suitable element to form a compound solute molecule. Iron itself happens to be one of the suitable elements, and when carbon is put into iron, each atom of carbon combines with three atoms of iron to form a molecule of carbide of iron, Fe_3C.* This substance being soluble in iron, the molecules so formed immediately dissolve in the remaining iron; and since iron is only capable of dissolving a small proportion of this or any other carbide, the remaining iron constitutes much the greater part of the whole mass. Another suitable auxiliary element is tungsten, which combines with carbon as a carbide of tungsten, WC, which is also soluble in iron. A third element of the auxiliary kind is chromium, which combines with carbon as a carbide of chromium having the formula Cr_3C_2.† Several other suitable elements of the auxiliary kind are employed in combination with carbon as solutes in different kinds of steel, but we may confine our attention to carbide of iron (Fe_3C), carbide of tungsten (WC), and carbide of chromium (Cr_3C_2), since apart from alien substances these three compounds alone are met with in magnet steels at the present time. In carbon steel, only the carbide of iron is present. In tungsten magnet steel, carbide of iron and carbide of tungsten are both used and in such proportions that there are roughly the same number of molecules of each. In chromium steel both the carbide of iron and the carbide of chromium are likely to be present, but as this steel is inferior to tungsten steel as a material for permanent magnets its composition has not received much attention.

Each of the three carbides just referred to is soluble in iron to a small extent; and when in solution, but not otherwise, each endows iron with potency. The greater the quantity of carbide in solution the greater the effect, up to a limit which is reached when the proportion of carbide compound, reckoned in terms of its carbon content, is about one per cent of the weight of steel. In treating of magnet steels, therefore, we are not concerned with any steel containing more than about one per cent of carbon.

There is no simple quantitative relation between the proportion of carbide in solution and the resulting potency of the steel; but by ascertaining the quantity of carbide by analysis and determining the potency by measuring the Hopkinsonian coercive force, a curve can be prepared connecting the carbon content with the coercive force and therefore establishing the relation between the particular solute molecule and the potency it creates in the iron. Curves of this kind have been experimentally determined by Madame Curie for carbon steel, and by the present writer for tungsten steel. These curves will be found in the sections of the present paper devoted to carbon steel and tungsten magnet steel, the author's curve, giving the carbon content and coercive force of tungsten steel, being now published for the first time.

The three carbides used for magnet steels differ in their power of creating potency. As a unit, a molecule of tungsten carbide is considerably more effective than one of iron carbide; nevertheless, the maximum value of the potency of a steel which contains only the carbide of tungsten is no greater than that of carbon steel. When both these carbides are present, as they are in tungsten magnet steel, they yield a far higher potency acting together than either carbide does by itself. This amplifying power might possibly be explained by supposing the two carbides to unite to form the double carbide Fe_3CWC, provided that molecule could be shown to possess a greater potency-giving power. But the evidence of analysis, and some newly acquired magnetic evidence referred to later on, seem to point quite clearly to the presence of the two carbides as separate entities. Which is the true view no one can say for certain, and how these two carbides by working in conjunction as solute molecules in tungsten magnet steel manage to create a greater potency than either solute can do by itself is a problem for the future to unravel.

The most powerful solute considered solely as a source of potency is the carbide of chromium, the molecule of which is some eight or nine times as powerful as a molecule of carbide of iron. Unfortunately, carbide of chromium also has the power of preventing molecules of iron from assuming the magnetic state. Although as a solute molecule it provides great potency, yet at the same time carbide of chromium greatly depletes the steel of its magnetic molecules, and the loss of magnetic power from this cause outweighs the gain in potency. For this reason chromium steel is inferior to tungsten steel as a material for permanent magnets. But by the introduction of another solvent, namely an alloy of cobalt with iron, Professor Honda appears to have removed this drawback and for the first time enabled carbide of chromium to be used without robbing magnetic molecules of their magnetism.

Potency and hardness go together in steel, both properties depending mainly on the presence of carbide molecules in solution. The same carbides, not in solution but present in the steel as distinctive crystalline substances, yield no potency. Presumably they give no hardness either.

None of the elements forming the three carbides used in magnet steels seem able by themselves to create potency. This is certainly true of the iron in carbide of iron. It also applies to tungsten. This element, when put into iron, combines with it to form the molecule Fe_2W,* which, being soluble, immediately dissolves in the remaining iron. But experiment shows that the presence of this solute gives the iron no potency. From analogy it may be conjectured that

* Fe_3C expresses the true proportion, and that is all that is material to the argument of the present paper. Whether the actual molecule is Fe_3C or Fe_6C_2 or $2(Fe_3C)$ does not seem to be known.

† ARNOLD and READ: *Journal of the Iron and Steel Institute*, 1911, vol. 83, p. 249.

* ARNOLD and READ: *Proceedings of the Institution of Mechanical Engineers*, 1914, pt. 2, p. 223.

chromium by itself is ineffective as a creator of potency, but there is no experimental evidence on the point. Lastly, carbon, by itself, is not able to endow iron with potency. Under some conditions carbon in its elementary form, not in combination with other elements, "free carbon" as it is called, is found in steel; even in steel which contains less than one per cent of carbon. Whether it is in a state of solution or not does not appear, but whatever the atoms of free carbon may be doing they are certainly not creating potency. Experimental evidence for this statement has long been available, and on a later page novel evidence will be given that free carbon does not endow iron with potency.

Although this brief examination of the action of each element of the various carbides has failed to identify the potency-creating power with any particular element, there is one consideration that seems to provide a clue. Each of the three carbides used in magnet steels is an effective creator of potency, and when it is borne in mind that the only thing these carbides possess in common is carbon, it is difficult to resist the conclusion that in a solute molecule that creates potency, carbon is the dominant element. True, it does not act by itself. Alone it is powerless, and apparently it is necessary for it to combine with auxiliary elements; yet when so combined in a solute molecule the atom of carbon appears to play the leading part.

If iron were an ordinary element, the rest of the story of steel as a solution could be told without more ado. It would almost suffice to refer to some good textbook treating of solutions in general,* for apart from the extreme slowness of travelling molecules in a solid, steel would behave much in the same way as the more familiar liquid solutions. But if there is any such thing as an ordinary element it is certainly not iron. It would be less wide of the mark to describe solid iron as four interchangeable elements, for it can exist in any one of four states which differ from one another almost as widely as one element differs from another. Of these four different kinds of matter, all described as iron, one is familiar to everyone because it happens to exist at ordinary temperatures. Of the other three it can only be said, at present, that although beyond the reach of the chemist, they are gradually becoming known to the metallurgist. It is this anomalous kind of matter that plays the part of solvent in steel, and its protean transformations must now receive attention.

(7) Iron as an Allotropic Element.

The word "allotropy" was coined a hundred years ago by the chemist Berzelius to describe certain strange substances, visibly and quite remarkably different in outward form, yet chemically indistinguishable from one another, and therefore presumably merely different forms of the same element. Carbon,† which takes the form of diamond, or graphite, or soot, is a familiar example. Another example is sulphur, which can exist as beautiful yellow crystals or as a sticky brown mess. Iron is not allotropic in this obvious sense; it undergoes no visible or tangible changes. Yet its allotropic transformations, although they make no direct appeal to our senses, are even more extraordinary than the difference between diamond and soot.

The recognition of iron as an allotropic element has been a long time coming. The first sign appeared so long ago as the year 1600 when Gilbert, the early father of permanent magnetism, discovered that iron, when heated red-hot, became non-magnetic. Then, to come at once to more modern times, some fifty years ago Gore discovered a whole series of changes taking place in red-hot iron. He found that in addition to the magnetic change, the specific heat, electric conductance, molecular structure and other characteristics, all showed marked changes when iron is heated above a red heat, indicating that it was far from being a normal element. Somewhat later Barrett discovered the phenomenon of recalescence, another sign of allotropy.

But the first systematic investigation of the allotropy of iron was begun in 1887 by F. Osmond, who set out to determine the temperatures at which iron changes from one state or variety to another. Every transformation of the kind is accompanied by an absorption or emission of energy in the form of heat, and on a time-temperature curve obtained from a test specimen that is being gradually heated or cooled an absorption or release of energy will be indicated by a more or less sudden, but temporary, alteration in the slope of the curve. It is possible to ascertain the temperature at which an allotropic transformation takes place by noting the position of the corresponding change in slope, but usually the changes in the slope of time-temperature curves are slight and by no means easy to detect with certainty. Osmond got over this difficulty by making direct observations of the slope itself. In principle, the quantity to be observed is the rate of change of temperature with time, or the reciprocal of that quantity. In practice it is easier to observe the reciprocal or inverse rate, and Osmond's inverse rate curve is obtained by observing the successive intervals of time corresponding with successive small increments, or decrements, of temperature, the time intervals being plotted as co-ordinates with the temperature. Any departure from the normal rate of heating or cooling is indicated by a marked excursion of the curve from its normal course, and hence excursions indicate absorption or release of energy by the specimen under test. By this ingenious method of observation Osmond definitely ascertained the existence of three allotropic varieties of iron, and provisionally determined the temperatures which constitute the boundaries between the different varieties.

The information afforded by Osmond's inverse rate method, and other differential methods derived from it, is mainly qualitative. An excursion of the curve from the normal course indicates the fact that an absorption or emission of energy took place, and points to the temperature at which the phenomenon began, attained its greatest activity, and came to an end. But that is all. Moreover, the time element only

* Mr. Whetham's "Theory of Solution" (Cambridge University Press) gives a comprehensive account of the subject.

† Carbon again! But this time merely as a handy illustration and not as the dominant element in a solute molecule.

appears as a differential, and to ascertain the duration of any absorption or emission of energy it is necessary to integrate the inverse-rate curve. The author has naturally made constant use of Osmond's method, but in this paper it will be necessary to pay particular attention to duration, because time is the key to hardening, and for that reason the allotropic changes in carbon steel and tungsten steel will be illustrated by curves plotted to a scale of time.

To acquire a sense of proportion with regard to the various allotropic transformations, it is necessary to measure the energy changes associated with them. This has frequently been attempted, usually with inconclusive, if not erroneous, results. The first experiment of the kind was made by Hopkinson, who tried to measure the energy released in iron and in carbon steel during the magnetic change.* Up to the present time the best experimental values are those obtained incidentally by Wüst, Meuthen and Durrer in the course of their recent determinations of the specific heat of pure iron in its different allotropic states.† Their method was to heat the test specimen to the required temperature and then to drop it into a Bunsen ice calorimeter and measure the total energy, each experiment being performed from beginning to end in a vacuum. In this way specific heats were determined with remarkable accuracy. The allotropic energy of the different transformations is readily deduced from the observational data, and the temperatures at which the transformations occurred were ascertained with a precision not previously attained. Pure electrolytic iron was employed, hydrogen and any other gases present in the iron being removed by melting the test specimen under a vacuum.

The more important facts relating to the allotropy of pure iron are given in Fig. 1 in the form of a diagram, in which the boundaries between the different varieties are shown against the scale of temperature. The diagram has been prepared by the author to represent present-day knowledge so far as possible, and is of course founded on the researches of Osmond and those who have followed him, with the addition of the quantitative data determined by Wüst and his co-workers. In the case of the energy which is absorbed or emitted over a somewhat ill-defined range of temperature extending from about 800° C. downwards, nearly to 0° C., the major portion arises from some unknown cause, and occurs below the point at which iron loses or regains its magnetism. It seemed worth while to distinguish between this unidentified energy and that properly attributable to the magnetic change, and the present writer has therefore computed the two quantities separately from the observational data given by Wüst. The values so calculated have been inserted in Fig. 1.

Osmond, having recognized the existence of three allotropic varieties of iron, named them "Alpha iron," "Beta iron" and "Gamma iron," in the order of ascending temperature. More recently a fourth variety has been discovered between Gamma iron and molten iron, and this is referred to as "Delta iron." Whether at temperatures below 0° C. iron assumes any other allotropic states does not seem to be known.

Ordinary iron, the most familiar of all metals, is Alpha iron. It is the iron of chemistry and has an international atomic weight of 55·85.* The specific heat at 0° C. is 0·1055, precisely what theory expects

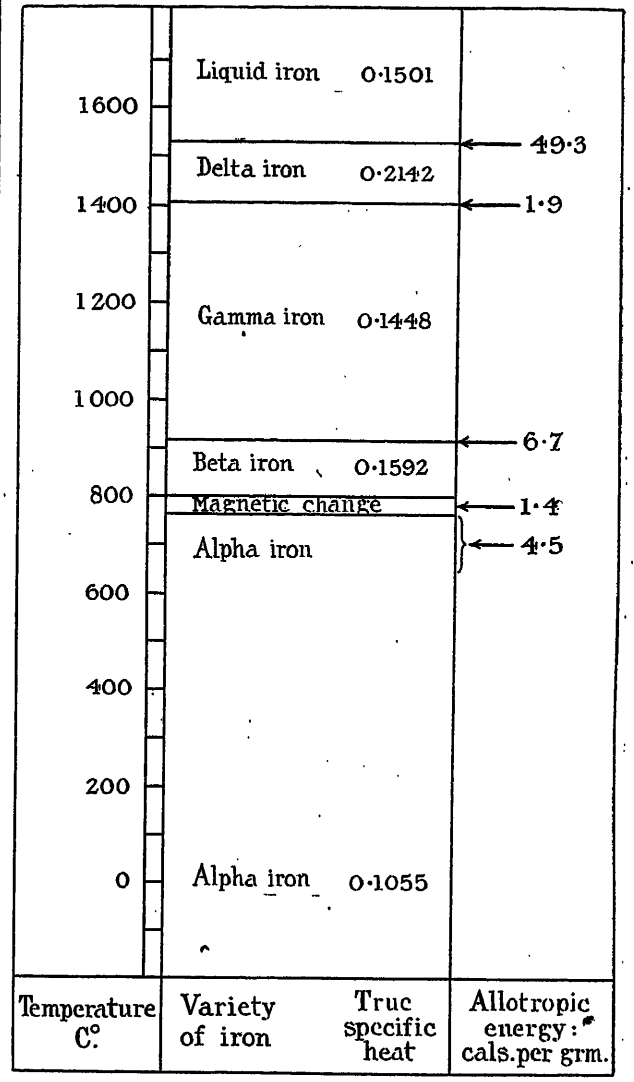

FIG. 1.—Allotropic varieties of iron.

it to be.† In short, Alpha iron behaves in every way as an old-fashioned chemical element should do.

Alpha iron is magnetic, the molecule of two atoms having a magnetic moment of about $4 \cdot 0/10^{20}$ C.G.S. units. With this moment, when all the Alpha molecules in a given volume are fully oriented, the magnetic moment of the oriented or magnetized mass is 1 700

* It would appear that there is some International Body which looks after the elements and their atomic weights.

† On the kinetic theory of gases the formula for specific heat is $\frac{1}{2}(n + 3)R/Jm$, where R is the gas constant, J the number of ergs in one calorie, m the mass of the atom. In a solid n is 3, and on this basis the specific heat of solid iron should be 0·1053, which agrees well with Wüst's observed value, 0·1055 at 0° C.

C.G.S. units per cm³; equivalent to a permanent magnetizing force of 17 000 ampere-turns per cm of length along the axis of magnetization.

For the purpose of this paper it is unnecessary to describe in detail the many phenomena observed in iron as the temperature is raised from 0° C., or thereabouts, to the melting point. But attention may be directed to the more significant among them, in order to mark the fundamental character of the allotropic modifications.

The first indication of anything abnormal in the behaviour of iron, as it is heated, is the gradual increase in the apparent specific heat,* a sure sign that the heat communicated to Alpha iron is not all utilized in raising the temperature; some of the energy taken in as heat is doing something else, probably effecting a change of some kind in the structure of the iron. This *precursor effect*, to give it a name, is noticed in nearly all metals, and it generally occurs as the melting point is approached. The singularity in iron is that the precursor effect seems to have no relation to the melting point. It becomes noticeable immediately above 0° C. and comes to an end somewhere about 750° C., a temperature nearly 800 degrees below the melting point. It seems that in iron the usual precursor effect occurs once for all while the iron is in the Alpha state, for it is significant that there is no such effect just below the melting point. It is a curious fact, and possibly one of significance, that the extraordinary temperature variations in the magnetization of Alpha iron, discovered by Hopkinson,† closely follow the course of the precursor effect. We are, however, not directly concerned with the precursor effect and it must be passed over with this bare reference.

At about 770° C. Alpha iron begins to change into Beta iron. This transformation is effected within a temperature range of about 40 degrees and is practically complete at 810° C.* Alpha iron is magnetic, Beta iron is entirely non-magnetic. That is to say, when iron passes from one state to the other the molecules, one after another, transform their electron orbits from the magnetic arrangement, in which their magnetic axes all point the same way and endow the Alpha molecule with its known magnetic moment and magnetomotive force, to the non-magnetic arrangement in which the algebraic sum of the magnetic moments of the orbits in the molecule is zero. In plain English, when Alpha transforms itself into Beta, iron becomes virtually a different element, the molecule having been reconstructed on a different plan. This fundamental reconstruction is marked not only by the entire loss of magnetic moment and magnetomotive force, but by an equally significant change in the specific heat; a change which points directly to some kind of atomic reconstruction.

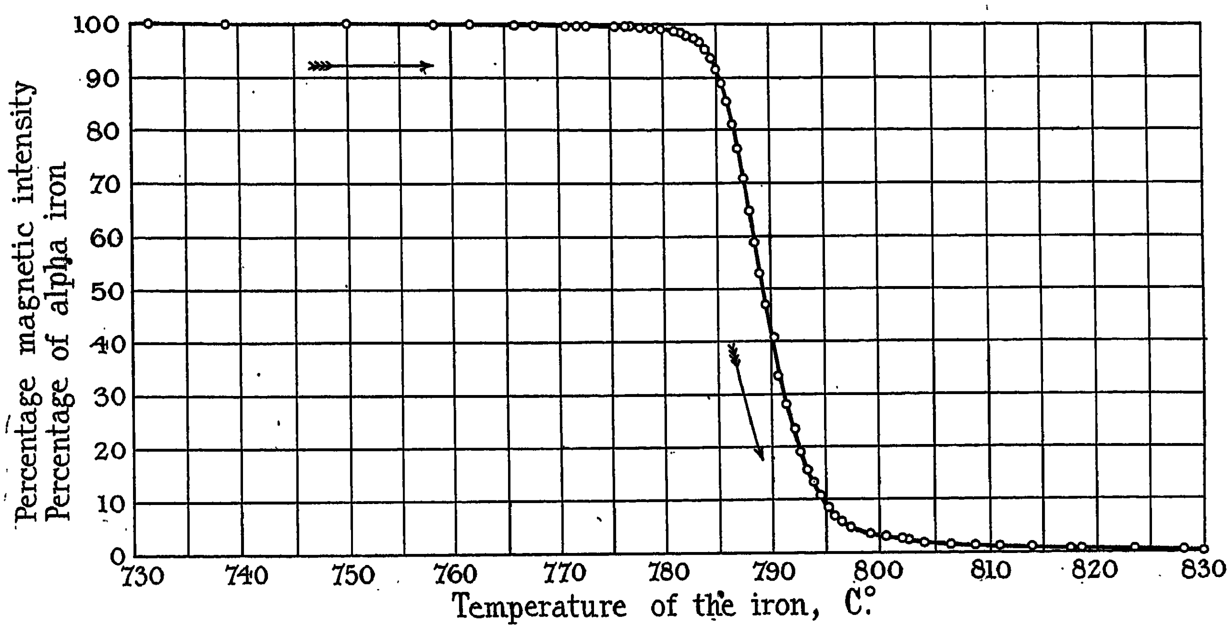

FIG. 2.—Loss of magnetism in pure Swedish iron.

Alpha iron being magnetic and Beta iron non-magnetic, the curve exhibiting loss of magnetism as the temperature rises from 770° to 810° C. indicates with the greatest precision the progress of the allotropic change from Alpha iron to Beta iron.† A curve of this kind determined for the purpose of this paper, from a specimen of very pure Swedish iron, is shown in Fig. 2. The intensity of magnetization is expressed

* When considering allotropic changes, specific heat is a trap for the unwary. Definitions of specific heat tacitly assume that the whole of the heat communicated to the substance goes to raise its temperature. When that is so then the quantity measured is the *true* specific heat. But when an allotropic change is in progress and absorbing energy, some of the heat supplied to the substance is used for that purpose and only the balance goes to raise the temperature. The observed quantity is then the *apparent* specific heat. The apparent specific heat of boiling water or a melting metal, or of iron changing from Gamma to Delta, is infinite.

† J. HOPKINSON, loc. cit.

* Very slight differences in the condition of pure iron, the presence of traces of absorbed gas, and other causes, are found to affect the temperatures at which the allotropic changes occur, frequently by as much as 10 degrees and sometimes even more. For this reason all the temperatures given in the text must be regarded as liable to modification. They are in all cases values actually observed in particular experiments.

† The author is responsible for this truism. No such statement is to be found in the textbooks. Indeed, whenever magnetism comes into view metallurgical writers seem only too ready to pass it by on the other side.

as a percentage of the intensity observed when the iron was wholly of the Alpha variety, and consequently the percentage intensity at any stage in the transformation is also the percentage of Alpha iron in the total mass of iron. Towards the end of the transformation the magnetic intensity approaches zero so very gradually that it is impossible to give an exact figure for the width of the temperature zone within which the entire change from Alpha to Beta is effected. But examination of a number of curves of the loss and recovery of magnetism in pure iron shows that 99 per cent of the whole transformation is effected within a temperature range of 37 ± 1 degrees, so that the width of the temperature zone of the magnetic change from Alpha to Beta, or vice versa, may be put in round figures at 40 degrees for pure iron. The re-arranging of the electron orbits in any individual molecule

put at 919° C., Beta iron is entirely converted into Gamma iron, provided sufficient time is given to effect the change, which is essentially a slow process. On passing the boundary formed by the critical temperature the mechanical and other properties of iron undergo further abrupt changes; but there is no magnetic change, Gamma iron being non-magnetic. The specific heat of Gamma iron is constant.

At a critical temperature, which Wüst has determined as between 1 404° and 1 405° C., Gamma iron is transformed into Delta iron, with a sudden increase of 50 per cent in the specific heat. The iron remains in this state up to the melting point and, the specific heat of Delta iron being constant, there is clearly no absorption of energy as a precursor to fusion.

Last of all, at 1 528° C. pure iron melts. There is a large absorption of energy, a sudden decrease in

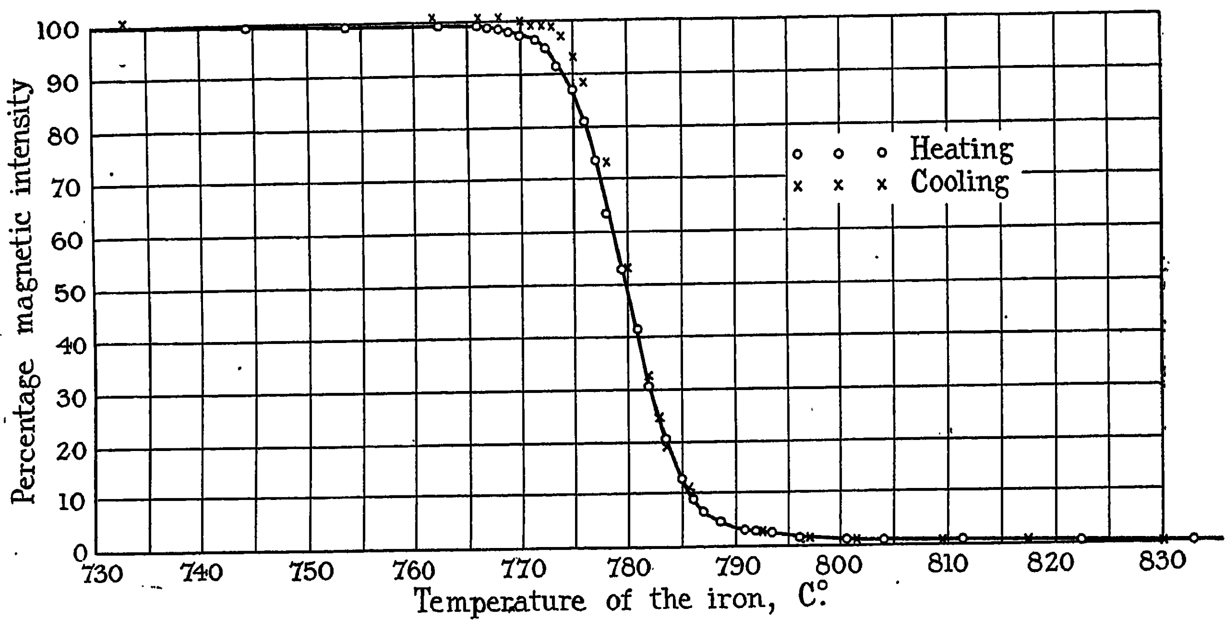

Fig. 3.—Curves of loss and recovery of magnetism in pure Swedish iron.

of iron being practically instantaneous, the width of the temperature zone should be entirely unaffected by differences in rates of heating and cooling. The author has verified this for rates varying from 1 degree a minute up to 12 degrees a minute, there being no observable difference in the width of zone within these limits.

At any given temperature within the narrow zone of 40 degrees, Alpha and Beta molecules exist together, in equilibrium, in a definite proportion, like two metals in an alloy. Any change in temperature in either direction is necessarily accompanied by a corresponding change in the proportion of Alpha molecules to Beta molecules. Besides the magnetic change, abrupt changes in mechanical and other properties are noticed as Alpha iron changes into Beta iron. The specific heat of Beta iron is constant, indicating that all heat communicated to it goes to raise the temperature.

The next transformation occurs at a critical temperature which Wüst found to be somewhere between 918° and 920° C. At this temperature, which may be

specific heat, a remarkable change of state, and an abrupt and total loss of mechanical strength. All these are characteristic symptoms of an allotropic change, yet for some reason, or for no reason, fusion is not included among the allotropic changes.*

When molten iron cools, the allotropic transformations take place in the reverse direction, one after the other, and the allotropic energy absorbed at each change of state is released again and appears in the form of heat. Many observers have noticed that, on cooling, the transformations occur at temperatures a few degrees below the points at which they took place when the temperature was rising, but careful observation has failed to disclose any difference in pure iron between the temperature of the change from Alpha to Beta and the reverse change from Beta to Alpha. This is illustrated in Fig. 3, which records an experiment on the point made for the purpose of this paper.

* The probable reason is that fusion was discovered by primitive man; and being primitive, he knew nothing of the art of coining a word from the Greek whenever anything happens that is not understood.

The curves of loss and recovery of magnetism given in the figure show that within the limits of experimental error (about 2 degrees C.) the change from Alpha to Beta coincides exactly with that from Beta to Alpha. The author has obtained similar curves at widely different rates of heating and cooling without finding any evidence, so far as pure iron is concerned, that the position of the temperature zone of this transformation on the scale of temperature shifts up or down according to whether the iron is being heated or cooled.

Among the allotropic phenomena briefly described in the preceding paragraphs, two are of primary importance, namely, the magnetic change and the marked changes in specific heat. Both point directly to some change in the atom or molecule. The kind of reconstruction implied by the magnetic change has already been indicated. The import of a sudden change in specific heat is equally fundamental. True specific heat is inversely proportional to atomic weight, and the specific heats of the four varieties of iron, namely 0·1055, 0·1592, 0·1448 and 0·2142, correspond with atomic weights of about 56, 37, 41 and 27. Hence if it were not known that Alpha, Beta, Gamma and Delta were varieties of iron it might well be supposed that they were four distinct elements of those atomic weights. Now 56, 37, 41 and 27 being approximately the atomic weights of iron, chlorine, calcium and aluminium, the natural inference to draw seems to be that Alpha, Beta, Gamma and Delta iron differ from each other in much the same degree as those four elements do. It is not suggested that iron which begins as an irreproachable international element actually converts itself successively into chlorine, calcium and aluminium, but it manifestly does something quite as revolutionary in effect.

So far no explanation of the allotropy of iron has been forthcoming. The specific heat of Delta iron being about twice that of Alpha, it might be supposed that the atom of Alpha iron breaks up to form two atoms of Delta, the positive nucleus of the Delta atom containing half the number of protons and therefore constituting an atom of about half the atomic weight. But conjecture, however plausible, is of little use, and the time is hardly ripe for an explanation of the allotropy of iron. It will eventually come from a better knowledge of the construction of the atom and the way it works as a dynamic system.

(8) Carbon Steel.

Turning again to the consideration of steel as a solution, we come back to our subject fully aware of the extraordinary nature of the solvent iron. It is in this shifty element that the several kinds of carbide used in magnet steels must be dissolved. Now the carbides dissolve freely enough in Delta, Gamma and Beta iron, but these varieties of iron all being non-magnetic are, of course, useless as the foundation of a permanent magnet. To make a magnet the steel must be magnetic, that is to say, the iron must be in the Alpha state, and unfortunately none of the carbides at present available for use in magnet steel dissolve in Alpha iron, under normal conditions, in sufficient quantity to make a powerful magnet. In these circumstances, in order to convert the steel into a material fit for the purpose, it is necessary to make use of a process of unique character handed down to us from time immemorial. The steel is first heated so as to transform the iron into Beta or Gamma, in order that a sufficient quantity of carbide may be dissolved in it, and then, by means of the ancient process called hardening, the whole quantity can be retained in solution when the iron, on cooling down, returns to the Alpha state. The state of things brought about in this way is quite abnormal, the solution being in unstable equilibrium; nevertheless, no better way of making a good permanent magnet is known at the present time.* A comprehensive account of hardening will be found in Section (15), and in the meantime it is enough to know that in hardened magnet steel all the solute carbon compounds are held in solution, thus giving the steel the required potency.

Nowadays, carbon steel is seldom or never used for permanent magnets; but as a solution containing only one solute substance, the carbide of iron Fe_3C, it will afford the simplest possible illustration of the principles underlying the process by which steel is made fit for use as a magnet.

When carbon is put into molten iron it immediately dissolves. There is no direct proof that the carbon first forms the carbide Fe_3C, which then becomes the solute substance in the molten iron, but the probabilities all seem to point that way. The best evidence that the molten iron, with the carbon in it, is a solution, is the fact that the temperature at which the liquid begins to solidify is progressively lowered as the proportion of carbon is increased.

The temperatures at which Delta changes into Gamma, and Gamma into Beta, show a similar gradual fall with increasing carbon. Making use of a method of illustration introduced by Roberts-Austen, all these temperature-changes may be shown as so many curves in a diagram, each curve marking the temperature boundary between different states in which the iron-carbon solution or alloy, carbon steel, can exist. The Roberts-Austen iron-carbon diagram in its entirety is a highly complex affair, and a perennial source of controversy among metallurgists, who are by no means agreed either as to how the diagram should be drawn or as to the interpretation of the facts it is intended to embody. In this paper, however, we are only concerned with the first and least contentious part of the diagram, where it relates to iron-carbon solutions containing amounts of carbon not exceeding one per cent, since magnet steels never contain more than that proportion. This part of the diagram is shown in Fig. 4, where all the boundary lines have been plotted from such observational data as are available at the present time.

In pure iron, solidification occurs at a critical temperature, but with the introduction of carbon the solidifying process becomes selective and extends over a wider and wider range of temperature as the percentage

* It need hardly be said that the discovery of hardening, which seems to imply a profound metallurgical knowledge, was made by accident. Some very primitive blacksmith, in a hurry to cool a piece of red-hot steel, plunged it into water, and simultaneously civilization took a long stride forward.

of carbon increases. This is illustrated in the diagram by the lines AL and AS, which mark the boundaries where solidification begins and ends respectively.

The temperature boundary where the iron changes from Delta to Gamma is approximately indicated by the line DY, which begins at the temperature determined by Wüst for pure iron, and passes through a point determined for the author by Mr. R. Rolfe for a steel containing 0·7 per cent of carbon. It has been assumed that as regards curvature this boundary line would resemble that between Gamma and Beta iron.

The boundary line GE shows where the iron, on

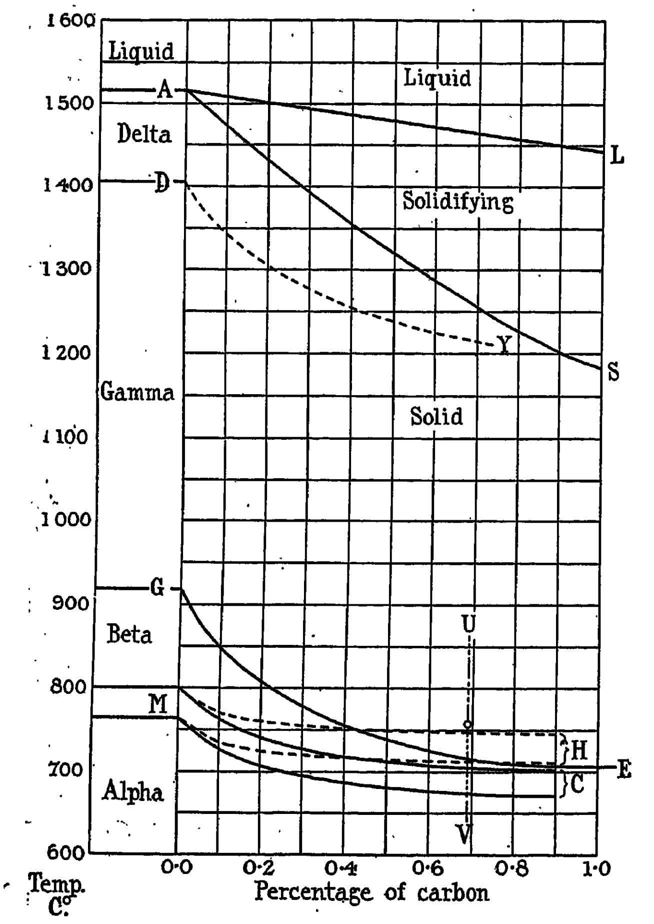

FIG. 4.—Roberts-Austen iron-carbon diagram, up to a carbon content of 1 per cent.

cooling, changes from Gamma into Beta. This line and the two solidification lines have been plotted from experimental data obtained by Carpenter and Keeling.*

Below the Gamma-Beta boundary are the diverging temperature zones, MH and MC, within which the Alpha to Beta and Beta to Alpha transformations occur during heating and cooling respectively. These have been plotted from curves, obtained by the author, representing the loss and recovery of magnetism. It will be noticed that with increasing carbon content the gradual lowering of the temperature of the Gamma-Beta transformation is so much greater than that of the Beta-Alpha or magnetic change, that the two phenomena begin to overlap when the carbon content is about 0·5 per cent. As the carbon is increased beyond that proportion and the extent of overlapping grows, it becomes increasingly difficult to secure experimental conditions that will result in a record of the two allotropic changes as distinct effects; with a falling temperature, for example, the heat emitted as the result of the Gamma-Beta change becomes only too easily merged in that associated with the Beta-Alpha transformation.

We are now in a position to follow the course of events as some particular specimen of carbon steel cools down and the iron passes in succession from Gamma to Beta and Beta to Alpha. The specimen chosen by way of example is one from which thermal and magnetic data have been obtained to illustrate this paper, being a pure carbon steel containing 0·687 per cent of carbon, by analysis. Steel of about this

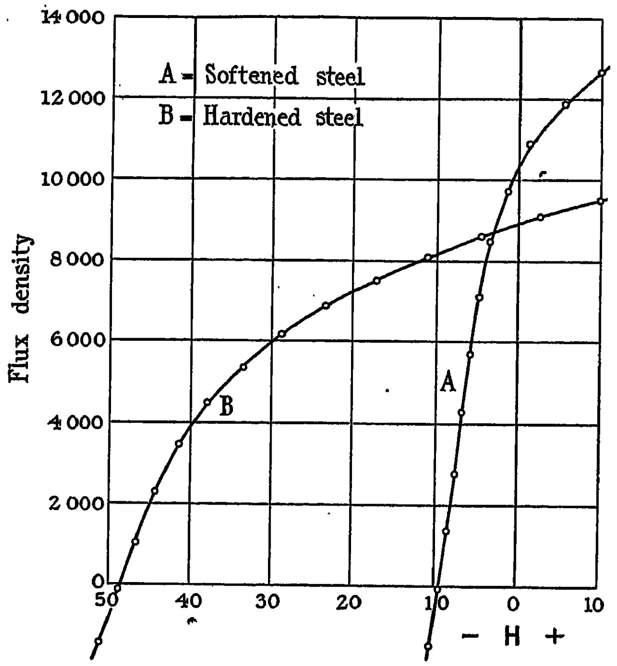

FIG. 5.—Demagnetization curves of pure carbon steel:—
Curve A, the steel in the softened state.
Curve B, the steel completely hardened.

carbon content makes a good magnet and represents the material commonly used for the purpose before the introduction of tungsten magnet steel. The two demagnetization curves given in Fig. 5 were obtained from a specimen of this steel, first in the softened condition and then in the hardened state. Curves of the loss and recovery of magnetism in the same steel are shown in Fig. 6, and it will be noticed at once that the introduction of carbon has not only lowered the general position of the curves on the scale of temperature, but also brought about a wide separation between the temperatures at which loss and recovery of magnetism occur.

* CARPENTER and KEELING: *Journal of the Iron and Steel Institute*, 1904, vol. 65, p. 224.

The rate of change of temperature with time, as the steel cools down through the Gamma-Beta-Alpha transformations, is shown in Fig. 7, where the rate of change of magnetic intensity and the corresponding portion of the time-temperature curve are also given,

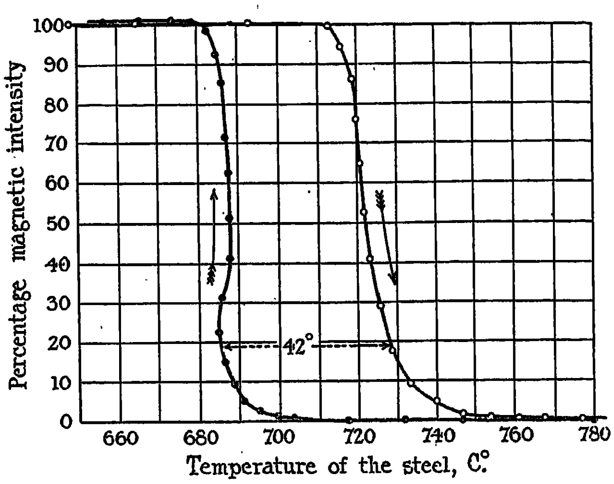

FIG. 6.—Loss and recovery of magnetism in pure carbon steel containing 0·687 per cent of carbon.

having solidified, the iron remains in the Delta state over a range of 30 or 40 degrees and then transforms itself into Gamma iron. In this state it remains over a wide range of more than 400 degrees. So far, nothing has happened that suggests any change in the steel as a solution. There does not appear to be any direct proof to be had, but it is universally believed that in the Gamma iron the carbon is still in solution and that the solute is the carbide of iron, Fe_3C. The cooling continues and at a temperature of 757° C., reading from Fig. 4, which is based on determinations by Carpenter and Keeling, or at 754° C. reading from Fig. 7, which contains the author's determination of the same point, the first sign of a departure from the normal rate of cooling makes its appearance; Gamma is beginning to be converted into Beta and the associated allotropic energy begins to be released as heat (Fig. 7). Three minutes later, at about 715° C., the first sign of magnetism appears, indicating the beginning of the change from Beta to Alpha. At about 5 minutes the completion of the transformation of Gamma into Beta is marked by the abrupt change, seen at P, in the course of the differential curve. At 11½ minutes the recovery of magnetism is complete, showing that the whole of the iron has been converted into Alpha iron.

Here we must stop to inquire what has become of

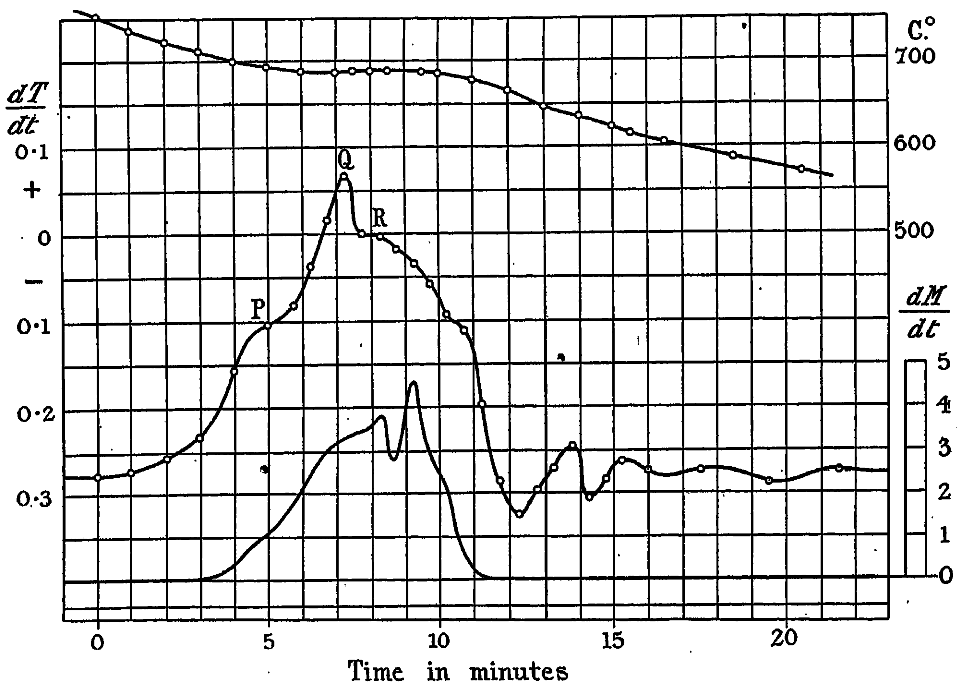

FIG. 7.—Pure carbon steel cooling from 900° C. Curves showing fall of temperature, departure from the normal rate of cooling consequent on the release of energy as heat (middle curve), and rate of change of magnetic intensity during recovery of magnetism.

all these observational data having been obtained concurrently. For convenience, the scale of time starts from the point where the differential curve first begins to depart from the normal course.

In Fig. 4 the cooling of the specimen of carbon steel is represented by the vertical line UV. The steel the surplus proportion of carbide of iron which is not soluble in Alpha iron. The total quantity of carbide in the steel being known, the surplus can only be ascertained if we can discover how much carbide is retained in solution by the Alpha iron. Information on this point is scanty and vague. Carbon steel, even

when softened, is much harder than pure iron, from which it may be inferred that it contains some carbide in solution, though not so much as there is in hardened steel. As to the amount, we have only the casual statement occasionally to be met with, that steel containing no more than 0·25 per cent or 0·30 per cent of carbon (for different amounts are named) cannot be hardened.* The statement is true enough, but presumably what it means is not that steel containing, let us say, 0·25 per cent of carbon is no harder than iron, but that when heated red-hot and plunged into water it is no harder than it was before. To anticipate a little, it is easy, by magnetic means, to ascertain approximately the amount of carbide in solution in steel "that cannot be hardened," and the amount that apparently dissolves in Alpha iron is found to correspond roughly with a carbon content of 0·26 per cent. Deducting that percentage from the total carbon content of the specimen of carbon steel, namely 0·687 per cent, the remainder, 0·427 per cent, represents the surplus carbide that is left with no available solvent when the whole of the iron has been converted from Beta into Alpha iron. Hence when that transformation takes place, the surplus carbide crystallizes out of solution, and in doing so the associated energy which went to create and maintain the state of solution is released as heat. The energy is considerable. In the present example it amounts to, roughly, 40 joules per gramme of steel, to which must be added about 6 joules per gramme for the energy released when Beta iron changes into Alpha. Altogether the energy released as heat was not far short of 50 joules per gramme of steel, the emission beginning at the third minute and spreading over about 8 minutes (Fig. 7). It is the emission of this heat, at an increasing rate, that gives rise to the extremely rapid variation in the rate of change of temperature which is noticeable in the curve in Fig. 7 between the points P and Q. The quantity of heat was sufficient to cause slight recalescence, the rise in temperature attaining a maximum at the point R.

The irregular oscillations in the curves in Fig. 7 may be just referred to in passing. They have their origin in experimental conditions for the most part, and proceed from thermal causes analogous to those which set up "hunting" in moving machinery. This sort of thermal hunting is seldom entirely absent in such experiments as these, and it is one of the many difficulties in the way of exact measurement.

The carbon steel specimen has now cooled down into the final stage in which the iron is wholly of the Alpha variety. Of the total amount of carbon in the form of carbide, namely 0·687 per cent, only 0·26 per cent remains in solution; the surplus 0·427 having crystallized out of solution because Alpha iron cannot in normal circumstances dissolve so much.

At this point it will be useful to recall the behaviour of a saturated solution of salt in water, in order to contrast it with the fundamentally different behaviour of steel as a solution. When the temperature of the salt solution is lowered the proportion of salt that is surplus at the lower temperature comes out of solution. Fall of temperature and quantity of surplus go together, and the amount of salt remaining in solution is solely a matter of temperature. In the course of these changes the solvent itself undergoes no modification; water it was, and water it remains. Contrast this with what happens in the steel, where it is the chameleon-like solvent that changes. It is converted from one kind of substance to another of a very different kind, from Beta iron to Alpha iron, and the surplus of solute arises from the fact that the carbide is less soluble in Alpha than it is in Beta; very much less soluble. Moreover, the amount of surplus is not governed by temperature, except within the narrow range where Beta is undergoing conversion into Alpha. Once that conversion is complete the surplus solute is a fixed quantum, the difference between the amount of carbide originally present in solution in the Beta iron, and the amount which Alpha iron can retain in solution as a system in stable equilibrium.

To create in the salt solution something analogous to the state of things in the steel, it would be necessary to endow the water with the power of transforming itself into, say, alcohol, and to suppose salt to be much less soluble in alcohol than it is in water. Then if, in a saturated solution of salt, the water happened to change into alcohol, the surplus salt would crystallize out of solution, just as the surplus carbide does when Beta changes into Alpha iron, and for the same reason. In a salt solution, such a transformation of the solvent as we have imagined would be regarded as an unexampled happening in a solution, yet when the change occurs in the solution called steel, metallurgical writers pass it over without so much as a hint to their readers that anything at all out of the way has taken place.

(9) Carbon Steel: The Quantity of Carbon in Solution and the Resulting Potency.

The relation between the carbon content and the Hopkinsonian coercive force of carbon steel in the hardened state was determined many years ago by Madame Curie * from a number of specimens of steel containing different proportions of carbon, the coercive force of each specimen being measured and the carbon content determined by analysis. The data so obtained, when plotted as co-ordinates, gave the curve which is reproduced in Fig. 8. The test specimens being in the hardened state, it may be assumed that the whole of the carbon was in solution as carbide of iron, and looking on coercive force as a measure of the potency of the steel, the curve gives the empirical relation between the proportion of carbide in solution and the resulting potency.

The reversed curvature of the carbon-coercive-force curve suggests that two opposing actions are at work, but of their nature nothing is known. There can be little doubt that a complete interpretation of the entire curve will one day be forthcoming, and when it appears it can hardly fail to throw light both on the mechanism of solution and on the molecular pattern that gives rise to potency in steel.

Meanwhile, the carbon-coercive-force curve is useful

* See, for example, Sauveur: "The Metallography and Heat Treatment of Iron and Steel," p. 295. (Sauveur and Boyston, Cambridge, Mass., U.S.A.)

* Mme. Curie: "Propriétés Magnétiques des Aciers Trempés," *Bulletin de la Société d'Encouragement*, 1898, vol. 3.

merely as a means for ascertaining one co-ordinate when the other is known. For example, by measuring the coercive force of a piece of softened carbon steel and referring to the curve (Fig. 8), the quantity of carbide of iron in solution is determined: a measurement that gives the solubility of the carbide in Alpha iron under conditions of equilibrium, provided the steel contains an excess of carbon. To soften the steel it would be sufficient to maintain it at a temperature of about 700° C. for 10 minutes, thus giving ample time for all the surplus carbide to pass out of solution, and leaving in solution only that quantity which is naturally soluble when the iron is in the Alpha state. The specimen of carbon steel referred to in Section (8) serves for a determination of this kind. The demagnetization curve (Fig. 5) for this steel in the softened state shows that the coercive force in that condition was 9·3. Reading from Mme. Curie's curve (Fig. 8), the corresponding carbon content is found to be about 0·26 per cent, or 27 molecules of carbide per 1 000 molecules of iron. From this it appears that 1 000 diatomic molecules of Alpha iron can retain 27 molecules of the carbide (Fe_3C) in solution; the surplus carbide, amounting in the present example to 44 molecules per 1 000 of solvent iron, having crystallized out of solution when the Beta iron changed into Alpha.

At the time Mme. Curie's experiments on carbon steel were made, the difficulty in ensuring identity in the composition of the magnetic test-piece and that of the sample chosen for analysis was not fully appreciated, and for this reason the curve reproduced in Fig. 8 must be regarded as no more than a good approximation. Nevertheless, Mme. Curie's observational data demonstrate conclusively that the relation between carbon content and coercive force in hardened carbon steel is expressed by a curve of reversed curvature, an *S*-shaped curve. In the following section we shall see that just as the solute molecule Fe_3C in carbon steel results in a curve of *S* shape, so other solute molecules of the potency-giving kind give rise to curves of similar shape.

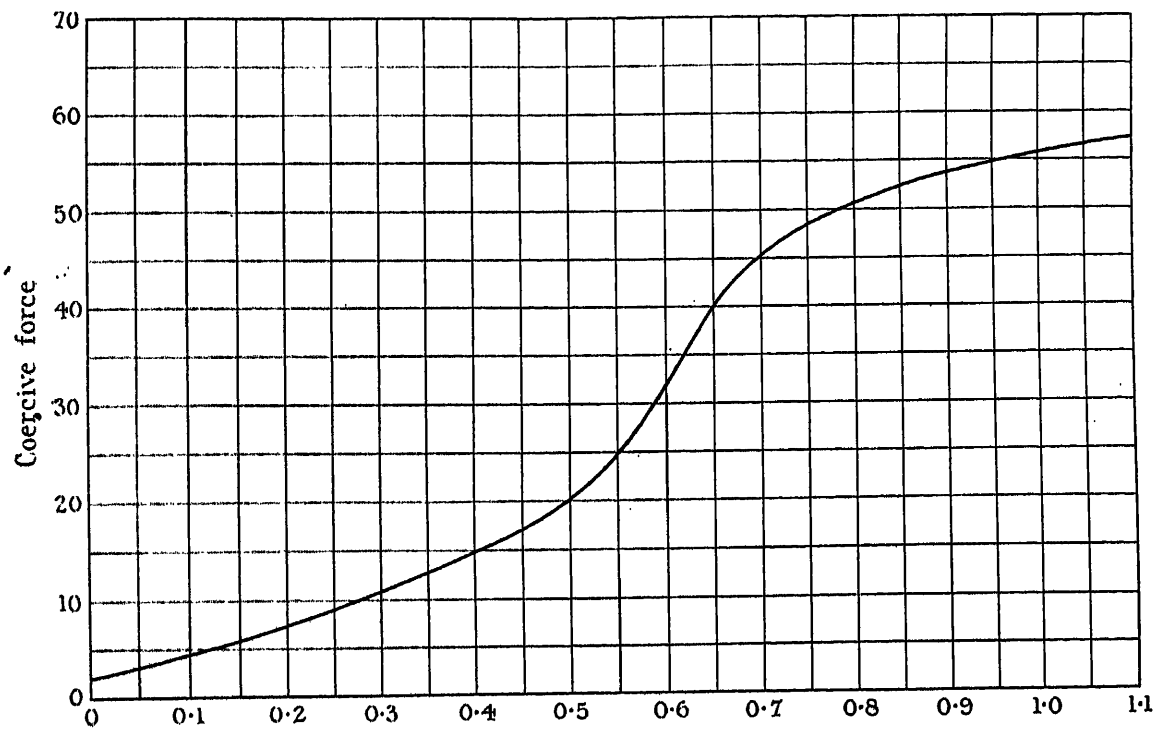

FIG. 8.—Pure carbon steel in the hardened state. Relation of coercive force to carbon content. (Mme. Curie.)

(10) Tungsten Steel: The Carbides and Coercive Force.

Tungsten magnet steel might be described as carbon magnet steel in which about half the carbide of iron has been replaced by carbide of tungsten, the total content of carbon remaining unchanged. The effect of this part replacement of one solute substance by another is to increase the Hopkinsonian coercive force from rather less than 50 to rather more than 70, and this increase in potency leads to a large increase in the magnetic energy which the hardened steel can maintain, the useful energy being about 7 200 ergs per cm^3 for carbon steel and as much as 14 000 ergs for good tungsten steel. This improvement in useful effect is all the more remarkable because carbide of tungsten by itself is unable to accomplish it; it needs the cumulative action of both the carbides.

Quite apart from the significance of the changes in the magnetic properties of steel that follow the intro-

duction of tungsten, metallurgists have been, and probably still are, divided in opinion as to the composition of the carbon compounds in tungsten steel. There seems, however, hardly room to question the conclusions arrived at by Arnold and Read from their analyses of the carbide residues of tungsten steels in the softened state. Assuming their interpretation to be correct, the formation of the series of compounds found in tungsten steel may be briefly described as follows: We shall begin with a mass of pure iron containing N atoms of iron, the quantity being defined symbolically as NFe. If x atoms of tungsten are added to the mass, they combine with $2x$ atoms of iron as the tungstide of iron Fe_2W, a compound which dissolves in the remaining iron. The solution so formed is represented by $(N - 2x)\mathrm{Fe} + x\mathrm{Fe_2W}$. We now add y atoms of carbon to the solution, and tungsten having a greater affinity for carbon than for iron, y atoms of tungsten leave the tungstide of iron in order to combine with the carbon as the carbide of tungsten WC. This sets free $2y$ atoms of iron, and hence the solution is now

$$(N - 2x + 2y)\mathrm{Fe} + (x - y)\mathrm{Fe_2W} + y\mathrm{WC},$$

the carbide of tungsten dissolving in the iron.

By increasing the quantity of carbon, we next arrive at a stage when the proportion of carbon to tungsten, by weight, is that of the atomic weights of the two elements, namely 12 to 184. With this proportion the quantity of carbon just suffices to combine with the whole of the tungsten. That is to say $y = x$, the whole of the tungstide of iron having been decomposed. The solution is now $N\mathrm{Fe} + x\mathrm{WC}$, being solely carbide of tungsten dissolved in iron. To this solution we now add some more carbon. The additional carbon combines with some of the iron as the carbide of iron Fe_3C, and if the number of carbon atoms added in this way is z, then the solution will be represented by $(N - 3z)\mathrm{Fe} + x\mathrm{WC} + z\mathrm{Fe_3C}$, both the carbides dissolving in the iron. This last formula represents the composition of tungsten magnet steel, and in good magnet steel z is approximately equal to x; that is to say, the number of molecules of carbide of iron is roughly equal to the number of molecules of carbide of tungsten. Since each solute molecule contains one atom of carbon, equality in number of molecules corresponds with equality in weights of carbon, equality in percentage weights.

Two points should be noticed before going on. First, that although carbon combines easily with iron, yet when put into iron which already contains tungsten, it combines with the tungsten in preference to the iron and only combines with the iron when all the tungsten has been utilized. Evidently carbon has a greater affinity for tungsten than it has for iron. This fact has an important bearing on the spoiling of tungsten magnet steel, a subject treated in Sections (13) and (14).

The second point is one which deserves more attention than it has received from metallurgical writers. The carbide residues on which Arnold and Read founded their conclusions were obtained from steels in the softened state in which, of course, the iron was of the Alpha variety. It seems to be tacitly assumed that the particular carbon compounds proved by analysis to be present in Alpha iron at room temperatures, must also be present as identically the same compounds in Beta iron or Gamma iron at the high temperatures at which those allotropic varieties exist. The assumption is probably correct, but it would be more satisfactory if a proof of some kind could be found.

In what follows it will be assumed, for the present without proof, that if the compounds WC and Fe_3C are present in Alpha iron then they must have been present also when the iron was in the Beta, the Gamma and the Delta states, present as identically the same compounds.

Assuming the existence of the two carbides WC and Fe_3C as the active solute substance in hardened tungsten magnet steel, it would be useful to know how and in what degree those solute molecules contribute to the potency of the steel. What is needed is a graph for tungsten steel expressing the relation between the carbon content and the coercive force, after the manner of Mme. Curie's curve for carbon steel. Some years ago the present writer would have said that observational data for the preparation of such a graph existed in abundance. Numerous experimenters having published the values they had obtained for the coercive force of specimens of tungsten steel of widely varying composition, it seemed that it should only be necessary to bring those values together and the relation of carbon content and coercive force would be disclosed once for all. But on plotting various tests of the kind, culled from many sources, astonishing discrepancies became apparent in the results of different observers and even in those of the same observer. Not even an approach to systematic arrangement could be discovered, and it became evident that to establish the required relation it would be necessary to investigate afresh from beginning to end. This the author determined to do and the necessary experiments were put in hand. Many unforeseen difficulties were encountered, and it was only after several years of continuous research that the work was brought to a successful conclusion in the spring of 1923.

A previous attempt of the kind had been made by Dr. Swinden * to establish the relation between carbon-content and coercive force in steel containing about 3 per cent of tungsten, but the wide discrepancies in the observational data, partly attributable to the use of the magnetic balance of Du Bois, partly to other causes, completely masked the underlying law.

In the author's investigation all the samples of steel contained the same percentage of tungsten, which was that commonly used in magnet steel at the present time, namely 6 per cent. The carbon content of the samples varied step by step from about 0·06 per cent up to 1·3 per cent. All the magnetic tests were made with an astatic moving-coil magnetometer giving direct readings, by mirror and scale, of the applied magnetizing field and the resulting intensity of magnetization. Test-pieces of ellipsoidal form were used throughout the research, in order to avoid the ambiguities so frequently introduced into magnetometer

* T. Swinden: "The magnetic properties of a series of carbon-tungsten steels," *Journal I.E.E.*, 1909, vol. 42, p. 641.

work by the use of cylindrical test-pieces. On the whole the accuracy of the magnetic tests was in excess of what was needed, being considerably greater than the accuracy attained in the analysis of steel.

The distribution of carbon in a bar of rolled steel is seldom uniform, and in testing pieces of steel taken from a bar it is always a matter of uncertainty whether the carbon content of the piece used for the magnetic identity in carbon content was removed, and it was only by the adoption of this method throughout the final tests that consistent results were secured.

Ordinary chemical analysis only gives the percentage quantities of the various elements in the steel; it does not indicate whether and in what way the elements are combined, and there is nothing to show whether the carbon, for example, is present as a carbide

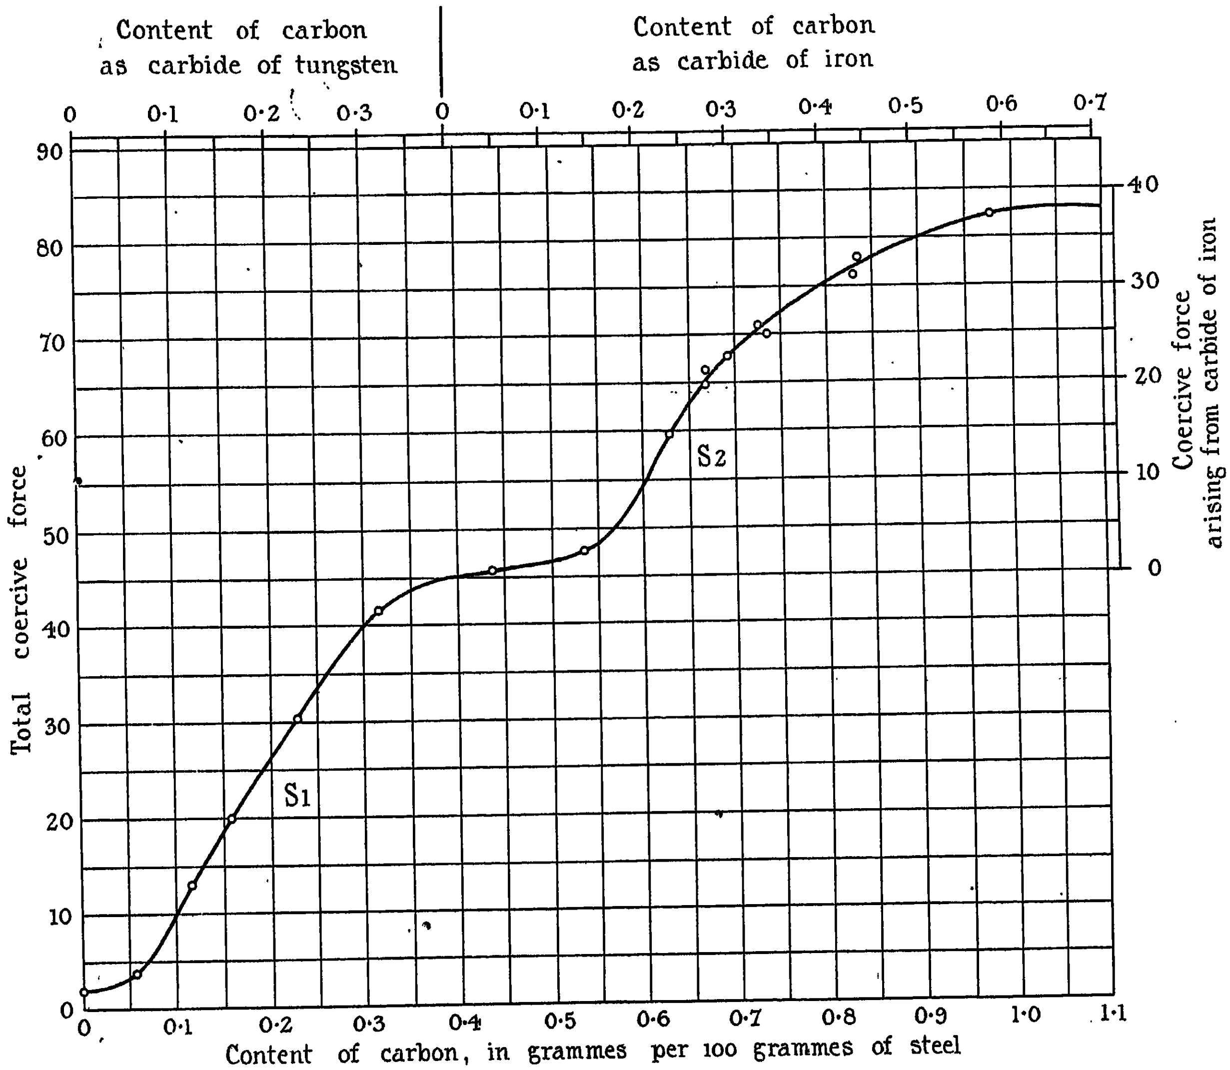

FIG. 9.—Tungsten magnet steel in the hardened state, the steel containing 6 per cent of tungsten. Relation of coercive force to carbon content.

tests is identical with that of the sample chosen for analysis. In the preliminary tests many errors were traced to this cause although the greatest care had been taken to avoid them by choosing, as the samples for analysis, portions of the rolled bar immediately adjacent to the ends of the magnetometer test-piece. The procedure finally adopted was to prepare the magnetometer test-piece and then, after the completion of all the necessary magnetic tests, to analyse the test-piece itself. In this way all chance of error from want of or not. Now tungsten steel and cobalt steel are very rarely free from a defect described in a later section under the heading spoiled steel. In spoiled magnet steel, the carbide compounds are partially decomposed and therefore more or less ineffective as solute molecules of the potency-creating kind. In short, loss of potency, as the result of spoiling, is the rule.

This prolific source of error runs through all previous work on tungsten magnet steels, and is largely responsible for the extraordinary discrepancies in the results obtained

by so many different observers. It was essential to avoid it, and this was done by making use of the method of restoring spoiled steel described in Section (13). Some of the samples were obviously in need of restoration, others were practically unspoiled; but to be on the safe side every sample was subjected to the process of restoration, whether it appeared to need it or not, this being done before making the magnetometer test-pieces. All the test-pieces were hardened by quenching them in an aqueous solution of calcium chloride from a temperature of 850° C.

The final outcome of this prolonged investigation * is recorded graphically in Fig. 9 as a curve connecting percentage carbon content with coercive force in hardened steel containing 6 per cent of tungsten. It is at once apparent that the introduction of tungsten, which we have assumed to result in the presence of the two carbides WC and Fe_3C, gives rise to two *S*-shaped curves, S1 and S2, following one after the other.

The proportion of carbon needed to combine with 6 per cent of tungsten as WC is, of course, 6 multiplied

TABLE 1.

Carbon content		Carbon steel		Tungsten steel		Gain and loss of coercive force
	Per cent	Carbide	Coercive force	Carbides	Coercive force	
1st portion	0·39	Fe_3C	14·2	WC	45·0	30·8 +
2nd portion	0·33	Fe_3C	32·8	Fe_3C	25·4	7·4 –
Totals	0·72		47·0		70·4	23·4 +

Gain and loss of potency in magnet steel containing 0·72 per cent of carbon, when about half the carbide of iron is replaced by tungsten carbide.

by the ratio of atomic weights, namely 12/184. The required proportion is therefore 0·391 per cent, and on referring to Fig. 9 it will be seen that 0·39 per cent of carbon corresponds quite well with the point of inflexion where curve S1 ends and curve S2 begins. This is conclusive as to the origin of curve S1. The increasing potency, measured by coercive force, manifestly arises from the gradual introduction of molecules of carbide of tungsten, and the curve necessarily comes to an end at the point where the quantity of carbon just suffices for 6 per cent of tungsten. This, so far as the author is aware, is the first definite proof of the existence of the carbide of tungsten WC in hardened tungsten steel, and it is worth noting that the fact is established from magnetic data.

Curve S1 being clearly accounted for by the presence of carbide of tungsten, the second curve, S2, must arise from the balance of carbon in excess of 0·39 per cent, and we may assume that it is in the form of carbide of iron, Fe_3C. Scales have been added in Fig. 9 giving the percentage of carbon and the coercive force for curve S2 separately, for convenience in computing the coercive force of tungsten magnet steels.

Carbon, when added to steel which already contains carbon in the form of carbide of tungsten, is not so effective in creating potency as it would be if added to steel containing the same quantity of carbon as carbide of iron. For this reason the gain in potency, consequent on the replacement of some of the carbide of iron by tungsten carbide, is partly set off by a loss of potency due to the diminished effectiveness of carbide of iron in tungsten steel. An example of this is given in Table 1 for steel containing 0·72 per cent of carbon, the total being divided into two portions, the first amounting to 0·39 per cent, and the second to 0·33 per cent. It will be seen that the gain of 30·8 units of coercive force, due to the introduction of 6 per cent of tungsten, is set off by a loss of 7·4 units as the result of the decreased efficacy of the carbide of iron. The table has been prepared from Mme. Curie's curve for

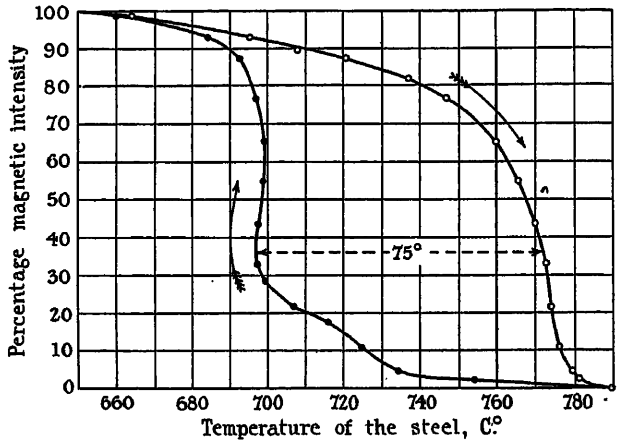

FIG. 10.—Loss and recovery of magnetism in tungsten magnet steel.

carbon steel and the author's double curve for tungsten steel.

It follows from the form of the curves S1 and S2 in Fig. 9, that in a steel containing somewhere about 0·72 per cent of carbon the content of tungsten may be varied considerably without materially affecting the coercive force, there being a certain degree of give and take about the two curves. This inference is borne out in practice, for the content of tungsten may be varied from about 5 per cent to about 6·5 per cent without causing any material change in coercive force.

It may be anticipated that when the shape of Mme. Curie's curve for carbon steel has been interpreted, the explanation of the two curves in series which express the relation of Hopkinsonian coercive force to carbon content in tungsten steel will also be forthcoming. These two curves have an immediate practical use, however, for since they represent restored—that is to say unspoiled—tungsten magnet steel, a comparison of the analysis of any particular batch of tungsten steel with the ordinates of the curves indicates at once the degree of spoiling, or decomposition,

* Work on the samples of steel was held in abeyance for over a year pending the discovery of an entirely trustworthy method of restoration.

as measured by the deficiency in coercive force. The author has also made use of the curves in Fig. 9 for another purpose, which will be referred to in Section (14).

The temperatures at which the several allotropic changes take place in tungsten steel are known to be so nearly the same as those determined for carbon steel that the iron-carbon diagram, of which a portion has been given in Fig. 4, serves well enough for tungsten steel. One reservation must be made, however. It has already been shown in Fig. 6 that in carbon steel there is a wide temperature difference between the curves of loss and recovery of magnetism. In tungsten steel of the same carbon content the difference of temperature between loss and recovery of magnetism is much greater, as will be seen on referring to Fig. 10. Hence to represent tungsten steel the iron-carbon diagram given in Fig. 4 would need a modification in the position of the temperature zone in which the transformation from Beta iron to Alpha occurs, the separation of the zone of loss of magnetism from the zone of recovery being roughly 42 degrees C. for carbon steel, and about 75 degrees C. for tungsten steel, when both steels contain 0·70 per cent of carbon.

(11) Pressure as the Force which Controls the Magnetic Change.

The zones of temperature in which the allotropic changes take place from Alpha iron to Beta, and vice versa, are indicated in diagrams representing the loss and recovery of magnetism. Examples have been given in Figs. 3, 6 and 10, showing the magnetic change in pure Swedish iron, carbon steel and tungsten magnet steel. In any kind of steel, and in most specimens of iron, there is a noticeable interval, on the scale of temperature, between the zone where magnetism is lost on heating and the zone where it is regained on cooling, recovery of magnetism occurring at the lower temperature. The existence of a temperature interval has been known for a generation or more, and it has been supposed that loss and recovery of magnetism in the magnetic elements necessarily occur at different temperatures.* That loss and recovery of magnetism are nearly always separated by an interval of temperature, recovery taking place at the lower temperature, does not admit of doubt, but the fact has remained without explanation and the forces which determine the position of the magnetic change on the temperature scale have so far remained unidentified.

To-day, however, the facts are better known. The experiments with Swedish iron, of which a typical example is recorded in Fig. 3, have shown that when the iron is sufficiently free from other elements the zone where magnetism is regained on cooling coincides with the zone where it is lost on heating. It follows that the separation commonly observed between loss and gain arises from the presence of foreign elements in the iron, and this being granted there is no difficulty in attributing the separation seen in Fig. 6 to the carbon, and the wider interval in Fig. 10 to the presence of tungsten in addition to carbon. In both these examples the foreign elements are known to form compounds which dissolve in the iron, and this at once suggests the possibility that the interval between loss and gain of magnetism has something to do with solution. Guided by these deductions from experiment it seems possible to account in a simple way for the lowering of the temperature at which magnetism is recovered when iron contains elements or compounds in solution. In its present tentative form the explanation does not account for all the facts, but it may be given here because it has grown naturally out of the ideas on which this paper is founded, and seems to provide a clue which may be usefully followed in future research.

* See, for example, Ewing, 2nd edn., chap. 6, pp. 178–179.

We assume that, so far as magnetism is concerned, the iron molecule of two atoms behaves as though each atom were a tiny coil or current ring carrying a constant electric current, thus accounting for the constant magnetic moment and magnetomotive force which the iron atom is known by observation to possess. To simplify the problem as much as possible, we may imagine the two current rings to be separated by a fixed distance and that each is free to turn about a diameter. For this electromagnetic system the only position of stable equilibrium is that in which the two rings are in parallel planes with their currents flowing in the same sense. In that position the magnetomotive forces of the two current rings act in the same direction, the system possesses a magnetic moment, and the two rings represent the electrical system of an iron molecule in the magnetic or Alpha state. To convert the molecule into the non-magnetic form, the aspect of the two current rings with regard to each other must be reversed (by a movement equivalent to turning one of them round through half a revolution) so that their currents flow in opposite senses. In this condition, which is one of unstable equilibrium, the two magnetomotive forces will be in opposite directions and the system will have no resultant magnetomotive force and no magnetic moment. In short, when the two current rings are back to back, as it were, they represent the iron molecule in its non-magnetic form.

In undergoing the change from the magnetic to the non-magnetic state the system of two current rings passes from stable equilibrium to unstable equilibrium and force must be applied to effect the change. Moreover, if the force is withdrawn or reduced below a certain critical value, the system will at once revert to the magnetic state of stable equilibrium. In other words the two current rings, in virtue of their electric currents, exert forces on each other which constantly tend to cause them to revert to the magnetic arrangement—a statement which is equally true of any system of electric circuits carrying constant currents. We may therefore regard the iron molecule as an electrical system endowed with a *force of reversion* which, if it is not balanced by an opposing force, will cause the molecule to assume its magnetic form. From this point of view it will be seen that when an iron molecule retains the non-magnetic form it must be because the inherent force of reversion is outweighed by some opposing force, and if the opposing force should diminish until the balance of forces turns the other way, then the molecule would revert to the

magnetic form. As to the nature of the opposing force, the phenomena of the magnetic change point unmistakably to one characteristic. For at any temperature below the region of the magnetic change all the iron molecules are magnetic, and above that region they are all non-magnetic. Hence, whatever the opposing force may be, it is clearly one which acts indiscriminately on all the iron molecules, and in seeking for it we must look for some force of a general kind capable of acting equally on every molecule throughout a solid mass.

We proceed on the supposition that inside any solid body there is a pressure arising in the same way as the pressure in a gas, proportional to the absolute temperature but no doubt depending on more complicated factors than those governing the simple law of gas pressure. In pure iron this temperature force will be the only pressure at work, but when any substance, either elementary or compound, is dissolved in the iron there will be an additional general force, the pressure of solution. The purist may perhaps say that these two sources of pressure cannot be distinguished from one another, but for mental convenience we shall regard heat pressure and solution pressure as separate components, the total pressure acting in the iron or steel being the sum of the two.

Our next step is to jump to a conclusion, by assuming that the total pressure is the force acting in opposition to the force of reversion inherent in the iron molecule. On this assumption, so long as the total pressure exceeds the reversion force, every iron molecule throughout the mass will be compelled to remain in the non-magnetic state; but when, for any reason, the opposing force of pressure falls to a value at which it is outweighed by the reversion force, then every iron molecule will revert to its magnetic arrangement. How the complex forces hidden in the word "pressure" are brought to bear on the electrical system of the iron molecule so as to act in opposition to the inherent force of reversion, we do not know. This, and much more, is at present far beyond our ken. But if we adopt the hypothesis that what is called pressure in some mysterious way controls the iron molecule in its magnetic changes, then it will be found that the facts disclosed by the curves which represent loss and recovery of magnetism arrange themselves in a more or less orderly fashion.

To begin with pure iron. Here the only pressure is that arising from temperature. Raise the temperature of a piece of Alpha iron, that is to say, increase the pressure, and at a certain point the rising pressure will outweigh the reversion force of the iron molecules. Accordingly the iron will be compelled to transform itself into the non-magnetic form, and at any temperature above the critical zone in which the change occurs every molecule in the piece of iron will be forcibly held in the non-magnetic form by the preponderating force arising from the heat pressure.

The iron being now in the non-magnetic state, let the temperature be lowered. There will be a corresponding fall in the heat pressure and, as the falling temperature traverses the critical zone, the diminishing pressure will be outweighed by the reversion force and the iron will therefore return to the magnetic state. That is to say, above the critical zone the pressure exceeds the reversion force, and below it the reversion force outweighs the pressure; and since in pure iron the only source of pressure is the temperature, the change from one state of things to the other must take place within the same critical zone of temperature whether the change is from magnetic to non-magnetic or the other way about. This is in agreement with the experiment recorded in Fig. 3.

Now consider the case of iron with something dissolved in it, so that in addition to the heat pressure there will be the pressure arising from the state of solution. We may take carbon steel as an example. Disregarding the peculiar action of carbon in creating the molecular pattern that gives carbon steel its potency, attention must be confined to the fact that carbon forms a soluble compound which dissolves in the iron and therefore gives rise to solution pressure. It will be convenient to begin by supposing that the steel is cooling down from a temperature at which the solvent iron is in the non-magnetic state, so that the conditions governing the pressure may be noted as the temperature falls.

It may be taken for granted that the strength of the electromagnetic forces at work within the iron molecule will not be affected by the mere presence of neighbouring solute molecules, and consequently the critical pressure at which reversion to the magnetic state will occur as the metal cools, should be the same in the carbon steel as it is in the iron. But in the steel the pressure is augmented by the solution pressure, and hence, when the temperature has fallen to the point at which pure iron reverts to the magnetic state, the total pressure in the steel will exceed the reversion force by the amount of the solution pressure and the iron molecules will therefore still be held in the non-magnetic state. To bring about reversion to the magnetic state the total pressure must be reduced to the critical value, and this can only be done by lowering the temperature so as to neutralize the increment of pressure due to solution by a corresponding decrement in the heat pressure. In other words, when iron contains anything in solution so as to give rise to additional pressure, the temperature at which reversion to the magnetic state occurs must necessarily be lower than the temperature of the magnetic change in pure iron. This deduction, also, is in agreement with observation.

Small variations in the temperature at which the magnetic change occurs in successive tests of the same specimen of iron are frequently observed, the critical temperature often rising three or four degrees with each succeeding test. Discrepancies of this kind are readily explained as the result of small changes in the total pressure. Gases of different kinds dissolve freely in molten iron and a good deal of gas may remain in solution in the cold metal. Each time the specimen is heated some of the gas is likely to escape. The result would be a small reduction in the solution pressure and a corresponding rise in the temperature required to bring the total pressure to the critical value.

A striking example of the effect which dissolved

gas may have in lowering the temperature of the magnetic change came under the author's notice when investigating a sample of ingot iron; iron of quite exceptional purity and free from all but a mere trace of carbon. Much to the surprise of the experimenter, the mean temperature of the zone of the magnetic change was found to be 756° C., an extraordinarily low value for iron free from impurities. Judging from numerous specimens of pure Swedish iron, the mean temperature of the magnetic change in pure iron is 780°, or possibly three or four degrees higher. In the case of the ingot iron, therefore, there is a lowering of at least 24 degrees to be accounted for. There can be little doubt as to the cause. The intention in making ingot iron is to obtain the greatest possible purity and, more particularly, to eliminate carbon. For that purpose the molten metal is "washed" with oxygen, a process which affords ample opportunity for the gas to dissolve in the iron. The metal when cold may be described as a saturated solution of oxygen in pure Alpha iron, and it is to the pressure arising from this state of solution that we may attribute the lowering of the temperature of the magnetic change by 24 degrees.

The most remarkable example of the effect of solution in lowering the temperature at which magnetism is recovered on cooling is afforded by the nickel-iron alloy discovered by Hopkinson.* The true composition of the alloy appears to be exactly one part of nickel to three parts of iron. The magnetic change of any mixture of these two metals would naturally be expected to occur somewhere between the temperatures of the allotropic change in iron and in nickel, that is to say between 780° and about 350° C. In any case it would not occur below the latter temperature, even if nickel alone determined the magnetic change. But Hopkinson's experiments showed that with any proportions of nickel and iron the point at which magnetism was regained was very considerably below 350° C., and from this it was clear that the metals formed an alloy. It was found, moreover, that the amount by which the temperature of recovery of magnetism was lowered grew suddenly to a sharply defined maximum when the proportions of the metals were exactly one to three, the recovery of magnetism then taking place at about 50 degrees below 0° C.

The existence of a maximum implies that one part of nickel and three of iron form a definite alloy possessing distinctive properties, and among other qualities solution pressure would presumably attain a maximum value. It seems very probable that in such an alloy—a mutual solution of two metals—the pressure of solution would be far greater than it is when a fractional percentage of carbon is dissolved in iron, and on the pressure hypothesis the much higher solution pressure would necessitate a much lower temperature for the recovery of magnetism. All this accords well with the fact that the temperature of magnetic recovery in the nickel-iron alloy is lowered to an extraordinary extent.

From the above examples of the recovery of magnetism it appears that the pressure hypothesis, founded on the supposition that the electrical system of the iron molecule behaves like a system of coils or current rings, agrees well with what is known about the varied temperatures at which magnetism is regained on cooling.

Turning to the converse problem, loss of magnetism in iron which contains other elements, the outstanding fact is the interval which separates the temperatures at which magnetism is lost and regained, the temperature difference between loss and gain varying from a few degrees when a little carbon is dissolved in the iron, to many hundred degrees when iron and nickel are mutually dissolved in each other. For ease of comparison the curves of magnetic loss and recovery for pure iron, carbon steel, tungsten steel and the

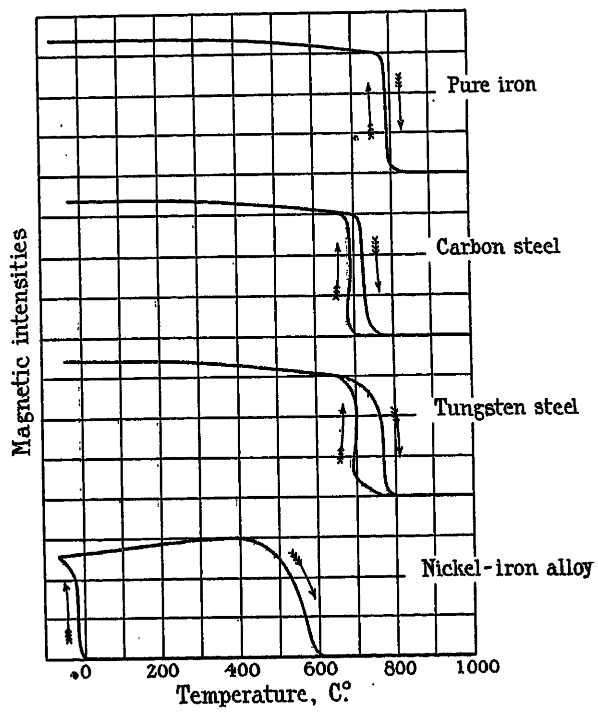

FIG. 11.—Comparison of loss and recovery of magnetism in pure iron, carbon steel, tungsten magnet steel and nickel-iron alloy.

nickel-iron alloy have been brought together one under the other in Fig. 11. In these curves it is noticeable that although the temperature at which magnetism is lost varies to some extent, yet in the main the separation between loss and recovery is brought about by the lowering of the temperature at which magnetism is recovered.

So far as the carbon steel is concerned, the temperature separation between loss and gain of magnetism is readily accounted for on the pressure hypothesis. When magnetism has been regained, that is to say when all the solvent iron has reverted to the Alpha state, any surplus carbide passes out of solution. This decreases the pressure and causes the total pressure to fall well below the critical value which brought about the recovery of magnetism. To compel the iron to become non-magnetic once more, the total pressure

* J. HOPKINSON: *Proceedings of the Royal Society*, 1889 and 1890. The principal results will be found in EWING, 2nd edn., chap. 8.

must be brought up to the critical value, and to do that the temperature must be raised. If the whole amount of carbide passed out of solution, reducing the solution pressure to zero, the required critical pressure would only be attained when the temperature reached the zone where pure iron loses its magnetism. But we know that the whole of the carbide does not pass out of solution when the solvent iron assumes the Alpha form. Roughly one-third of it remains in solution and, consequently, there is still a solution pressure although it is, of course, much reduced. Taking the reduced solution pressure into account, it is clear that the critical pressure should be attained at a temperature well above the zone of recovery, but certainly below the zone of the magnetic change in pure iron. Hence loss of magnetism may be expected to occur at a somewhat lower temperature in the carbon steel than it does in pure iron, and a reference to Fig. 11 shows that this is in fact what happens.

In tungsten steel the fact that loss of magnetism takes place well above the temperature of recovery is to be explained in the same way. But in this case there are discordant features for which the pressure hypothesis as it stands offers no satisfactory explanation. Apparently some factor has been left out of account, and to explain the behaviour of tungsten steel it seems necessary to assume that, for any given quantity of solute, the solution pressure in Alpha iron is less than that in Beta iron. Again, in the nickel-iron alloy where, on the face of it, nothing passes out of solution when the two elements undergo their transformation from the non-magnetic to the magnetic state, our hypothesis can only explain the wide separation between recovery and loss of magnetism on the supposition that the solution pressure of an alloy of Alpha nickel with Alpha iron is ever so much less than that of the Beta nickel with Beta iron alloy. Independent evidence on the point is wanting and there is therefore nothing either for or against the idea that solution pressure may differ according to whether magnetic molecules are in their Alpha state or their Beta state.

One other matter deserves notice connected with the magnetic change in steels which contain more carbon than is freely soluble in Alpha iron. In such cases the curves of loss and recovery of magnetism frequently differ in their slope, the recovery curve being more upright than the curve of loss. This agrees well with the pressure hypothesis and it can be shown that, of the two curves, it is the curve of loss which truly represents the normal progress of the transition from one state to the other, the curve of recovery being liable to distortion.

Here, for the present, the pressure hypothesis must be left. It affords but a partial explanation, marshalling some facts in their order, leaving others unexplained. Complete agreement was not to be expected, for to apply to solid steel the simple ideas about pressure which we derive from the behaviour of gases, is to ignore the effect of the want of molecular freedom in

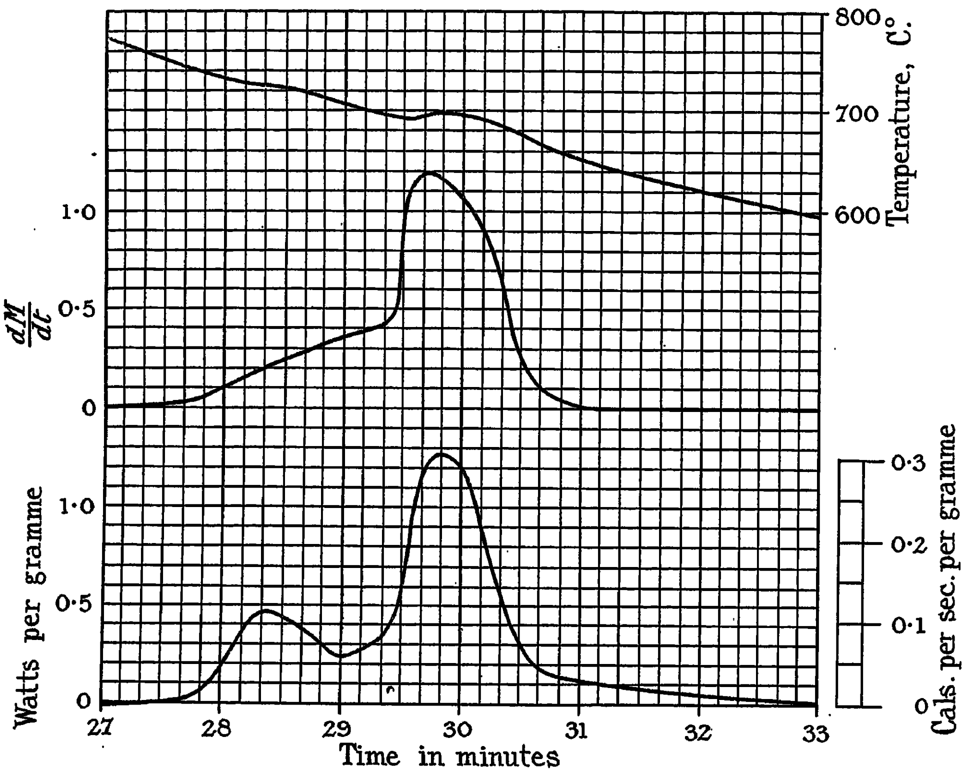

FIG. 12.—Release of energy when tungsten magnet steel cools from 900° C. Curves showing fall of temperature, rate of change of magnetic intensity during recovery of magnetism, and the rate at which energy was released as heat.

the solid. But on the supposition that the electromagnetic forces inherent in the electrical system of the iron molecule naturally cause it to revert to the magnetic state, the idea that pressure acts in opposition to the force of reversion seems to hold the promise of a rational explanation of the relation between temperature and the magnetic change.

(12) The Energy Released in Tungsten Steel on Cooling Down.

The sequence of events as tungsten magnet steel slowly cools down, and the molecules of iron pass from Gamma to Beta, and Beta to Alpha, is illustrated in a novel way in Fig. 12, where in place of the customary inverse-rate curve, or a time differential curve similar to the one already given for carbon steel (Fig. 7), the actual rate of release of energy is given in joules per

Table 2.

Allotropic change	Energy per gramme of steel: Joules	Energy per gramme of steel: Calories
Gamma iron to Beta iron	26·4	6·3
Beta iron to Alpha iron	5·9	1·4
Transfer of carbide from solution to crystal	47·9	11·4
Reversal of the Precursor effect ..	18·6	4·5
Totals	98·8	23·6

Allocation of the allotropic energy released during the cooling of tungsten magnet steel ($C = 0 \cdot 65$; $W = 6 \cdot 0$) from 900° C., the tabular figures being obtained by integration of the energy curve in Fig. 11.

Note.—As determined from Fig. 11, the energy released when Gamma iron changes into Beta is 6·3 calories per gramme of *steel*. This corresponds with 6·85 calories per gramme of *iron* in the steel, a figure which compares with the value determined by Wüst from calorimeter tests of pure iron, namely 6·67 calories per gramme.

second (watts) per gramme of steel, thus for the first time presenting the facts in a quantitative form. The ordinates of the energy curve have been computed by the author from data obtained by concurrent observations of the temperature of the steel test-piece and the difference of temperature between the test-piece and the walls of the furnace, making use of the radiation formula:—

$$\frac{dE}{dt} = \frac{ra}{m}(T_2^4 - T_1^4) + s\frac{dT_2}{dt}$$

Here E denotes energy, T stands for absolute temperature, r is the radiation constant, a the superficial area of the test-piece and m its mass. The specific heat of the steel, which is of course a variable, is denoted by s.

The released energy, represented by the area of the graph in Fig. 12, comes from four sources, namely (1) the change from Gamma to Beta, (2) the change from Beta to Alpha, (3) the passage of the surplus carbide molecules from solution to crystal, and (4) the energy previously absorbed by the precursor effect and given out again on cooling. Although there is some overlapping, it is possible to separate the whole quantity of energy into its components, as shown in Table 2. To engineers who think in kilowatt-hours, 98·8 joules per gramme conveys nothing, until it is discovered that the energy is equivalent to nearly 28 kilowatt-hours per ton of steel.

It will be noticed in Fig. 12 that the carbides present in the steel began to come out of solution at the 29th minute of the experiment and that by the 31st minute the passage from solution to crystal was complete—a duration of 2 minutes. This is the shortest time the author has observed for this essentially slow process. The temperature at which the carbides began to crystallize out of solution was 708° C., and that is therefore the limiting temperature below which it would be impossible to retain the whole quantity of carbide in solution by any method of sudden cooling, a point which will be referred to again in Section (15).

(13) Spoiled Magnet Steel and its Restoration.

So far it has been assumed that in magnet steel all the constituent elements are playing the parts assigned to them in the magnetic mechanism; that the whole of the solvent iron is generating magnetism, and that the entire carbon content is usefully employed in the form of potency-giving molecules. But magnet steel as it comes from the steelworks falls a long way short of that ideal condition, the heat treatment which the steel receives in course of manufacture causing serious injury to the properties on which the power of a permanent magnet depends. It is not generally recognized how much harm is done. The injury is of two kinds, giving rise to a deficiency in the inherent magnetomotive force and a loss of potency. In effect, both the factors of magnetic energy suffer degradation.

Deficiency of magnetomotive force arises from the ultraheating of magnet steel. It is the lesser of the two evils, because the magnet maker who is aware of it can easily apply a complete remedy. Ultraheating will repay careful study by the metallurgist as well as the magnet maker, but to describe the tangled phenomena here would involve a long digression and the subject is therefore treated separately in an Appendix.

The loss of potency, which is due to the spoiling of magnet steel by decomposition, is a much more serious injury and there is no practicable remedy for it that can be applied after the steel has left the steelworks. This almost universal defect in magnet steel is the subject of the present section and it will be shown that the injury is preventible.

When starting on a journey through unknown country it is often helpful to be told where we are going. The author, having been compelled to spend four or five years investigating spoiled steel, has already made the journey and the outcome can be summed up in a few sentences. If the solute carbide molecules in magnet steel were stable chemical compounds, there would be no such thing as spoiled steel. Unfortunately,

the very molecules on which we rely for the creation of potency, suffer decomposition at temperatures to which magnet steel is exposed during manufacture. Decomposition of the carbide molecules breaks up the molecular pattern identified with potency, and hence magnet steel which has been exposed for some considerable time to any temperature within a certain danger zone loses much of its power to act as a permanent magnet. For the purpose of making magnets the steel is spoiled. Both tungsten magnet steel and cobalt magnet steel suffer degradation by spoiling, but the research now to be described was confined to tungsten steel.

Magnet makers are of course familiar with the fact that magnets made from the same batch of steel vary widely in their magnetic power, the difference between the best and the worst being much the same in every lot of steel. Without tracing this persistent lack of uniformity to its source, it was easy to attribute it to a number of causes, namely, the variable composition of the steel, the way it was rolled, the forging of the magnet, the temperature for hardening, the nature of the quenching bath, and the way the steel was immersed in it. All these would be suspected in turn, and from time to time modifications in practice would be introduced, more or less at random. But no matter what was done, excessive variation in magnetic power remained. It is to-day, as it ever was, the magnet maker's greatest trouble, and it has not been mastered because there was no obvious clue to the underlying cause.

The author found himself in possession of a clue by accident. Some years since, a Sheffield steel maker supplied a quantity of magnet steel nominally containing 0·7 per cent of carbon and 6 per cent of tungsten, proportions that should give a coercive force of about 69 in the hardened steel. The batch of steel consisted of a large number of lengths of rolled bar, and in the ordinary course two samples were cut off each length for testing purposes. The samples having been hardened and their coercive force measured, the values obtained were found to vary from about 46 in the best sample to 27 in the worst, the average of the whole lot being 36.

Deficiency of coercive force may arise, and frequently does arise, from deficiency of carbon. In the present case this cause was immediately suspected and a sample bar fairly representative of the whole lot was submitted to analysis. The steel was found to contain 0·69 per cent of carbon and 6·2 per cent of tungsten, a sufficiently close approximation to the specified composition. The coercive force corresponding with the composition ascertained by analysis should be 68, the observed average value being only 36.

This remarkable steel, then, contained carbon and tungsten in quantities which, if these elements were properly combined as solute molecules, should give a coercive force of nearly twice the observed value. The only possible explanation seemed to be that by some means or other the carbide molecules had been decomposed and that their constituent atoms, although still present in the steel as shown by the percentage analysis, were not in the condition that gives rise to potency and coercive force. In short, as a material for permanent magnets the steel was entirely spoiled.

The cause of the spoiling was not far to seek. On inquiring what had happened in the steelworks, it was ascertained that in order to soften the steel after rolling, the whole batch had been heated to about 900° C. and maintained at that temperature for a prolonged period (more than 24 hours), the steelmaker being apparently unaware that to soften tungsten magnet steel for easy machining it is only necessary to keep it at 700° C. for at most 10 minutes. It being evident that 900° C. is a dangerous temperature for tungsten steel, this clue formed the starting-point for an experimental investigation.

The first thing to be done was to verify the fact by subjecting some good magnet steel to prolonged heating at about 900° C. For this purpose three rolled bars were selected from a batch of tungsten magnet steel of standard composition, choosing bars which represented the characteristic variations in magnetic quality. Short lengths having been cut off each bar to serve as test-pieces, they were hardened and tested for coercive force. The values obtained were 76·0, 71·5 and 62·5.

TABLE 3.

Test-piece	Initial coercive force	Coercive force after heating at 900° C. for 7 hours	14 hours	21 hours
L31	76·0	55·0	43·5	36·5
L22	71·5	55·0	43·5	—
L49	62·5	51·0	43·5	38·5

Progressive decrease in the coercive force of hardened tungsten magnet steel, consequent on previous heating at 900° C.

The three test-pieces were next put into a furnace and heated to 900° C., and that temperature having been maintained for 7 hours the test-pieces were taken out of the furnace and allowed to cool down. Having removed the scale oxide formed during the prolonged heating, the test-pieces were hardened again and tested for coercive force. This cycle of operations was repeated twice more, so that by the end of the experiment the test-pieces had been subjected to a temperature of 900° C. for three periods of 7 hours each, or 21 hours altogether, with intermediate hardening and testing for coercive force. The result of the experiment is recorded in Table 3, showing the gradual spoiling of the steel that goes on at 900° C. After 7 hours at that temperature, tungsten steel is reduced to a condition in which it is little better than carbon steel as a material for permanent magnets, and at the end of 21 hours it is much inferior to carbon steel. The experimental data given in Table 3 have been used to construct the curve given in Fig. 13, which illustrates the gradual spoiling of tungsten magnet steel, of normal composition, at 900° C.

It is noticeable that although, to begin with, the

three test-pieces differed widely in coercive force, 14 hours at 900° C. reduced them all to the same level of inferiority. Why this should be was not understood at the time the experiment was made (June 1918), but a reference to the carbon-coercive-force curves now available for tungsten steel (Fig. 9) at once suggests a reason. Attention has already been drawn to the fact that carbon combines more readily with tungsten than with iron, and it is reasonable to suppose that when the conditions are favourable to decomposition, the carbide of iron will decompose more readily

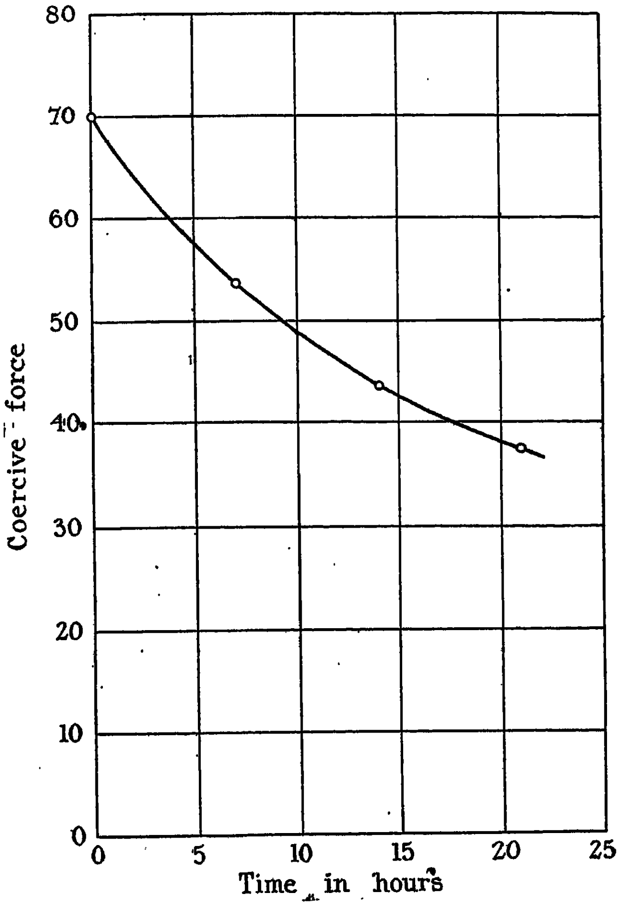

FIG. 13.—Spoiling of tungsten magnet steel. Curve showing the progressive degradation in the coercive force of the hardened steel consequent on previous heating at 900° C.

than the carbide of tungsten. Now the quantity of carbide of tungsten is determined by the quantity of tungsten and, since in this respect all three test-pieces are alike, the potency and coercive force arising from carbide of tungsten will be the same in all of them. Hence the initial differences in coercive force must be attributed to differences in the content of carbide of iron, and when the whole of that carbide has been decomposed, the remaining coercive force will be that due to carbide of tungsten: the carbon-coercive-force curve (Fig. 9) shows that under those conditions the coercive force cannot exceed 45, and it will be less than that amount if there has also been some decomposition of the carbide of tungsten. The experiment therefore indicates that at the end of 14 hours each test-piece had already arrived at this stage of equality in degradation; all the carbide of iron had already been decomposed.

Before going on with the investigation of spoiling, it will be convenient to describe a first attempt at the restoration of spoiled steel, made immediately after the conclusion of the experiment in spoiling recorded in Table 3. If we assume that spoiling is decomposition and that none of the dissociated elements escape at the surface of the steel, then it should evidently be possible to restore spoiled steel by re-melting it, because in that way the iron, the tungsten, and the carbon would, as it were, begin life all over again. But a little consideration suggested that restoration might take place at some temperature short of the melting point. It seemed probable that the high temperature to which high-speed tool steel is heated, in order to leave it hard on cooling down, might be intended incidentally to re-combine any solute carbide molecules that had suffered decomposition during the making of the steel, and in that case a similar high-heat treatment ought to restore magnet steel.

To put this idea to the test of experiment it was proposed to heat one of the three spoiled test-pieces to a temperature well above 1 200° C. for some minutes. The test-piece selected for the purpose was that made from the length L31 for which the initial coercive force was 76. It was anticipated that a good deal of carbon might have escaped from the surface of the steel in the course of the 21 hours' heating it had undergone, and to avoid a misleading result from this cause the surface of the test-piece was removed in the lathe to a depth of about 1·5 mm, leaving a cylindrical core for the experiment. This core was then heated in a bath of molten barium chloride to a temperature just over 1 300° C., at which point it was maintained for nearly half an hour*; it was then removed from the heating bath and allowed to cool down. After this treatment the core was hardened in the usual way by quenching from 850° C. The coercive force of the hardened core was then measured and found to be 71. This figure compares with 76 when in the initial state and 36·5 in the spoiled state. Although the potency of the restored cylindrical core, measured by coercive force, fell somewhat short of the initial value, the experiment was encouraging.

Here we may again interpret the result of an early experiment in the light of information which was not available at the time. Referring again to the carbon-coercive-force curve (Fig. 9), it will be found that the values 76 and 71 obtained for the coercive force in the initial and the restored states correspond with carbon contents of 0·81 per cent and 0·73 per cent respectively. Heating for 21 hours at 900° C., followed by about half an hour at 1 300° C., had therefore resulted in the abstraction of carbon from the entire section of the test-piece, the loss in the cylindrical core amounting to just 10 per cent of the quantity originally present in the steel.

* A couple of minutes at 1 300° C. would have been ample time for restoration; but this was not known at the time the experiment was made.

A steel test-piece which has been denuded of carbon to even a very small depth below the surface gives entirely spurious values for coercive force, the decarbonized layer acting as a magnetic shunt applied to the central core. For this reason, loss of carbon at the surface of the test-pieces added greatly to the difficulties encountered in a prolonged investigation of the spoiling effect. The one likely remedy, keeping the heated steel in a carbon-laden atmosphere, was deliberately put on one side, because there was no certainty that the steel would not take in carbon from its surroundings; and, if it did, there was no easy means of measuring the quantity so absorbed. In all the experiments adduced in this paper the effect of the inevitable loss of carbon has been eliminated either by removal of all the steel found to be denuded of carbon, or by analysis of the steel at the different stages of experiment. In a test-piece 2 or 3 cm^2 in sectional area,

Spoiling tungsten magnet steel. Results of experiments on a bar of rolled steel, spoiled by heating at 900° C. for 1·5 hours, showing that the central core is degraded by spoiling although it has lost no carbon.

loss of carbon in the central portion of the section only begins to be noticeable after spoiling at 900° C. has gone on for a good many hours. It was therefore an easy matter to avoid losing carbon in the central core of a test-piece by restricting the duration of spoiling to one or two hours, the degree of spoiling in even so short a period as an hour being easily measurable by the decrement of coercive force. A typical experiment of this kind is recorded in Table 4.

The figures given in the table were obtained from test-pieces made from a bar of steel of exceptional uniformity as regards carbon content and almost free from spoiling. The samples for the first analysis, giving the average composition of the whole sectional area of the bar in its initial state, were taken from positions contiguous to the ends of the piece of bar from which the two test-pieces were made. The test-pieces were cylinders 10 cm in length and 0·64 cm in diameter. Having measured the coercive force of the hardened test-pieces in the initial state, one of them was heated to 900° C. and maintained at that temperature for 1·5 hours. It was then put into the lathe, and the surface having been turned off to a depth of 1·08 mm, the central core in its spoiled state was hardened and tested for coercive force. This having been done, the content of carbon and tungsten in the central core was determined by analysis, the core being softened and turned into shavings for the purpose. It will be seen from the figures in Table 4 that although the spoiled central core happened to contain slightly more carbon than the average content of the original section, yet the coercive force had decreased by 10·5 units as the result of 1·5 hours' heating at 900° C.

Having demonstrated the fact that spoiling takes place when tungsten magnet steel is heated at 900° C., the next step was to ascertain how the rate of spoiling varies with the temperature. For this purpose a number of samples were cut from a bar of magnet

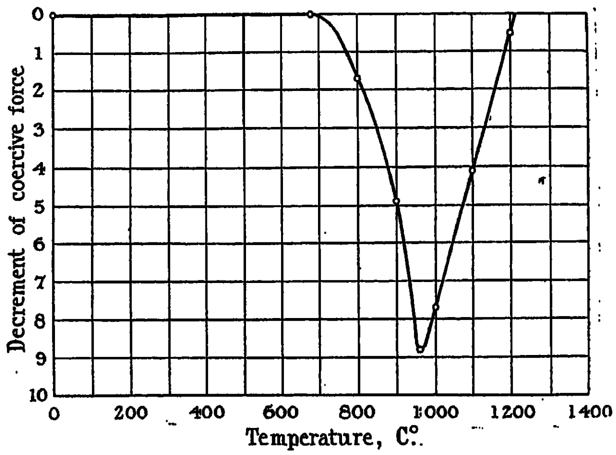

FIG. 14.—Spoiling of tungsten magnet steel. Curve showing the variation in degradation consequent on previous heating for 2·5 hours at different temperatures.

steel of about 3 cm^2 sectional area, and heated one at a time at different temperatures from 800° to 1 200° C., the time each particular temperature was maintained being 2·5 hours. After the heating, a cylindrical test-piece of small diameter was made from the central core of each sample, and hardened by quenching from 850° C. The coercive force of the hardened cylinders was then measured and the difference between the coercive force of the steel in its initial state and its spoiled state, that is to say the decrement due to spoiling, was plotted against the temperature of spoiling as a graph connecting temperature and rate of spoiling. The graph is reproduced in Fig. 14 and it is seen at once that spoiling goes on at the greatest rate at a temperature of 950° C.

Comparing the graph with the iron-carbon diagram given in Fig. 4, it is clear that the region of temperature within which spoiling occurs coincides with the region in which the iron in carbon steel, and presumably in tungsten steel also, is in the Gamma state. In Fig. 14 the exact course of the graph below 800° C. is a little

uncertain, but as a previous experiment had shown that magnet steel which had been maintained at 680° C. for 7 hours remained entirely unspoiled, the course of the curve cannot be far wrong. If any spoiling goes on below 750° C., that is to say when the iron is in the Beta state, it is evidently negligible in amount.

Above 1 000° C. the graph is a straight line, and when produced beyond 1 200° C. it cuts the line of zero spoiling at 1 214° C. There can hardly be a doubt that this is the point at which the allotropic change from Gamma to Delta iron takes place, and, assuming that to be so, the Gamma region is the danger zone of temperature for tungsten magnet steel, any temperature between 750° and 1 214° C. being a spoiling temperature.

The abrupt termination on the danger zone at 1 214° C. makes it natural to inquire what happens immediately above that temperature. The answer is to be found in an experiment made long before that to

TABLE 5.

Attempt to restore spoiled tungsten magnet steel by heating at 1 240° C. The coercive force is that of the test-piece when hardened after the heat treatment.

which Fig. 14 relates. After making the first experiment in restoration, described above, an attempt was made to restore some of the magnet steel which had been completely spoiled by the steelmaker in the circumstances already mentioned. It will be remembered that the coercive force of this batch of steel varied from 27 in the worst bar to about 46 in the best. Before trying to restore the worst of the batch it was thought better to see what could be done with the best of it, and accordingly a bar which, in the hardened state, gave a coercive force of 45·5, was selected for trial. A dozen rods of small section having been cut from this bar, they were assembled in pairs and immersed in a bath of molten barium chloride, the temperature of which was maintained constant at 1 240° C., within a few degrees either way, during the experiment. The rods of steel attained the temperature of the bath in 40 seconds, as nearly as the time could be measured, and at pre-arranged intervals after that epoch the pairs of rods were withdrawn from the bath and allowed to cool down. All the rods were then hardened by quenching from 850° C., and tested for coercive force. The observational data obtained in this experiment are given in Table 5. In Fig. 15 a curve has been plotted from the data given in the table, showing a rapid initial rise in coercive force followed by a less rapid fall.

As a method for restoring spoiled steel to a condition in which it would be fit for making magnets the experiment was a failure. Estimated from its composition by analysis, the steel should give a coercive force of 68 when unspoiled, or completely restored, whereas the highest value attained, as the result of the heat treatment described, was only 56. Why the coercive force, after rising with great rapidity as the result of the first minute and a half in the heating bath,

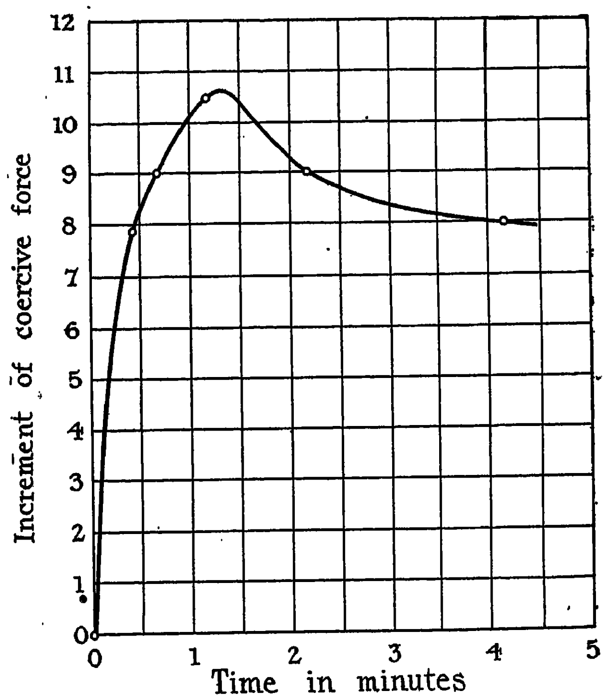

FIG. 15.—Curve showing the partial restoration of spoiled tungsten magnet steel by heating at 1 240°C.

should then begin to fall off, was not understood at the time. Long afterwards, when the effect of loss of carbon had been investigated, it was realized that in this experiment a decarbonized layer developed during the heating in the bath and rapidly increased in depth. Hence when the test-pieces came to be tested for coercive force each was in the condition of a bar magnet closely surrounded by a magnetic shunt of soft iron, the thickness of the iron and magnitude of the shunting effect depending on the duration of the heating. In these circumstances the values obtained for the coercive force became more and more erroneous as the decarbonized layer increased in thickness, and the only measurements on which reliance can be placed are those made on the test-pieces which had been withdrawn from the heating bath before the decarbonized

layer grew to an appreciable thickness. Interpreted in this way the falling off in coercive force seen in Fig. 15 indicates the steadily growing thickness of the decarbonized layer and the consequent increase in the shunting effect.

Knowing the cause of the falling off in the apparent coercive force (the spurious coercive force of a shunted magnet), we may disregard the erroneous figures and concentrate our attention on what took place before the loss of carbon began to have an appreciable effect. The first pair of test-pieces to be removed from the heating bath had been at a temperature of 1 240° C. for 15 seconds. But assuming that restoration actually began as soon as the temperature rose above 1 214° C. (the point at which the spoiling effect ceases) an addition of from 10 to 15 seconds must be made for the time occupied by the steel in rising from 1 214° to 1 240° C., making at the most a period of 30 seconds at a temperature above 1 214° C. Within that time the condition of the steel was restored to an extent which, when the test-pieces were subsequently hardened, gave an increase of 7·85 units in the coercive force. From this it appears that before carbon escaped in appreciable quantity, restoration was going on at a rate corresponding with an increase of more than 15 units of coercive force in a minute.

Now the initial coercive force of the steel in the spoiled state having been 45·5, and the value for unspoiled steel of the composition given by analysis being 68·0, the number of units of coercive force to be added for complete restoration would be 21·5, and hence at the rate of restoration of 15 units a minute the restoring process would be completed in less than 2 minutes, provided the rate were maintained to the end and that the escape of carbon could be prevented.

Comparing this experiment with the one recorded in Fig. 14, we find that at 950° C. spoiling is proceeding at the maximum rate, the coercive force decreasing by roughly 9 units in 2·5 hours, a rate of 3·6 units per hour. At 1 200° C. spoiling is still going on, although with extreme slowness, the coercive force falling less than a unit in 2·5 hours, a rate considerably under 0·4 units per hour.

On passing the boundary temperature, which Fig. 14 places at 1 214° C., a sudden and astonishing change takes place, and at 1 240° C., only 26 degrees above the boundary, restoration is found to be going on at the rate of 15 units of coercive force *a minute*. This is equivalent to a rate of 900 units per hour and is to be compared with a maximum rate of spoiling which, as we have just seen, was only 3·6 units per hour. In other words, restoration above the boundary temperature is 250 times as quick as the spoiling below the boundary.

Assuming the boundary temperature, 1 214° C., is that between Gamma and Delta iron, and that spoiling and restoring result from decomposition and recombination of the solute molecules WC and Fe_3C, this great disparity in the rates of spoiling and restoring is a clear indication of some fundamental difference in the chemical reactions of Gamma and Delta iron on the solute carbides. We have already seen in Section (7) that if sudden changes in specific heat are equivalent to changes in atomic weight, Gamma and Delta differ from each other much as one element differs from another, and it is therefore by no means surprising that they should be found to possess very different chemical properties.*

Two more experiments may be referred to. After investigating the effect arising from loss of carbon, a number of samples, taken from one of the least badly spoiled bars in the batch of steel which had been "softened" by the over-zealous steel maker, were heated to a restoring temperature for different periods of time, and the central cores remaining after the removal of the decarbonized layer were hardened and tested for coercive force. The values obtained are given in Table 6. The spurious values of coercive

Experiments showing the complete restoration of the central core of test-pieces made of badly spoiled tungsten magnet steel. For steel of the composition found by analysis, and in the unspoiled state, the estimated coercive force is 67·0.

force obtained from the whole section of the test-piece, before removing the decarbonized layer, are included in the table to show how utterly misleading they are. The mean value of the coercive force of the central cores, namely 67·8, should be compared with that corresponding to the carbon content of the steel, which analysis showed to be 0·691 per cent; making use of the carbon-coercive-force curve (Fig. 9) to translate carbon content into coercive force. It will be found, on making the comparison, that the condition of the steel in the central cores was fully equal to that of unspoiled tungsten magnet steel.

The last experiment to be noticed is recorded in

* The low-temperature chemist cannot tackle red-hot substances like Gamma iron and Delta iron. But what the chemist cannot do magnetism has accomplished, affording, perhaps for the first time, a clue to the chemical attributes of the allotropic varieties of iron.

Fig. 16 in the form of three demagnetization curves: one obtained from a specimen of tungsten magnet steel selected from a large number of bars as being in an almost unspoiled state; the second from the same sample after spoiling at a temperature of 942° C. for 13·1 hours, and the third from the same sample bar after restoration at 1 300° C. In the course of the prolonged period of spoiling at 942° C. the steel lost carbon throughout the entire sectional area, analysis showing that the carbon content of the central area, which was initially 0·736 per cent, had decreased to 0·708 per cent as the result of the prolonged heating. Reference to the carbon-coercive-force curve shows that in unspoiled steel a carbon content of 0·708 would give a coercive force of 69·0. The actual coercive force of the steel containing that percentage of carbon

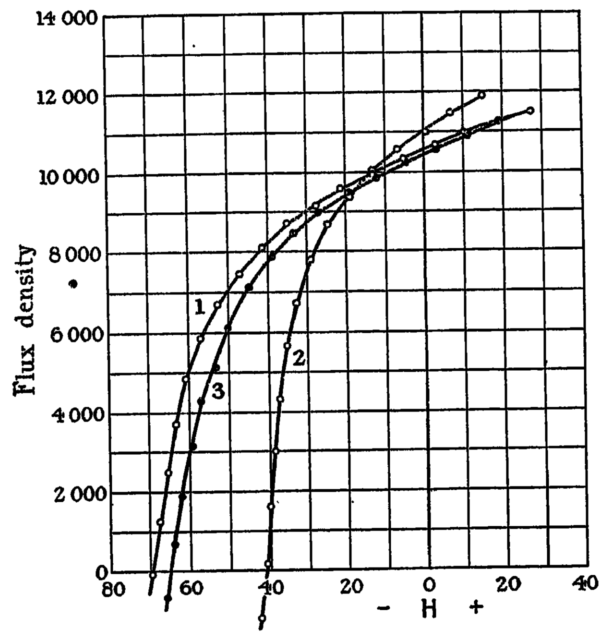

FIG. 16.—Demagnetization curves obtained from hardened tungsten magnet steel in different molecular states:—

(2) After being spoiled by heating at 942° C. for 13 hours.
(3) After being restored by heating at 1 300° C.

(after spoiling for 13·1 hours at 942° C.) was only 41·5, a degradation of 28 units.

The piece of steel taken from the same sample for the purpose of restoration was first spoiled along with the specimen last referred to. That is to say it was spoiled for 13·1 hours at 942° C. Having been spoiled it was raised to a temperature of 1 300° C. and maintained at that point for 21 minutes, a duration much in excess of what was needed. During this time a good deal of carbon diffused from the central portion of the large sectional area into the outer portion which had been greatly denuded of carbon during the spoiling. The result of this transference of carbon is seen in the low carbon content of the central core, namely, 0·669 per cent. Unspoiled steel containing that amount of carbon has a coercive force of 65·7, which compares with the observed value 64·9 for the restored specimen. There was reason to suspect that, in heating the test-piece preparatory to hardening it, insufficient time had been given for the complete solution of all the carbide in the solvent iron. The test-piece was therefore hardened a second time, taking care to give ample time for the carbide to dissolve. When tested after the second hardening, the steel was found to have a coercive force of 66·4, which is slightly greater than the computed value, given above, for steel containing 0·669 per cent of carbon. Complete restoration was, therefore, finally effected in this case, in the sense that the whole of the carbon remaining in the steel after the spoiling was recombined as solute carbide molecules.

In the foregoing account of the phenomena of spoiling, frequent reference has been made to unspoiled magnet steel. Strictly speaking, however, an absolutely unspoiled condition at room temperature is unattainable, since a piece of steel which has been perfectly restored at a temperature within the Delta region necessarily passes through the danger zone on cooling down, and during that passage some degree of spoiling is inevitable. But under the conditions of cooling that ordinarily occur in practice the steel is only within the danger zone for a brief period of time and the resulting loss of coercive force is negligibly small. As a rather extreme example, we may suppose that as much as three hours is occupied in cooling the steel from 1 220° to 100° C. Now the time occupied in traversing the Gamma region, or danger zone, from 1 220° to 750° C., is always about one-twelfth of the whole time occupied in cooling down to 100° C., and hence at the given rate of cooling the danger zone would be traversed in about 15 minutes. But the extent of spoiling within 15 minutes would decrease the coercive force of the subsequently hardened steel by no more than half a unit in a total of 70, and in practice, steel which has only suffered spoiling to that extent may fairly be described as unspoiled.

The investigation of the spoiling and restoring of tungsten magnet steel involved, in all, more than four years of almost continuous experimental work. Nature did nothing to assist the experimenter. The confusing facts presented themselves in no sort of logical sequence, and the significance of many of them was not grasped until the time arrived to review the research as a whole. Looking back, it is easy to perceive that the four experiments recorded in Figs. 13, 14, 15 and 16, contain in themselves the gist of the whole matter.

Although the experiments described in this section demonstrate the fact that spoiled tungsten magnet steel can be restored, the problem that faces the magnet maker remains unsolved. He receives from the steel maker a batch of rolled steel the bulk of which is more or less spoiled, and usually about a quarter of it will be very badly spoiled. But the steel is not only spoiled. It has also lost carbon, the superficial layer of each spoiled bar being more or less denuded of carbon. Now to bring the spoiled bars into a condition fit for making magnets it is not enough to restore the steel as it stands. It is essential to secure uniformity of carbon content throughout the sectional area, and to do that the deficiency of carbon in the superficial layer must be made good by adding carbon, and adding it in just the right quantity. By no means an easy problem to solve,

yet it is not impossible that a convenient process might be discovered by research.

However that may be, the true remedy for spoiled magnet steel is prevention, and that rests with the steel maker. It should not be difficult to avoid the production of spoiled magnet steel, and in practice the steel maker already makes a few bars of unspoiled steel now and again, by accident. He has only to do it on purpose and the problem will be solved.

(14) Spoiled Steel: Chemical and Magnetic Analysis Compared.

When the degradation of spoiled tungsten magnet steel has been determined in terms of coercive force, the carbon-coercive-force curve (Fig. 9) enables the loss of coercive force to be translated into the quantities of the two carbides which have been decomposed under given conditions of time and temperature. Deducting these amounts from the quantities initially present in the steel, as determined from a percentage analysis, the remainder values give the molecular composition of the spoiled steel. To justify the assumption that spoiling is decomposition, it would, of course, be necessary to ascertain the molecular composition of the spoiled steel by the elaborate process of separating and recovering the carbides as residues, and then determining their molecular composition by chemical analysis.

The researches of Arnold and Read leave little room for doubt that in tungsten magnet steel, in the softened state, the carbon is present in the form of the two carbides WC and Fe_3C, and if there is still any doubt about the presence of those two carbides when the steel is in the hardened state such a comparison as that described in the last paragraph should settle the question one way or the other.

By a fortunate chance the necessary chemical data for a comparison of that kind are already available, having been obtained incidentally by Professors Arnold and Read in the course of their work on the carbide residues of tungsten steels. On turning to the technical details of their method of research* it appears that, as a preliminary, each specimen of steel to be examined was first heated to 950° C. and maintained at that temperature for a period of about 6 hours. We are not concerned with the object of this procedure. It is enough to know that each specimen received this preliminary thermal treatment, and that by so doing the steel was partially spoiled. Moreover, the temperature chosen, 950° C., happens to have been that at which spoiling goes on at the greatest rate (Fig. 14). It was, therefore, from specimens of steel degraded to that particular degree that the carbide residues were obtained; and consequently the molecular compositions deduced from the analysis are those of tungsten steel which had been spoiled for 6 hours at 950° C.

With these accurate chemical determinations at hand, it was possible to make the comparison between the chemical and the magnetic methods of ascertaining the molecular composition of spoiled tungsten magnet steel. Among the tungsten steels examined by Arnold and Read was one † which had almost exactly the percentage composition of the best tungsten magnet steel, analysis showing that it contained 0·71 per cent of carbon and 5·37 per cent of tungsten. This sample was therefore chosen by the present writer for the computation of the molecular composition from magnetic data. The arithmetical work occupies too much space to be given here and it must suffice just to indicate the method. To begin with, the degradation in 6 hours at 900° C. was ascertained from the curve in Fig. 13. Next, the ratio of the degradation at 950° C. to that at 900° C. was determined by means of the graph in Fig. 14; and the final step was to compute the quantity of carbide of tungsten decomposed in 6 hours at 950° C. from the value of the coercive force determined for spoiled steel by the demagnetization curves given in Fig. 16. Throughout these calculations the carbon-coercive-force curve given in Fig. 9 was used for translating differences in coercive force into percentages and quantities of carbon and carbides.

Molecular composition of badly spoiled tungsten magnet steel. Percentage composition of the steel: Carbon 0·71 per cent, tungsten 5·37 per cent.

The comparative figures for the molecular composition of the spoiled steel, deduced from the chemical and from the magnetic data, are given in Table 7, where the molecular composition is stated in each case for quantities containing a total of 100 atoms of carbon. The first line gives the composition of the carbon compounds when the steel is unspoiled, based on the percentage analysis given by Arnold and Read. The figures in the second line are taken from their analysis of the carbide residue obtained from the spoiled and softened steel. The third line gives the result of the present writer's computation, based on the coercive force of hardened tungsten steel of the given percentage composition.

The figures given in Table 7 may be left to speak for themselves. Whether the problem of spoiled tungsten magnet steel is investigated by the chemical analysis of residues obtained from the steel in the softened state, or by the magnetic phenomena of hardened steel, the

answer is the same: spoiled steel is decomposed steel. At any temperature between 800° and 1 200° C., to state the limits in round numbers, the carbide molecules on which the potency of magnet steel depends, suffer gradual decomposition, marked by a corresponding decrease in the coercive of the steel when it is subsequently hardened. To restore the potency, the broken-up molecules must be put together again, a recombination which quickly takes place when the temperature of the steel is raised a few degrees above the boundary where the solvent iron changes from Gamma into Delta iron. But the full potency can only be regained provided the dissociated elements remain inside the steel. In steel of large sectional area such as the ingot or billet of the steelworks, this condition would be reasonably well fulfilled; but in pieces of steel of the size of permanent magnets some of the carbon always manages to escape and complete restoration is then impracticable.

(15) Hardening, Softening and the Surplus Solute.

Alpha iron provides the mechanism that generates the magnetic flux in a permanent magnet, but the other factor, the potency, is of the feeblest in soft iron. The very small coercive force of pure soft iron, rather less than 2 units, indicates an almost perfect uniformity in the distribution of the magnetic molecules, and if iron is to serve any useful purpose as a permanent magnet, the potency of the magnetic mechanism must be very greatly increased by importing variformity.

One obvious way of bringing about a variformity of distribution is to squeeze the iron by rolling or hammering or wire drawing, and it is well known that by any of these ways of distorting the crystalline structure, it is possible to increase the trifling coercive force of iron by several units. Incidentally, the hardness is also increased a little. But apparently the increase in potency and hardness arises from a bodily shifting of whole crystal groups rather than any modification in the crystal elements themselves, and to obtain any large effect, to endow the iron with the potency required in a permanent magnet, something more subtile than mechanical distortion is needed. Something must be done to modify the molecular pattern in a regular fashion throughout the crystalline mass of iron, so as to produce a systematic variformity in the distribution of the magnetic molecules. That something consists in dissolving certain compounds of carbon in the iron; and what mechanical squeezing does feebly and in a somewhat irregular way, a number of solute carbide molecules will do with far greater effect. Where a steam hammer manages to add two or three units to the coercive force, the solution of a fractional percentage of carbon will increase it by 50 units, or 70 or even 200 units according to the nature of the carbon compounds employed as potency-giving solute molecules.

Where the carbide molecules find their place in the magnetic mechanism, how they act on the molecules of iron, and why they only have the desired effect when they are in solution, is not known, or but vaguely surmised. But wherever they are, they certainly act individually and systematically throughout the mass of solvent iron which serves as the magnetic mechanism, doing by atomic force what the hammer or the rolling-mill can never do. By their presence carbide molecules convert iron into steel, and when they are in solution they create the potency which renders the steel fit for a permanent magnet.

To make a powerful magnet, the magnetic mechanism must combine great potency with a high degree of inherent magnetomotive force, and both factors must be taken into account in determining the best proportion of potency-giving carbon compounds in magnet steel. It is found by experiment that a permanent magnet maintains the maximum amount of useful magnetic energy when the steel contains about 0·72 per cent of carbon in the form of soluble carbides, the whole amount being in solution. It is, of course, essential that the iron in the steel should be in the magnetic state, and since Alpha iron only dissolves about 0·24 per cent of carbon (one-third of the whole carbon content) as a solution in stable equilibrium, the problem is how to induce the remainder of the carbon, two-thirds of the whole, to enter into solution.

It was mentioned at the outset of Section (8) that complete solution of the whole of the carbon in magnet steel is effected by the ordinary process of hardening. Like a good many other things discovered or invented by primitive man, the hardening operation is of the simplest character. The temperature of the steel having been raised to a bright red heat, the metal is suddenly cooled by plunging it into cold water. Here again we have an example of formidable difficulties masked by an outward simplicity. It is very much easier to perform the hardening operation than it is to explain it. Nevertheless, an explanation will be attempted here in order to help the reader in forming some idea of the peculiar condition of hardened magnet steel.

What the hardening process effects is the solution of the whole of the carbon, notwithstanding the fact that the solvent iron is in the Alpha state, and since the amount of carbon in magnet steel is about three times as much as Alpha iron naturally dissolves, it seems impossible to believe that the molecular condition in the hardened steel is one of equilibrium. Let us imagine the state of things when a solute molecule has been put into the position it must occupy among the molecules of Alpha iron, as a constituent part of a solution which is not in equilibrium. If the molecule is free to move it will certainly not remain in the solution position, and until someone discovers how to bring about equilibrium under the assumed conditions, the only way to prevent the molecule from moving away is to deprive it of the power to move. Hence to endow the steel with the potency required in a permanent magnet needs two operations. First, the whole quantity of carbide in the steel must be dissolved by some means or other, and then while the carbide molecules are still in their solution positions, they must be deprived of their mobility. In this way the whole of the carbon present in magnet steel can be made to play its part in creating the potency-giving molecular pattern. It is the pattern of solution and serves the intended purpose —so long as it lasts—but it can hardly be a condition of equilibrium.

Taking the two parts of the hardening process in turn,

the first is the dissolving of the whole of the carbon. Now any of the allotropic varieties of iron, other than Alpha iron, will readily dissolve a good deal more carbon than 0·72 per cent. The first step therefore must be to transform the solvent iron into Beta, or Gamma, or Delta, by heating the steel to the appropriate temperature. But although any of these varieties of iron will dissolve all the carbon, no one of them does so better than the others, and hence there is nothing to be gained by raising the temperature much beyond the point at which the whole of the iron assumes the Beta form. In tungsten magnet steel the conversion of Alpha into Beta iron is completed at a temperature of 790° C., and for cobalt steel the corresponding temperature is 870° C. Allowing a small margin, the temperature to which the steel should be raised for the purpose of dissolving the carbide might be 820° and 900° C. respectively. Within three or four minutes after attaining the necessary temperature, which must be well within the Beta region, the whole of the carbon will have dissolved and the first operation is over.

Complete solution has now been accomplished, but only by converting the solvent iron into one of the non-magnetic varieties. The next thing to be done is to re-convert the iron into the magnetic or Alpha state by lowering the temperature, and at the same time prevent the carbide molecules from passing out of solution when the iron assumes the Alpha form. That is to say the solute molecules must be deprived of their mobility before they have had time to move from their solution positions. But at the high temperature where the change from Beta to Alpha occurs, the molecular mobility is so considerable that the whole of the surplus quantity of carbon, about two-thirds of the whole amount in the steel, would pass out of solution within a couple of minutes after the allotropic change had taken place. Hence the necessity for robbing the carbide molecules of their mobility in the shortest possible time. Now there is only one way to deprive molecules of mobility, and that is to lower the temperature of the steel to a point at which mobility, if not entirely suppressed, is at all events negligibly small. Probably the last trace of mobility only vanishes at the absolute zero of temperature, but fortunately for the toolmaker and the magnet maker molecular mobility decreases with such extreme rapidity as the temperature falls below a red heat that by the time a piece of steel has cooled down to room temperature the solute molecules have almost entirely lost their freedom.

The second operation therefore consists in lowering the temperature of the steel as quickly as possible from some point at which the whole of the carbon is in solution, down to room temperature. As the temperature falls below the region where the change from Beta to Alpha takes place, the solute carbide molecules lose their equilibrium as constituent parts of a stable solution; but before they have time to move the steel is cold and the mobility gone. Robbed of the power to move there is nothing for the carbide molecules to do but stop where they are, in the positions characteristic of the state of solution, and consequently the molecular pattern that gives potency is completely preserved in the steel. Briefly, the steel is first heated to bring about the pattern of solution and then by the more or less sudden cooling to a low temperature the carbide molecules are, so to speak, frozen in their solution positions, thus preserving the pattern that gives the steel both hardness and potency.

From time immemorial the primitive workman has been hardening steel by the method of sudden cooling, successfully performing the operation without giving a thought to the sequence of events on which success depends. It is only natural to suppose that steel which has been hardened by quenching will retain its hardness for ever. Very likely it would if the solute molecules which give the hardness were absolutely unable to move, but in fact they still have a modicum of freedom at ordinary room temperatures; a mobility so slight that it has hitherto received little attention if it has not escaped notice altogether. But slow changes in the structure of hardened steel, arising from molecular mobility, are easily detected by magnetic means and in Section (16) evidence will be given of the gradual decay of potency in steel which has been hardened by rapid cooling.

In course of time, then, hardened steel may very slowly decay, but while we are actually engaged in hardening a piece of steel it is the immediate effect that matters, and so far as that goes the molecular mobility at any temperature from 100° C. downwards is so exceedingly small that it may be dismissed as negligible. In short, when the temperature has fallen to 100° C. the steel is as good as cold so far as the hardening process is concerned. Again using the analogy of freezing, a temperature of 100° C. may be regarded as the freezing point of the operation of hardening, a conventional point below which the little mobility that remains may safely be ignored for the time being.

In the foregoing explanation of the process of hardening by quenching, the cooling of the steel has been described as taking place very quickly if not suddenly, no particular rate of cooling being implied. We must now turn our attention to the effect which the rate of cooling has on the degree of potency and hardness. If the steel is cooled slowly, the whole of the surplus carbide has time to pass from solution to crystal long before the steel is cold and the mobility gone. But if the rate of cooling is gradually increased, sooner or later a critical speed will be attained which gives only just enough time for the whole quantity of surplus carbide to pass out of solution before the temperature falls to the conventional 100° C., the point of zero mobility for our present purpose. At the critical rate of cooling complete softening ends and hardening begins, for at any greater speed there will not be enough time for all the surplus carbide to pass out of solution, and since some fraction of it will remain in solution the steel will have acquired a corresponding increment of hardness and potency.

Although carbon passes out of solution because Alpha iron, under normal conditions of equilibrium, cannot dissolve the whole amount of carbide present in magnet steel, the passage from solution to crystal does not begin with the first appearance of Alpha iron. It has already been noticed that with 0·72 per cent of carbon dissolved in Beta iron the solution is not saturated,

and it is clear that any carbide molecules, released from solution when the first portions of Beta iron are undergoing conversion into Alpha, will easily dissolve in neighbouring unsaturated solution. This transference of solute carbide molecules from what was Beta but has become Alpha, to the solvent iron which is still Beta, will go on until the remaining Beta iron can dissolve no more, having become a saturated solution. From this point onwards the solute carbide molecules, rejected from solution in consequence of the continued allotropic transformation from Beta to Alpha iron, are debarred from taking refuge in the remaining Beta and their only alternative is to assemble themselves in the crystalline form, intermingled with crystals of Alpha iron. Hence it is found that when a piece of magnet steel is slowly cooling down, the presence of Alpha iron begins to be indicated by the appearance of magnetism some little time before there is any sign of carbon passing out of solution. But a little later the saturation point is reached and the Beta iron can dissolve no more carbon. At that moment the carbon compounds begin to pass out of solution with a very noticeable release of energy in the form of heat. All this is well seen in Fig. 12 (page 748), where the curves indicating the magnetic change and the release of energy relate to a sample of 6 per cent tungsten magnet steel containing 0·65 per cent of carbon. As nearly as it is possible to judge from the overlapping waves, the saturation point occurred at the 29th minute of the experiment, the temperature of the steel being 708° C. at that moment. The first sign of magnetism, and therefore of Alpha iron, had made its appearance a minute and a half earlier when the temperature was 750° C. At the end of the 31st minute the whole of the surplus carbide had passed out of solution, the transfer from solution to crystal having occupied just two minutes, during which time the temperature fell from 708° to 652° C., a drop of 56 degrees. The rate of cooling at this stage was therefore 28 degrees a minute, and obviously this speed must be greatly exceeded if any of the surplus carbide is to be retained in solution in order to achieve a hardening effect.

To ascertain the effect of a considerable increase in the rate of cooling, let us imagine the same experiment to be performed at twice the speed, so that just below the saturation point the temperature will be falling at the rate of 56 degrees a minute. For a first approximation we may suppose that the transfer of the surplus carbon from solution to crystal occupies the same time as before, namely, 2 minutes, since the rate of transfer depends only on the mobility and the mobility on the temperature. But in 2 minutes at 56 degrees a minute the temperature will fall 112 degrees, and hence the transfer of carbide will now end at 708 — 112 degrees, which is 596° C. That is to say, when the rate of cooling is doubled, the temperature at which the passage of the surplus carbon out of solution comes to an end will be 56 degrees lower down the temperature scale. This example makes it clear that although surplus carbide must always begin to pass out of solution at the saturation point, the process will spread down the temperature scale as the rate of cooling is increased. Moreover, since the point at which the transfer of the surplus quantity comes to an end will be carried further and further down the scale, the mean temperature at which the passage of carbide takes place will be progressively lowered and with it the mobility. Hence, as the speed of cooling is steadily increased the point that marks the end of the transfer of surplus carbide from solution to crystal will fall down the temperature scale at a growing rate.

An illustration of the way in which the transfer of the surplus carbon gradually spreads from the saturation point down the scale of temperature is given in Fig. 17, where the graph expresses the relation between the

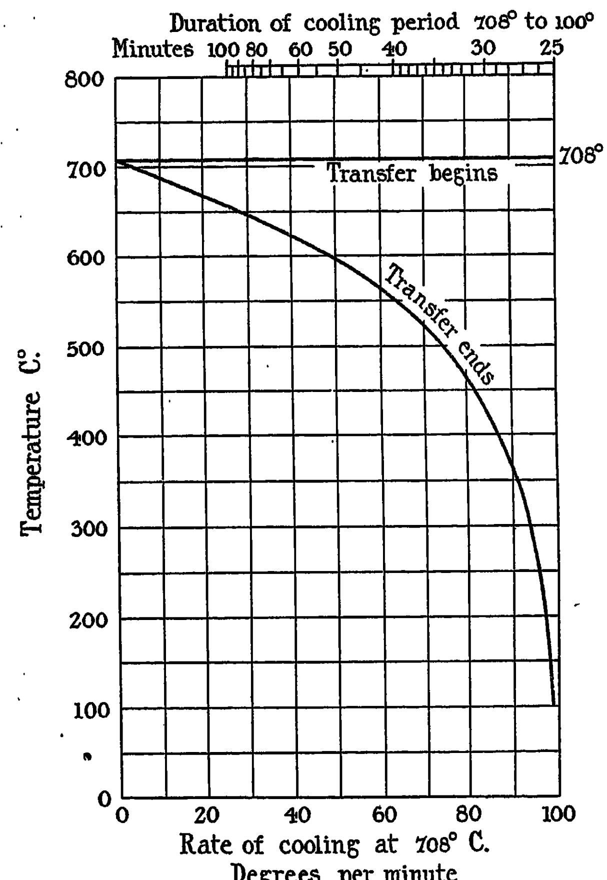

FIG. 17.—The softening of tungsten magnet steel. Curve showing how the range of temperature within which the surplus carbide passes out of solution, increases gradually as the speed of cooling is increased. (Computed by the author.)

speed of cooling and the point on the temperature scale where the transfer comes to an end. The same data have been used in constructing the graph shown in Fig. 18, where *the time* occupied by the passage of the surplus carbon from solution to crystal is plotted against the speed of cooling. These two diagrams relate to tungsten magnet steel with a carbon content of 0·72 per cent and tungsten 5·5 per cent. Two-thirds of the carbon, 0·48 per cent, is assumed to be the surplus which is insoluble in Alpha iron under normal conditions of equilibrium. The forms assumed by graphs of the kind shown in Figs. 17 and 18 depend both on the shape of

the cooling curve and on the law connecting the rate of transfer of carbon with the temperature. In the present example the diagrams are based on a cooling curve of the ordinary pseudo-logarithmic shape obtained experimentally from a bar of steel cooling in the open air of a room. Horizontal ordinates in both Fig. 17 and Fig. 18 give the rate of cooling at a temperature immediately below the saturation point. An inverse scale has been added in order to show the time occupied in cooling from 708° down to 100° C.

Observational data from which to determine the law connecting rate of transfer of carbon with temperature are very few and far between, and for this reason the two diagrams have no great claim to attention on the score of numerical accuracy. Nevertheless, they show in a general way how things go; how the rate of

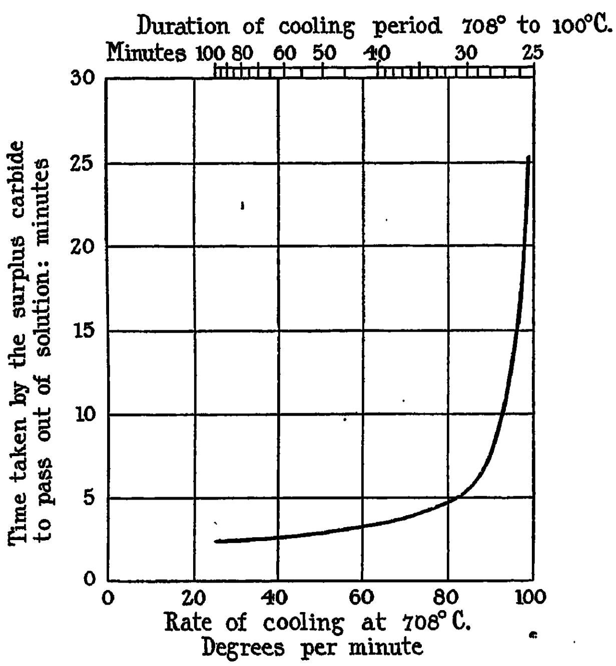

FIG. 18.—Softening of tungsten magnet steel. Curve showing how the time taken by the surplus carbide to pass out of solution gradually increases as the speed of cooling is increased. (Computed by the author.)

cooling governs the passage of the surplus carbide from solution to crystal at cooling speeds below the critical value where complete softening ends and hardening begins. In short, Figs 17 and 18 embody the cooling conditions which leave the steel in the completely softened state. The object of softening magnet steel is to enable it to be machined with ease, and that object is attained as soon as the whole of the surplus carbide has passed out of solution. Whether the passage of the carbide occupies 2 minutes or 2 hours is immaterial. Again, after the passage of the whole of the surplus carbide from solution to crystal has been accomplished, it is quite immaterial how slowly or how quickly the steel cools. As an example, let the initial rate of cooling be about 30 degrees C. a minute. We see from Fig. 17 that at this cooling speed the transfer of the whole of the surplus carbide in magnet steel will have come to an end, and the softened state will have been created by the time the temperature of the steel has fallen to 650° C. At this point, although the steel is still red hot, it may be suddenly cooled by plunging it into cold water without in any way affecting the softness, complete softening having taken place before the quenching began. True, the cooling robs the carbide molecules of their mobility, but to deprive them of mobility when they have already passed from solution to crystal is equivalent to locking the stable door after the steed is stolen. It is more than likely that this unusual instance of rapid cooling will leave some readers of this paper unconvinced, so deep-rooted is the notion that quenching red-hot steel in cold water must necessarily make it harder. Another idea, equally deep-rooted, is that steel is best softened by exceedingly slow cooling; yet it is easy by a few simple experiments to demonstrate the fact that all rates of cooling not exceeding the critical rate are equally effective in bringing about the completely softened state in steel. The curve given in Fig. 17 presents the same fact in another way and, by linking it with the passing of the surplus carbide out of solution, gives it a rational explanation.

We now pass to the consideration of rates of cooling in excess of the critical speed which marks the end of complete softening and beginning of hardening. When the cooling from the saturation point downwards goes on so quickly that the temperature has fallen to 100° C. before the whole of the surplus carbide has passed out of solution, the steel acquires additional potency and hardness commensurate with the amount of surplus carbide which is retained in solution.

In what follows, it will be convenient to refer to the region of temperature extending from the saturation point down to 100° C. as the *mobile region*, since it is the region within which the carbide molecules are impelled to pass out of solution and have the requisite mobility to do so. Looking at Fig. 18, we see that when the temperature of the steel was falling at such a rate that the time occupied in traversing the mobile region was about 25 minutes, there was just enough time for the whole of the surplus carbide to pass out of solution. The magnet steel to which Fig. 18 relates contained 0·72 gramme of carbon per 100 grammes of steel, of which about 0·24 gramme would be retained in solution under normal conditions, when the solvent iron was converted into the Alpha state. The remainder of the carbon, about 0·48 gramme, would constitute the surplus. Hence a duration of 25 minutes within the mobile region just gives enough time for 0·48 gramme of carbon to pass out of solution. Now, without in any way changing the shape of the cooling curve, let the cooling speed be doubled. The duration within the mobile region will be halved and consequently there will only be enough time for half the surplus carbon to pass from solution to crystal and the other half, 0·24 gramme will be retained in solution, notwithstanding the allotropic change of the solvent iron from Beta to Alpha. When the steel is cold, the amount of carbon in solution will now be the quantity which is normally soluble in Alpha, namely 0·24 gramme, plus the 0·24 gramme which has remained in solution, or at all events quasi solution, for want of time to pass from solution

to crystal. The steel will therefore contain twice as much carbon in solution as it would retain under normal conditions of equilibrium; and with twice the quantity of carbon in solution the potency and hardness will be largely increased.

But by quenching a piece of steel in water it can be cooled through the mobile region in very much less time than half 25 minutes. For example, a magnet weighing a couple of pounds, quite a large size for a permanent magnet, can be quenched in about 15 seconds. This is just 1/100th part of 25 minutes, and consequently if the steel cools through the mobile region in 15 seconds there will only be enough time for 1/100th part of the surplus carbon to pass out of solution. That is to say, 0·0048 gramme of carbon will pass out of solution and the remainder of the surplus, namely, 0·475 gramme, will be compelled to remain in solution. Adding this quantity to the 0·240 gramme, which is normally soluble in Alpha iron, the steel when cold will contain 0·715 gramme of carbon in solution, out of a total carbon content of 0·720 gramme per 100 grammes of steel. These figures show that by rapid cooling in water rather more than 99 per cent of the entire carbon content of magnet steel can be retained in solution, even in the case of a large magnet.

The smaller the magnet the quicker it cools and the greater the percentage of carbon retained in solution. A good example of this is afforded by the test-pieces of magnet steel from which the demagnetization curves given in this and the previous paper were obtained. The test-pieces are bar magnets of ellipsoidal form with major and minor axes 10·6 cm and 0·51 cm respectively, and it has been observed that when these little pieces of steel are hardened by quenching in an aqueous solution of calcium chloride, the temperature of the steel falls from above the saturation point down to 100° C. in rather less than 2 seconds, less than 1/30th of a minute. Since 25×30 is 750 there is only time for 1/750th part of the surplus carbide present in magnet steel to pass out of solution. In effect the quantity of carbon retained in solution when the steel is cold amounts to 99·9 per cent of the carbon content of the steel, so that the test-pieces when hardened only fall short of the maximum possible potency by an insignificant fraction. In these examples it has been assumed that the critical duration within the mobile region is that indicated by the graphs in Figs. 17 and 18, namely about 25 minutes. The reader has already been warned not to place too much reliance on the numerical accuracy of these two diagrams, and pending some verification of the scanty observational data on which they are founded, the value 25 must be accepted with reserve. But a very large error would have but little effect on the estimated percentage of the carbon content retained in solution. To exaggerate the possible error we might assume that the value 25 is twice the true value. That is to say we might suppose that the critical duration, where complete softening ends and hardening begins, is actually 12·5 minutes. In that case it is easily seen that the percentage for the large magnet would be reduced from 99 to 98, and for the small test-pieces from 99·9 to 99·8. These are relatively small differences and do not affect the proof afforded by the examples that almost all the carbon contained in magnet steel can be retained in solution by the ordinary process of quenching the steel in water.

The numerical examples given in the last paragraph show that in principle the rule for estimating the total amount of carbon which will be retained in solution by any given speed of cooling is of the simplest kind. It may be useful to embody the principle in a formula. Let C denote the total carbon content of the steel, C_a the quantity normally soluble in Alpha iron, and C_s the surplus quantity, all these being conveniently expressed as percentages of the weight of steel. Let r denote the mean rate at which carbon passes from solution to crystal during the time the temperature is falling from the saturation point to 100° C., the value of r depending on the law of cooling, that is to say on the shape of the cooling curve, within the mobile region. Let t be the actual time occupied in cooling the steel through the mobile region when the magnet is quenched for the purpose of hardening. Then the quantity of carbon which will find time to pass out of solution during the quenching will be rt, and putting q for the quantity retained in solution we shall have $q = C - rt$. The constant r may be determined by finding the shortest time of cooling from the saturation point to 100° C. which permits the whole of the surplus carbon to pass out of solution and leaves the steel in the completely softened state. The shortest time is of course the quantity referred to as the critical duration within the mobile region, and denoting it by D we have $r = C_s/D$ so that $q = C - C_s t/D$. But $C_s = C - C_a$ and hence:

$$q = C - (C - C_a)\frac{t}{D}$$

It will be understood that before this formula can be usefully employed in the practice of hardening, trustworthy data must be forthcoming from which to determine the constants involved. Nevertheless, the equation as it stands together with the diagrams given in Figs. 17 and 18 make it possible to follow the sequence of events when a piece of steel cools from a red heat, either slowly to soften it or quickly for hardening. Quantity of surplus carbide, molecular mobility, and the element of time are the factors that count both in hardening and in softening, and it will be seen that already there is promise of a simple arithmetical relation between them. The law by which the rate at which carbon passes from solution to crystal is connected with the temperature of the steel, needs to be known with far greater certainty than it is at present. But it may be anticipated that this and other gaps in our knowledge of the doings of molecules will be filled up before long, and we may therefore look forward with confidence to the day when the age-long mystery surrounding the process of hardening will be finally dispelled.

To understand softening is to understand hardening, for the two are merely opposite extremes of the same process. In giving an account of the softening of steel it has only been possible to watch the solute molecules passing from solution to crystal in vast crowds and to take a statistical view of their doings. Any attempt to trace the course of individual carbide molecules, as they shift from their positions as parts of a solution towards the positions they will occupy as mem-

bers of a crystal, is met by baffling difficulties. One or two details seem clear, however. The molecules do not all begin their passage at the same moment, there is a continuous stream of carbide molecules passing from solution to crystal and, so far as the rather vague experimental evidence affords any indication, it appears that at any given temperature within the mobile region the passage of carbide molecules from one state to the other goes on at a uniform rate from start to finish. Then, again, it is certain that in a solid body like a piece of steel the molecules must be too close together to enable them to move about with freedom, and it seems that translational movements of individual molecules must be greatly hampered by the interference of neighbouring molecules. For this reason the word "mobility" must be regarded as belonging to the statistical view of molecular movements, and must not be allowed to suggest anything of a smoothly flowing nature in the journeyings of individual molecules. What sort of movement is actually involved in the passage of molecules from solution to crystal is not known, but it seems more likely to resemble an obstacle race than a steady flight from one place to another.

Compared with the time occupied by the sluggish carbide molecule in shifting itself from solution to crystal, the conversion of a molecule of Beta iron into the Alpha variety is instantaneous. The re-arrangement of electron orbits which constitutes the allotropic change takes place at lightning speed and, no matter how rapid the cooling may be when a piece of red-hot steel is quenched in cold water, as soon as the temperature in falling reaches the appropriate allotropic change-point, the solvent iron will instantly transform itself into the Alpha or magnetic variety. Nothing we can do in the way of sudden cooling can prevent that transformation, and the moment it occurs the solute carbide molecules find themselves urged to pass out of solution. But the obstacle race from solution to crystal has scarcely had time to begin before the rapidly cooling steel is cold and mobility has vanished. Deprived of their freedom the carbide molecules have nothing for it but to stop where they are, in the positions characteristic of the state of solution. What keeps them there, whether they are in any kind of temporary equilibrium, stable or unstable, and what proportion of the total number of carbide molecules will stay permanently in the positions of solution, are all questions of deep interest, to be answered it may be hoped by research. But no matter what the answers may be the central fact will remain unshaken. So long as the carbide molecules can be induced to remain in what appears to be a state of solution the potency-giving pattern will be there and the hardened steel will be fit for a permanent magnet. Abnormal as the solution appears to be, it is none the less effective in giving potency to the magnetic mechanism.

(16) The Gradual Decay of Hardened Steel.

Nothing looks more likely to be lasting than a piece of hardened steel, and without giving a thought to molecular mobility we should naturally expect the steel to retain its high degree of potency for ever. But it is only necessary to make a few measurements of coercive force at suitable intervals of time shortly after the hardening of a magnet, to discover the disconcerting fact that from the moment the steel is hardened the potency begins to decay, and with the loss of potency the inherent power of the steel to maintain magnetic energy gradually decreases.

When it was first discovered that permanent magnets grow weaker with age, it seems to have been tacitly assumed that it was the magnetization alone which decayed, the steel itself being apparently regarded as immutable—at all events at ordinary room temperatures. If that conception of hardened steel survives, the evidence given in the present section will finally dispose of it, for it will be shown that what is done by plunging red-hot steel into a cooling bath immediately begins to come undone when the hardening process is at an end. Moreover, the undoing goes on year after year and so

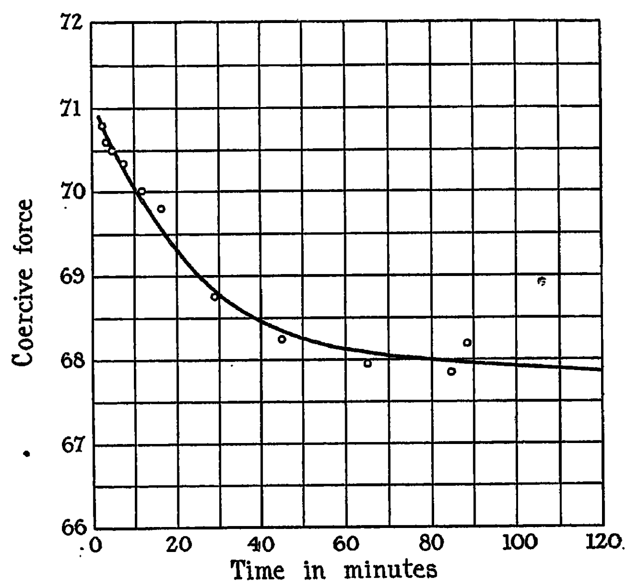

Fig. 19.—Decay in the potency of hardened steel. Curve showing the rapid loss of coercive force in tungsten magnet steel immediately after the hardening.

far as the investigation has gone at present, there is no sign of an approach to equilibrium. However it may be explained, there is no longer any doubt of the fact; the potency created in the steel by the hardening slowly disappears as time goes on.

That hardened steel should suffer a gradual loss of potency and hardness seems a foregone conclusion if steel is a solution of carbide molecules in iron. For the hardened steel certainly contains more carbon than is naturally soluble in Alpha iron at room temperature, and since the resulting condition must necessarily be one of instability, the tendency will be for carbon to pass from solution to crystal until the solution is in equilibrium. It follows that so long as there is the slightest molecular mobility in the solid steel, the dissolved carbide molecules must inevitably pass out of solution, however slowly; and to the extent that they do so, there must be a loss of potency and hardness.

It would seem that hardly anyone engaged in making permanent magnets could fail to notice the gradual

falling off in coercive force which takes place after the steel has been hardened, but although the fact must surely be known, it does not seem to have engaged the

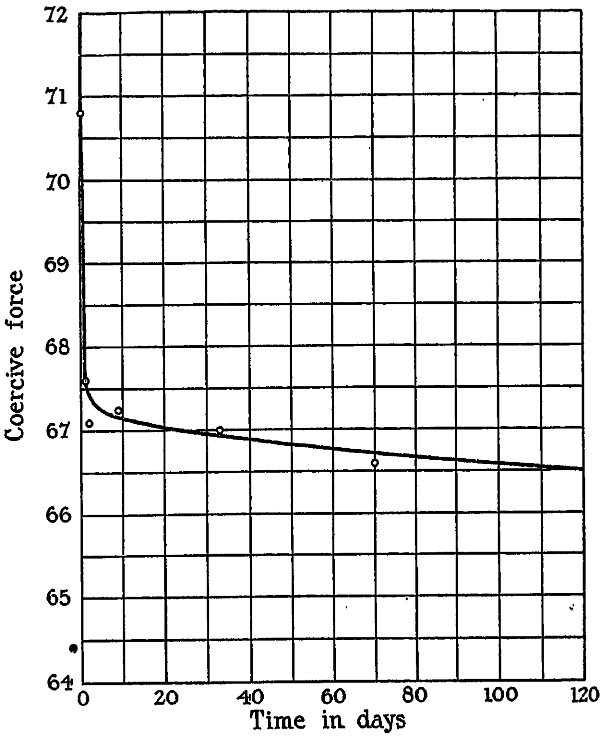

FIG. 20.—Decay in the potency of hardened steel. Curve showing the continued loss of coercive force in tungsten magnet steel during 120 days after the hardening.

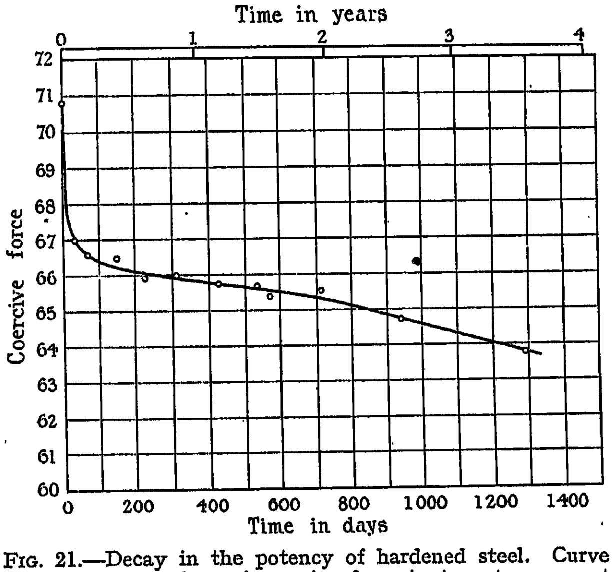

FIG. 21.—Decay in the potency of hardened steel. Curve showing the loss of coercive force in tungsten magnet steel going on for $3\frac{1}{2}$ years after the hardening.

attention of the metallurgist. At all events nothing relating to the subject appears to have been published, and the lack of information on a matter so closely connected with the constancy of the permanent magnet led the author, some years since, to set on foot a continuous series of tests of the coercive force of magnets from the time of hardening onwards. The method of experiment has been to measure the coercive force of a hardened steel bar of ellipsoidal form at lengthening intervals of time. Each test consists in first magnetizing the steel to the full extent and then making an accurate magnetometer measurement of the Hopkinsonian coercive force of the specimen. It will be noticed that by complete re-magnetization before

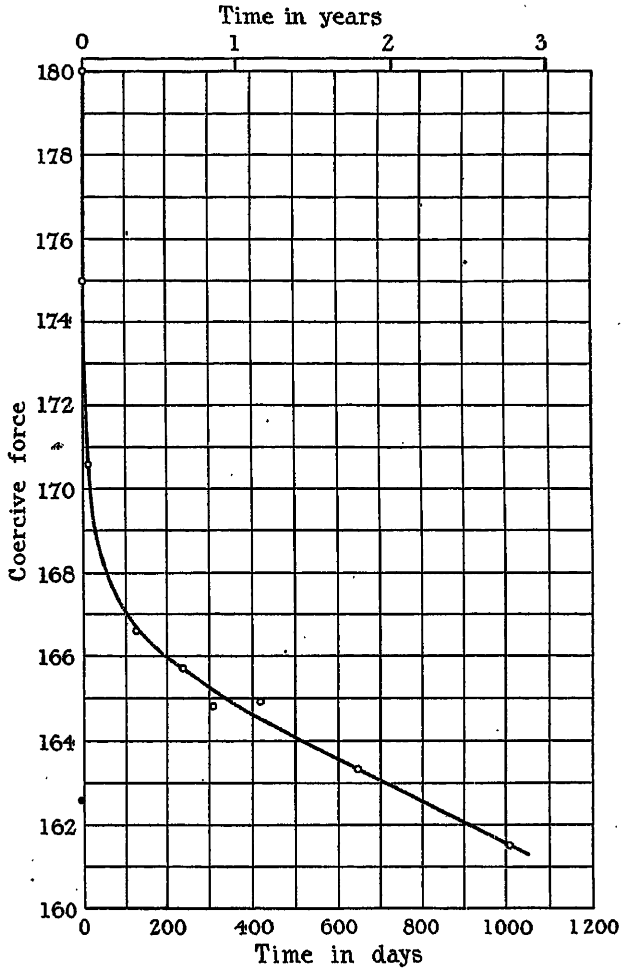

FIG. 22.—Decay in the potency of hardened steel. Curve showing the loss of coercive force in cobalt magnet steel going on for 3 years after the hardening.

each test all effects other than changes in the steel itself are eliminated. The magnetometer readings of coercive force are made to the nearest tenth of a unit, and each recorded value is the mean of at least two, and in most cases four, independent tests, these being made with the magnetization first in one direction along the steel bar and then in the other. All the tests are made with the steel at room temperature. In the intervals between the tests the specimens under observation are subject only to the small temperature variations of the air in the experimental room, the average temperature being about 18° C. and the maxi-

mum and minimum temperatures in summer and winter roughly 30° and 12° C. Tungsten steel and cobalt steel have been under observation in this way during the last four years. The tests are being continued, but they already afford convincing evidence that the hardened state in magnet steel is far from being a permanent condition.

The coercive force of hardened steel has its maximum value immediately after the hardening, and for the first hour or so afterwards a very rapid decrease takes place. But, as time goes on, the rate of change gradually diminishes, tending to become more or less constant after a month or two. An example of the gradual loss of potency is shown in Figs. 19, 20 and 21. These three diagrams relate to an ellipsoidal bar of tungsten steel which, having been hardened on the 20th November, 1920, has been kept under observation from that date to the present time, Fig. 21 recording the progress of decay from the day the steel was hardened up to June, 1924. The irregularities shown by the test points must not pass unnoticed. Many of them are too large to be explained away as observational errors, and some other cause must be looked for. We shall consider these apparent discrepancies again after examining the decay curves obtained from cobalt magnet steel, and in the meantime the smooth curves shown in the diagrams must be regarded as representing merely the general trend of decay in hardened tungsten magnet steel.

For the purpose of observation and measurement cobalt steel provides a better material for experiment than tungsten steel, since as a result of the greater potency of cobalt steel the phenomena of decay occur on a much larger scale. A curve of decay obtained from a typical specimen of cobalt magnet steel is given in Fig. 22. Fuller information is available in this instance, complete demagnetization curves having been obtained from the test specimen on each occasion when a decay test was made. Two of these curves are shown in Fig. 23 to illustrate the dependence of available energy on potency. The useful energy which the steel can maintain naturally falls off as the potency decays.

It will be noticed that some irregularity in the progress of decay is indicated by the position of a few of the test-points in Fig. 22. A clue to the origin of irregularities of this kind has at length been discovered by an examination of the decay tests made on another sample of cobalt magnet steel. It so happened that in this particular specimen a very noticeable *increase* in coercive force took place in the interval between two successive tests, and since it seemed obvious that something unusual was going on, the succeeding tests were made at intervals of two or three months, instead of adhering to the course adopted in other cases of increasing the intervals to six and twelve months as the rapidity of decay declined. The more frequent observations disclosed the fact that the general course of decay was accompanied by a cyclic change of decreasing amplitude. By the time the magnet had been under observation for several years, it became clear that the oscillation in the decay curve was a seasonal one with a complete period of twelve months. When this fact is taken into account all the test-points easily fall into their right places on a wavy line which represents the progress of decay combined with a seasonal oscillation of rapidly decreasing amplitude. This remarkable curve is shown in Fig. 24. The coercive force immediately after hardening the magnet

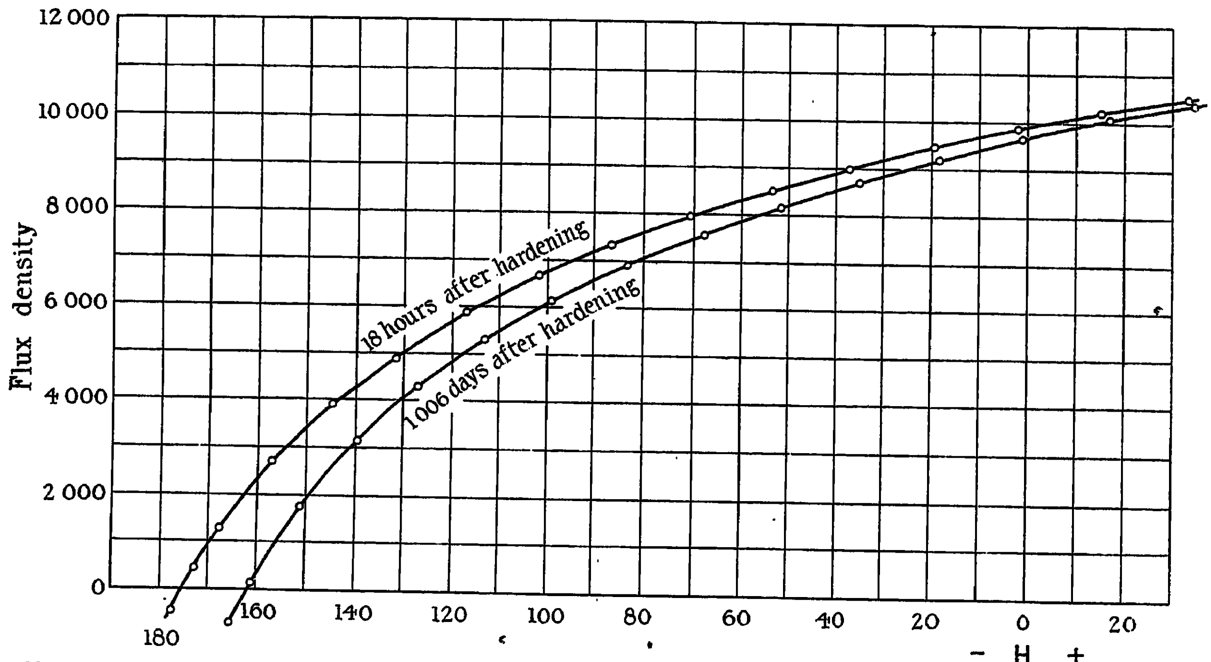

FIG. 23.—Decay in the potency of hardened steel. Demagnetization curves obtained from a specimen of hardened cobalt magnet steel, 1 day and 1 006 days after the hardening.

was 180·0, and the test made after the lapse of 4·4 years showed that the coercive force had declined to 161·8 in that time, a loss of 18·2 units or 10 per cent.

Seasonal changes having been recognized in cobalt steel it was natural to look for them in tungsten steel. Evidence of their existence has been sought by plotting the test-points recorded in Fig. 21 to a magnified vertical scale, and then completing the diagram by a line following the course indicated by the relative positions of the test-points, so far as it was possible to do so without

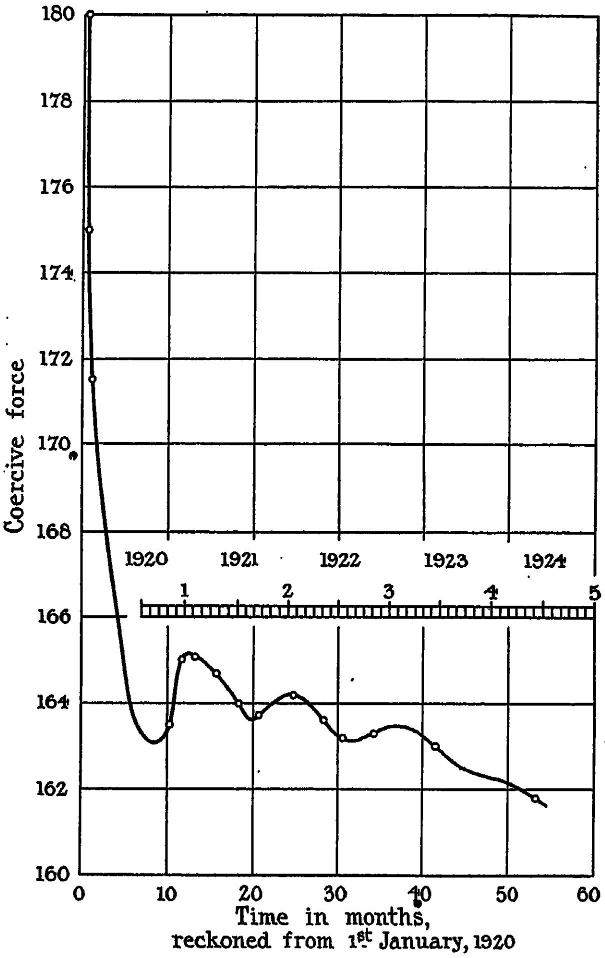

FIG. 24.—Decay in the potency of hardened steel. Curve obtained from a specimen of cobalt magnet steel, showing a seasonal change in the rate of decay during the first few years after the hardening.

making sudden changes in direction. The graph constructed in this way is reproduced in Fig. 25 and it will be seen that the test-points, which at a first examination showed numerous apparent errors, are actually quite consistent with the occurrence of a seasonal oscillation in the progress of decay in tungsten steel.

The continuous falling off in the coercive force of hardened magnet steel, demonstrated by the tests recorded in the diagrams, can only be attributed to the passage of carbide molecules out of solution. From the general course of the curves of decay it is clear that immediately after the hardening there is a rush of solute molecules out of solution, the coercive force decreasing by from 6 to 8 per cent in the course of the first 100 hours. With the lapse of time the progress of decay has tended to become a nearly uniform decline, apart from the influence of the seasonal changes. Within a year from the hardening the rate of decay in each of the specimens of steel under observation settled down to a more or less steady value, which has been maintained for three or four years without any noticeable abatement, the steady rate of decay being many thousand times smaller than the rate immediately after the hardening.

The rapid initial effect, followed by slow but persistent decay, suggests that the change from solution to crystal takes place in two distinct stages. In the

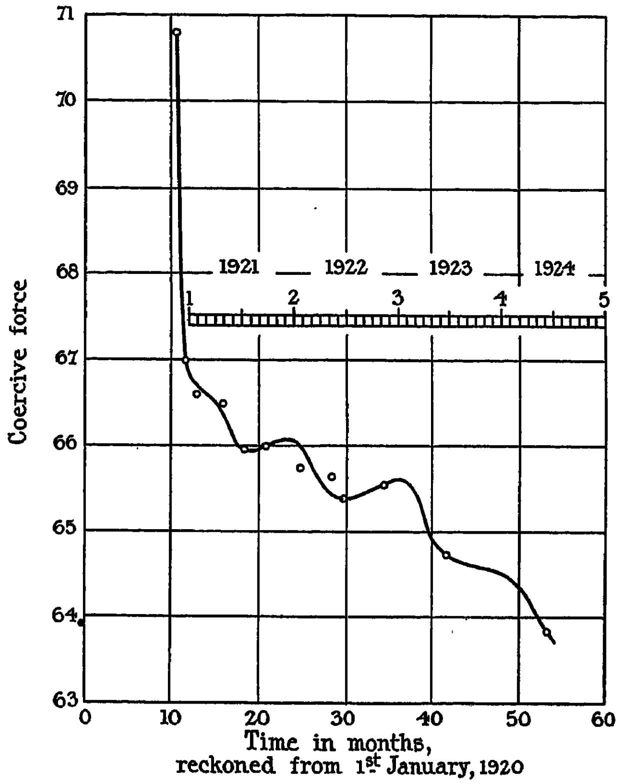

FIG. 25.—Decay in the potency of hardened steel. The curve given in Fig. 21 for tungsten magnet steel redrawn on the assumption of a seasonal change similar to that shown in Fig. 24.

first stage we may imagine the solute molecules to be leaving their solution positions and drifting into an intermediate condition of temporary independence, half way between solution and crystal. Released from the bonds of solution the molecules would be free to form other ties, and the second stage would consist in molecules coming together to form elementary crystals. At first there would be nothing to prevent a rush of molecules into the intermediate state, but as the sort of half-way house became crowded, molecules would experience more and more difficulty in leaving their solution positions. To account for the diminution in

the rate of decay we must suppose that the assembling of molecules as crystals relieves the crowding of the intermediate state, and on that assumption the rate at which molecules would pass into the half-way house would ultimately be reduced to an equality with the rate at which other molecules, already in a condition of independence, were assembling themselves as crystals. This would be the state of affairs when the decline of coercive force had settled down to a steady rate.

The intervention of the seasonal change makes it difficult to compute the steady rate of decay with any precision. So far as it is possible to judge from the curves of decay, the coercive force is at present decreasing at the rate of about 2·0 units a year in the specimens of cobalt magnet steel, and roughly 0·8 units per annum in the tungsten steel. These figures give a ratio of 2·5 and it is of interest to note that the figures for the initial values of the coercive force, namely 180 and 71, are almost in the same proportion. The inference must be that the carbide molecules in these two kinds of steel pass out of solution at much the same rate.

There is at present no indication of a falling off in the rate of decay but it is difficult to believe that it can continue unabated. Unless something unforeseen puts a stop to the progress of decay the whole of the surplus carbide will pass out of solution and the steel will ultimately return to the softened state. At the present time after four years of decay the coercive force of the cobalt steel is about 162 and that of the tungsten steel about 64. In the softened state the coercive force would be roughly 30 and 16 in these two steels, so that the ultimate loss, reckoning from the present condition, would be 132 and 48 units respectively. Hence if the present steady rates of decay were to continue unchanged, the cobalt steel would be completely softened in 132/2, or 66 years; and the tungsten steel would be reduced to the same condition in 48/0·8 or 60 years. Adding 4 years for the time already elapsed, it appears that the whole of the surplus carbide in hardened magnet steel might pass out of solution in the course of about 70 years from the time of hardening. But if the hardened condition of steel lasts no longer than that, the gradual softening with time could scarcely have remained undiscovered,* and the probability is that the rate at which the carbide molecules pass out of solution will fall off as the amount of carbide remaining in solution decreases. Assuming this as the probable course of events, the gradual change in the steel from the hardened condition to the softened state might easily occupy many times 70 years, if indeed any finite limit can be assigned to the duration of a process which would be going on at an ever lessening rate.

So far the seasonal oscillation of rapidly diminishing amplitude remains unexplained. We have learnt to associate oscillation with the exchange of energy between elasticity and inertia, or between electrostatic capacity and inductance, or more generally to the exchange between potential energy and kinetic energy, and when the amplitude decreases we know that some of the energy is being dissipated as heat or at all events escaping from the oscillatory system by some means or other. It is strange to find the well-understood phenomena of oscillation reproduced or imitated in a molecular disturbance where it would be least expected, and with the enormous periodic time of 365 days. That the seasonal effect is connected in some way with temperature variation may be taken for granted, but beyond this all is obscure. The amplitude of the oscillation decreases so rapidly that within four years from the time of hardening the effect has become barely perceptible and there can hardly be a doubt that from four years onwards the course of the decay curve will be steadily downwards without any noticeable oscillation.

The investigation thus briefly recorded leaves us in no doubt on the main point. Steel, magnet steel at all events, which has been hardened by rapid cooling from a red heat is not the immutable substance it appears to be. On the contrary, steel which has been hardened in that way in order to compel the whole of the carbon to remain in solution in Alpha iron, is essentially unstable. The sudden cooling has no sooner ended than decay sets in, the potency, and presumably the hardness, gradually decreasing as time goes on. After four years the loss of potency is found to be going on slowly, steadily and without any sign of coming to an end. Nothing short of continuous observation carried on for many years can tell us when and at what point this loss of potency, this gradual change from hardness to softness, from solution to crystal, is going to stop. So far as can be told at present, there seems no reason to anticipate an end to decay until the whole of the surplus carbon having at long last been transferred from solution to crystal the steel becomes a solution of just so much carbide in Alpha iron as can be retained in stable equilibrium.

The effect which the decay in the potency of hardened steel has on the magnetic power of a permanent magnet, and the extent to which the loss of potency can be forestalled, will be considered in Part IV under the heading of Ageing.

(17) The Essential Molecular Structure for a Permanent Magnet.

The preceding sections have been written in the belief that the readiest way to obtain a clear understanding of the behaviour of magnet steel at its best is to know what it might do at its worst. Much space has therefore been devoted to the various causes of magnetic weakness. In Gamma iron the potency-giving molecules decompose; in ultra-heated steel some of the solvent iron persists in the non-magnetic state; in hardened steel the potency decays with time. Each of these defects involves a loss of useful magnetic power, but after all they are matters incidental to the making of magnet steel or to the subsequent life of the steel as a permanent magnet. They are not the essentials of permanent magnetism, and after a long sojourn in the metallurgical jungle we emerge at last to obtain a clearer view of the magnetic mechanism which constitutes the essential magnet.

If the broad principle finds acceptance, that the magnetic potency of steel has its origin in the molecular pattern peculiar to the state of solution, then it will be acknowledged that, so far as the magnetic mechanism

* It would be interesting to learn whether an indication of softening with age has ever been observed in such things as swords or carpenter's tools, which are not infrequently preserved for generations.

is concerned, an absolutely uniform solution of potency-giving carbide molecules in Alpha iron would provide all that is essential in a permanent magnet. The structure of a solution being invisible in even the most powerful microscope, the structural appearances sometimes seen in hardened steel must be attributed to want of homogeneity, to incomplete solution due to imperfect hardening, or to decomposition, for unless particular care had been exercised in the choice of the specimen the steel would almost certainly be in a spoiled condition.* Any visible structures, due to such causes as these, far from being signs of magnetic power, would in all probability be impediments to its propagation and we may be sure that anything seen is not the essential mechanism.

But the solvent itself, Alpha iron, has a structure. Solid iron in all its varieties is crystalline, and if the picture of a permanent magnet as a solid solution is to resemble reality, the nature of the crystalline structure and the way it comes about must be borne in mind. Any metal which has solidified from the molten state is a crystalline substance. That is to say it is built up from elements each consisting of a few molecules forming some particular kind of orderly group, bound together by forces which compel them to assume that order and no other. This orderly structure having been initiated at some spot, some nucleus, which formed a convenient site for the assembling of the first elementary group, the conditions at that spot determined the angular aspect † in which the first element assembled itself, and thereafter all the elements, in obedience to the law of crystalline growth, were compelled to adopt the same aspect. The crystal elements are like the bricks in a plain wall, where the angular aspect is determined by the laying of the first brick.

Under normal conditions there are innumerable sites where crystal growth can begin, and each site or nucleus will determine once for all the aspect of the crystalline structure that grows up round about it, the aspect of the structure not being influenced in any way by the different aspects initiated at neighbouring sites. In the same way a number of bricklayers might begin building detached portions of a wall at all sorts of angles and inclinations. After a time—in practice quite a long time—the several portions of growing wall would meet, and as the result of the random choice of aspects, any orderly linking up of the pieces of wall would be impossible. The boundary between one piece of wall and another would be an irregular, badly fitting joint, and the most a bricklayer could do would be to fill in all the joints with bits of broken brick and mortar. Something like this happens with the several crystal structures. They grow element by element, brick by brick, until neighbouring structures come up against each other and the entire space becomes filled with the different crystal growths, each growth having begun at its own nucleus and preserved the angular aspect that had its origin there. As the result of the different aspects, the meeting places of adjacent growths will form rough joints of somewhat irregular outline, and it is even supposed that the joints are filled in with stray molecules of iron and impurities which play the part of the bricklayer's debris of broken brick and mortar.* The general appearance of the entire crystalline structure, if the individual crystal growths were large enough to be seen, would be something like that sketched in Fig. 26, the extent of the growth from each nucleus being marked by a boundary line indicating the irregular joint between adjacent growths. Each area is described by metallurgists as a crystal grain, or sometimes simply as a crystal.†

The general lack of visible structure in the interior of perfectly hardened magnet steel makes it difficult, if not impossible, to determine the size of the crystal grains of Alpha iron. Mere size is, however, immaterial.

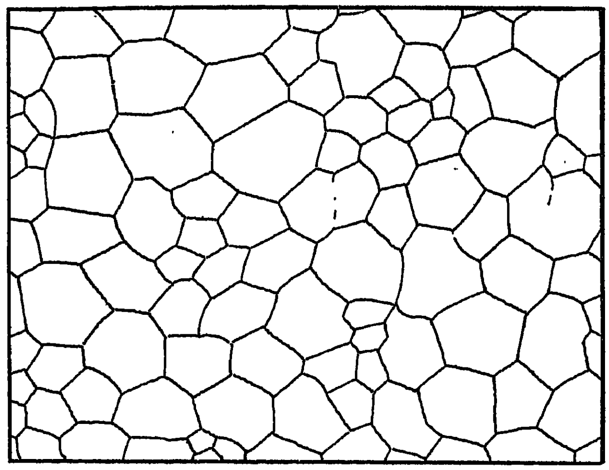

FIG. 26.—Sketch showing how crystal growth, starting from a number of originating sites or nuclei, results in a number of crystal grains, each restricted in size and shape by the growth of neighbouring grains. (Author, from a microphotograph by Sherard Cowper-Coles.)

Visible or invisible the crystal grains are there as the necessary outcome of the process of crystalline growth from a number of sites or nuclei. As a solution, therefore, a piece of hardened magnet steel is not a single entity, but an assemblage of innumerable crystal grains of Alpha iron each containing molecules of carbide in solution. Each grain is a homogenous solution, but since the distribution of carbon throughout a piece of magnet steel is never perfectly uniform the different crystal grains will vary in the proportions of solute carbide which they contain, and consequently the crystal grains will differ in their potency.

Within each crystal grain lies the magnetic generating mechanism on which attention has been concentrated in this and the previous paper. It is an affair of mole-

* In making experiments on tungsten steels it seems to have been the general practice of metallurgists to begin by heating the test specimens for an hour or more at some temperature between 900° and 1 000°, thus partially spoiling the steel—and the experiment.

† Orientation would be a better word than aspect, for the uniform angular arrangement of crystal growth. But in a paper on permanent magnets orientation stands for the deflection of the magnetic molecules by a magnetizing field, and to avoid confusion the word "aspect" is applied here to the crystal structure.

* The "amorphous layer" of Professor Beilby.

† The word "crystal" calls up a mental picture of a body of symmetrical shape bounded by flat surfaces. These wonderfully beautiful forms are, however, only possible when there is nothing whatever to interfere with orderly growth. Where crystal growth springs simultaneously from several adjacent nuclei, as in the case considered in the text, each crystal grain is hampered by the proximity of its neighbours and in the end its growth is confined to filling in any space that may still be available. The grain is a crystal in a sense; but it is a thwarted crystal, robbed of the beauty of symmetry in outward form.

cules, and relatively few molecules are needed to construct a complete microcosm of the permanent magnet. Assuming that by some means or other the magnetic molecules have been arranged in the required pattern, the potency-giving pattern, Ewing's model shows that less than 100 molecules of Alpha iron would suffice. But to include within the microcosm the means by which that pattern is created there must be a sufficient number of molecules of solvent iron and solute carbide to create the essential properties of a solution. Bearing this in mind, we may imagine a microcosm consisting of 1 000 000 molecules of Alpha iron as solvent, in which are dissolved 39 000 molecules of carbide of tungsten, WC, and 39 000 molecules of carbide of iron, Fe_3C, those being in round numbers the proportions of the best tungsten magnet steel. Being a solution of carbides in Alpha iron, the 1 078 000 molecules would arrange themselves in the particular pattern that creates potency. So small a number of molecules as 1 078 000 would constitute an inconceivably minute crystal grain, yet it would be endowed with the inherent magnetism and the potency of hardened magnet steel, and would behave in all respects, save one, like a permanent magnet.

The one exception just referred to arises from the fact that within an individual grain the crystalline structure has but one angular aspect, whereas a permanent magnet is composed of an immense number of crystal grains of every variety of aspect. Now in the single crystal grain with its uniformity of aspect, it is almost certain that the potency would be found to depend on the inclination of the axis of magnetization with respect to the crystalline aspect, and hence the power of the crystal grain as a permanent magnet would depend to some extent on the direction in which we chose to magnetize it. But in a piece of steel containing a large number of crystal grains, the resultant potency is the average of the various individual potencies of a number of grains of every variety of aspect, and being an average of that kind the resultant potency of the steel is, of course, the same in all directions. Apart from that one structural difference and the further fact, already referred to, that in the magnet the crystal grains would be more than likely to contain different proportions of carbon, the permanent magnet and the microcosm of 1 078 000 molecules would be indistinguishable in their magnetic properties.

(18) Conclusion.

Returning to the point from which we set out on our metallurgical journey, and recalling the extraordinary complexity arising from the allotropy of iron, to say nothing of the precarious existence of carbide molecules in Gamma iron, it could hardly have been anticipated that in the final view hardened magnet steel would take on so simple an appearance. But simplicity has only been arrived at by imagining a perfection of homogeneity beyond anything attained in steel-making, by disregarding many subsidiary matters and adhering, so far as possible, to essentials. Even so, the simplicity of the picture is to some extent an illusion, for wrapped up in the essentials are some of the most difficult of unsolved problems, such as the nature of solution, the character of the mechanism by which the state of solution creates magnetic potency, and, above all, the problem of the atom with its electrons whirling in planetary orbits.

In bringing this account of the metallurgy of magnet steel to a conclusion the author is only too conscious how much it falls short of what an exposition of so tangled a subject should be. At the risk of leaving out some vital link in the chain, much that forms the common stock of metallurgical knowledge has been omitted in order to attend to matters more directly bearing on the magnetic properties of steel. Tungsten steel has been taken as the typical magnet steel. Cobalt magnet steel behaves in much the same way, but on an exaggerated scale. Want of space has prevented separate notice of its distinctive features; its phenomenal potency—when made in the laboratory; its excessive degradation by spoiling—when made in the steelworks. Other omissions, conscious and unconscious, can only be set down to want of knowledge.

Yet, with all omissions, it is hoped that the picture of magnet steel has been so presented that it can be seen as a whole. It is so easy to miss seeing the wood because of the trees, and there never was a subject more crowded with trees and undergrowth.

PART IV.

PERMANENT MAGNETS IN THE MAKING.

(19) The Mediæval Art and Mystery of the Magnet Maker.

> "The compass needle, being the most admirable and useful instrument in the whole world, is so bungerly and absurdly contrived as nothing more."
> *Barlowe's Magnetical Advertisements*, 1616.

Industries rooted in tradition naturally lag behind and although three hundred years have gone by since Barlowe deplored the imperfections of the permanent magnet as he knew it, his apt words apply to much that goes on to-day in making magnets. Yet in some ways things have changed. There has, of course, been a vast extension in utility. Permanent magnetism serves many different purposes and the permanent magnet has become an indispensable adjunct in engineering. But with this incentive to progress the making of a magnet is still largely governed by rule-of-thumb notions as it was in Barlowe's time. Bungerly it was, bungerly it remains.

The deadening effect of tradition is not solely to blame for this lack of progress in a small but important industry. Something must be attributed to the subordinate position which the industry occupies. The manufacture of permanent magnets is not carried on as a separate branch of engineering like the making of other small adjuncts such as bolts and nuts or ball bearings. Permanent magnets are either made by the steelmaker for the user, or the user himself makes them as one of the components of the apparatus for which they are intended. As an industry, therefore, magnet-making rather falls between two stools and the

progress that comes from concentration of effort is lacking; for wherever the magnets are made, their manufacture is but a small branch subsidiary to the main stem. The natural consequence is that permanent magnets are for the most part made in the light of that kind of vague knowledge that leads nowhere.

The object of the present paper is to assist the magnet maker, whoever he may be, in overcoming some of the difficulties that beset him. It is hoped that in the following pages a useful light may be thrown on some of the many obscurities and particularly on those darker places in the way where the present writer, as one of the mediæval fraternity of magnet makers, has constantly found himself stumbling. Attention has first been directed to the metallurgical facts of magnet steel, in the belief that future improvement in the art of magnet-making must be founded on a better knowledge of the raw material than has hitherto been available. Consideration will now be given to the practical bearing of some of the subjects dealt with in Part III. In addition to matters relating to present practice, a novel departure in making permanent magnets by casting them in ordinary magnet steel will be described, and lastly some of the unsolved problems to which future research might well be devoted will be briefly referred to.

The earliest form of permanent magnet made of steel was the compass needle, and the art of magnet-making may be said to date from the invention of the mariner's compass. Just when that was no one knows, but the permanent magnet certainly antedates such things as the electric telegraph and the dynamo by untold centuries, and it is by no means surprising to find traces of its early origin still clinging to it. Throughout the making of a magnet from the mixing and melting of the ingredients of the steel in a crucible, to the hardening of the magnet, at every stage there is something to remind us of a mediæval art and mystery. To watch steel being poured from a crucible into an ingot mould or to see a workman harden a magnet is to live again in the middle ages. Of late years the metallurgical chemist and the pyrometer have made good progress in the uphill task of replacing tradition and rule-of-thumb by knowledge, but speaking generally the manufacture of permanent magnets, including the making of magnet steel, is still in a backward state and contrasts unfavourably with the precision and uniformity that has been attained elsewhere in modern engineering practice by the application of scientific method.

Up to the present time magnet steel has invariably been produced in the form of rolled bar, the common practice being to melt from 60 to 80 lb. of metal in a crucible and pour it into an ingot mould. The ingot, having been reheated and reduced to a smaller section by cogging, is finally rolled down to the particular section required by the magnet maker. A ton of steel produced in this way is the product of between 30 and 40 crucibles and, not unnaturally, variations in composition are frequent, more particularly in the vital matter of carbon content. The figures given in Table 8 show the extent of the irregularities that occur in practice. The wide variations in carbon above and below the specified percentage are quite enough to condemn the traditional method of melting steel by driblets in little crucibles.

Uniformity in composition can only be ensured by melting steel in bulk, a ton or more at a time. Mainly as the result of the introduction of electric furnaces, this improvement in practice has been generally adopted for steels which are used in large quantities, but the comparatively small demand and the different compositions which magnet makers, rightly or wrongly, believe to be necessary, have afforded little inducement to the steelmaker to mix and melt magnet steel in bulk. The time is ripe for the change, and so far as tungsten magnet steel is concerned there seems no reason why the optimum composition given in Section (21) should not be equally applicable to all purposes. Assuming the optimum composition to be generally adopted by magnet makers, the steelmaker would incur

Analyses of various batches of rolled tungsten magnet steel supplied by four Sheffield steelmakers.

no risk in melting steel of that composition in bulk; the resulting ingots being subsequently rolled down to suit the requirements of individual users.

A more insidious fault than want of uniformity in composition is the spoiled state in which rolled magnet steel leaves the steelworks. As the several processes of manufacture are conducted at present, spoiled magnet steel is the rule, unspoiled steel the exception. In this respect there is nothing to choose between one steelworks and another, common practice in making magnet steel being at fault.

Another troublesome defect in magnet steel is the presence of incipient cracks, or if not actual cracks a weakness of structure which easily gives rise to cracks. The final cause of cracking is, of course, the violent process of hardening by sudden cooling, but different

lengths of steel which have been rolled at one time are often found to differ greatly in the tendency to crack in hardening. This clearly indicates some occult structural weakness in the individual length of rolled steel, a weakness which might easily arise if the rolling ended at an unduly low temperature.

Having survived the perils of the steelworks, more or less impaired in magnetic quality and mechanical strength, the lengths of rolled steel become the raw material of the magnet maker. The first step is to cut up the rolled bar into short pieces of the appropriate length for a magnet. The magnet lengths are then heated to about 900° C. and forged or bent to the required shape. After trimming the ends and drilling holes for fixing screws, if they are required, the shaped pieces are hardened from a temperature of about 850° C. by quenching them in cool water or oil. The hardened pieces are then magnetized, the method of magnetization depending on the shape of the magnet. With a suitable outline, the magnet can be included in the magnetic circuit of a powerful electromagnet; but if the shape given to the steel does not lend itself to that simple and expeditious method, a temporary exciting coil must be wound round the magnet and a current of the necessary strength passed through it. In the author's practice the actual winding of a coil is avoided, the exciting coil consisting of a number of detachable links which are readily removed for the insertion of the magnet. After magnetization the magnet is usually subjected to some treatment intended to secure constancy of magnetic power.

The mischief done to the steel in making a magnet is confined to the processes of forging and hardening. It is impracticable to forge or even to bend a piece of rolled magnet steel without heating it to a temperature within the danger zone, and consequently some further degradation by spoiling inevitably occurs. But the spoiling at this stage is small compared with what the steel has already suffered in the steelworks, and by limiting the duration of heating the spoiling can be reduced to a negligible amount. The temperature to which the steel must be heated for the purpose of hardening is also within the danger zone, but here again spoiling is easily made negligible by limiting the duration of heating. Inherent in the process of hardening by rapid cooling is the risk of cracking and distortion, evils which after centuries of experience remain unmastered.

This brief history of the production of a magnet, from crucible to quenching bath, is enough to show the need for improvement in manufacture. Erratic composition, excessive spoiling, and the liability to cracking, are the outstanding defects. As regards the first, no one looks for perfect uniformity of composition, but it ought to be possible for the steelmaker to confine the errors within much narrower limits than he does at present. The prevention of spoiling during the manufacture of magnet steel is another matter for the steelmaker. The remedy has already been referred to in Section (13). It is a problem in heat treatment and will be readily solved when once it is attacked with knowledge. Cracking and distortion go together. Both need scientific investigation but the subject is full of difficulty, and research is likely to be prolonged. To find remedies for these evils is eminently a problem for industrial research—it will never be solved by the nostrums of the toolmaker.

Fortunately practice has a way of making light of the most baffling difficulties, and the magnet maker often manages to turn out a few wonderfully good magnets, in addition to a vast number of indifferent ones and many wasters for the scrap heap. Success is contingent on a number of chances occurring one after the other. If the steelmaker happens to mix the ingredients of magnet steel in the right proportions; if the carbon happens to distribute itself uniformly; if the steel when heated for the rolling happens to escape from the danger zone into the region of temperature in which restoration takes place; if the magnet maker happens to succeed in persuading all the potency-giving carbide molecules to remain in an abnormal state of solution in Alpha iron; and lastly if the magnet, in hardening, happens not to crack—if all these things happen in due order then a powerful permanent magnet is forthcoming.

All this relates to the practice of making permanent magnets from bars of rolled steel. The drawbacks incidental to rolling the steel and forging the magnet to shape, including nearly all the degradation by spoiling, would be gone if in place of the casting of ingots, followed by rolling and forging, the molten steel were to be cast at once in the shape of a magnet, pole pieces and all. In Section (23) it will be shown that cast magnets of ordinary magnet steel present many points of advantage over magnets of rolled steel and are in no way inferior in magnetic power.

Whether a magnet is to be a casting or a piece of rolled bar, the first step is the same. The designer must choose the kind of steel and the percentage composition that answers best to his requirement. These matters will therefore next engage our attention.

(20) The Cost of Magnetic Energy: Carbon Steel, Tungsten Steel and Cobalt Steel Compared.

The choice of steel for permanent magnets is governed by several considerations. Economy in cost is often the deciding factor, but even when some technical advantage to be gained outweighs economy, it is useful to compare the gain with the additional cost, provided the magnets are large enough or numerous enough to justify such a comparison. We shall, therefore, begin with the purely economic aspect of the problem as it affects the choice of steel for magnets of the dimensions commonly met with in electric supply meters, industrial measuring instruments, magneto generators, and other apparatus requiring magnetic energy in considerable quantity. Such magnets as these are large enough to be made either by casting them or by forging them from rolled bar; magnets which are too small to be made in those ways fall into a different class and will be considered separately.

In making a magnet either by forging it or by casting it, the various operations are the same whatever kind of steel is used, and consequently the only difference in cost between magnets made of different kinds of steel lies in the cost of the steel itself—the raw material.

The three steels which are suitable for permanent magnets differ greatly in price per pound, but in this instance, as in so many other manufacturing problems, to buy the cheapest (the business man's rule of life) is not the way to economy. Magnet steels differ not only in cost but also in the amount of magnetic energy they can maintain, and, other things being the same, the steel to choose is the one which gives the required energy at the lowest cost. Both factors must be taken into account in making a choice between one kind of steel and another, and it will, therefore, be convenient to embody them in a formula.

Let the total quantity of magnetic energy which a magnet is required to maintain in external space be denoted by E. That is to say, let E stand for the useful energy plus the energy in the leakage field. Let e denote the maximum available energy per cm³, which can be maintained by the particular kind of steel it is proposed to use; then the volume of steel for an economic magnet will be E/e cm³. Multiplying by the density d, and dividing by 453·6, gives the weight of the magnet in pounds, and, denoting the price of the steel by p, the cost of the steel for the magnet will be :—

$$\text{Cost of steel for energy } E = \frac{E}{e} \cdot \frac{d}{453 \cdot 6} p$$

In the previous paper it was shown that in a magnet the maximum available energy per cm³ of magnetized steel, when stated in terms of flux and potential difference, is numerically equal to the maximum product of co-ordinates of the demagnetization curve obtained from a closed ring of the same steel after complete magnetization.* Hence, assuming that a demagnetization curve of the steel has been obtained, the quantity e is known. It should be noticed that since E and e appear in the formula as a ratio, these quantities may be expressed either in ergs or in units of flux and potential difference.

The cost formula makes it easy to compare the relative values of different magnet steels, and as an example of the use of the formula a comparison of this kind is given in Table 9 for the three kinds of magnet steel in use at the present time. The tabular figures for the available energy e were obtained in each case from specimens selected for the purpose as being the best of their kind. The carbon steel is an excellent brand of pure carbon tool steel and, although it is not sold as magnet steel, the available energy is unusually high for carbon steel. The tungsten steel is of the standard composition and the figure for available energy was obtained from a length of rolled bar which happened to be almost unspoiled. The cobalt steel was received from the steelworks in a badly spoiled condition, the maximum available energy being only 23 800 ergs per cm³. The piece of steel from which the necessary demagnetization curve was obtained was first submitted to the restoration process, referred to in Part III as applied to tungsten steel. After this heat treatment the available energy was found to be 30 300 ergs, an improvement of 27 per cent. This is the highest value the author has so far obtained from any cobalt steel; and the figure 30 300 ergs has been used as the basis for the tabular figures of cost on the assumption that it is possible for the steelmaker to supply this steel in an unspoiled state. If, however, the spoiled condition in which the steel was supplied represents the best the steelworks can do, then 27 per cent must be added to the tabular figures for the cost of cobalt steel.

TABLE 9.

Description of Magnet Steel	e Energy per cm³	$\frac{E}{e}$ volume of steel	Density of the steel	Weight of steel in one magnet	Price of steel per lb.	Cost of the steel	
						1 magnet	1 000 magnets
	ergs	cm³		lb.	d.	d.	£
Tungsten ..	14 000	107	8·17	1·93	13	25	105
Carbon ..	7 170	210	7·82	3·62	11	40	166
Cobalt ..	30 300	49·5	8·27	0·90	90	81	337

Comparative cost of permanent magnets of equal power, made of Carbon steel, Tungsten steel, and Cobalt steel. E is assumed to be 1 500 000 ergs.

A glance at the cost table shows what an immense advantage tungsten steel has over the other two from the economic point of view. If the only question is how to provide any piece of apparatus with the magnetic energy it needs at the lowest cost, then the choice necessarily falls on tungsten steel. Carbon steel is 62 per cent more costly. Cobalt steel if unspoiled will cost three times as much as tungsten steel; and if it is spoiled it will cost more than four times as much. The disparity may be stated in another way. To bring the other two steels down to the same level of economy as tunsten steel costing 13d. per lb., the price of carbon steel must be reduced to 7d. per lb.; unspoiled cobalt steel to 28d. per lb., spoiled cobalt steel to 22d. per lb.

Turning now to the technical advantages of one steel over another, it is clear from the figures in the cost table that carbon steel is inferior to tungsten steel in cost, in volume and in weight. It is also evident that any advantage which cobalt steel may possess over tungsten steel will have to be paid for by an increase in the cost of steel for any given magnetic requirement. The cost table shows that of two magnets of the

* *Journal I.E.E.*, 1920, vol. 58, p. 798.

same magnetic output, one made of tungsten steel and the other of cobalt steel, the latter will occupy less than half the space. The cobalt steel referred to in the cost table has nearly three times the potency of tungsten steel and consequently the length of the cobalt steel magnet will be about one-third that of the other magnet, provided both are designed for maximum economy. In some circumstances the reduction in length would be a valuable feature. For example, it sometimes happens that the size of the box in which some piece of apparatus is enclosed is governed by the length of the magnet, and in such cases the additional cost of the cobalt steel magnet may be outweighed by a saving in the cost of the box. Again, in portable apparatus the lighter weight of the cobalt steel magnet is in its favour; but whether the saving in weight is worth the additional cost will depend on who carries the apparatus.

Although no one who has mastered the principle of magnetic economy, established in the previous paper, can be under any illusion, the idea is still widely prevalent that cobalt steel necessarily makes a more powerful magnet than tungsten steel. It cannot be too often repeated that if a permanent magnetic field of any given strength is required in any given space, it can always be supplied by a magnet made of any kind of steel which is magnetic. But different steels will result in magnets of very different size and cost, although they will one and all fulfil the given requirement. A cobalt steel magnet will be smaller than the tungsten steel magnet but it will cost more than twice as much, the two magnets being exactly equal in their useful magnetic power. Each will be capable of supplying the required magnetic field, neither more nor less.

However, the small size of the cobalt steel magnet is not the only point in its favour to be set off against the very high cost of the steel. Cobalt steel has another advantage—its unrivalled ability to withstand demagnetizing forces. Taking the simplest possible case for comparison, that of two bar magnets, one of tungsten steel the other of cobalt steel, both temporarily subjected to an adverse stray magnetic field of 20 units, the effect would be a permanent loss of strength amounting to about 14 per cent in the case of the tungsten steel magnet compared with rather less than 3 per cent in the cobalt steel magnet, an advantage of roughly 5 to 1 in favour of cobalt steel. Magnets which are bent so as to form a more or less closed magnetic circuit do not admit of so simple a comparison, but if two magnets of the same shape are subjected to a demagnetizing field, the cobalt steel magnet will have the same relative advantage over tungsten steel as regards loss of strength arising from the action of stray magnetic fields. Whether the advantage is worth the extra cost of cobalt steel will depend on the conditions of use. In many applications of permanent magnetism the magnet never comes under the influence of extraneous magnetic fields in excess of two or three units at the most, and when that is the case a tungsten steel magnet which has been properly treated for stability is just as good as one of cobalt steel, so far as stray fields are concerned.

The permanent magnets of ignition magnetos, and other magneto generators, are liable to be greatly reduced in strength by the action of the armature current. In this example of demagnetization cobalt steel has but little advantage over tungsten steel if both magnets have been designed for economy of steel. But if magnetic economy is entirely disregarded, the substitution of tungsten steel magnets by magnets of the same size and shape made of cobalt steel will be advantageous as regards demagnetization. But in this simple replacement the advantage is only gained at an extra cost far in excess of the relative figures indicated in the cost table.

In considering the pros and cons of cobalt magnet steel it must always be borne in mind that at present prices, and for any given magnetic power, tungsten steel is by far the cheaper steel. To bring the two steels to the same level of cost their prices must be in the same proportion as their maximum available magnetic energy, namely 14 100 to 30 000, a ratio of $2 \cdot 2$. In other words, if two magnets, one of cobalt steel and the other of tungsten steel, are to do the same useful magnetic work at the same cost for steel, then the price per pound for cobalt steel of the best quality must not be more than $2 \cdot 2$ times the price of tungsten steel.

Considerations of economy which govern the design and material of magnets of large size do not apply with the same force to small magnets which lend themselves by their size and shape to being stamped out of sheet steel or cut to length from drawn rod or wire. In magnets which are formed by such means as these, magnetic economy is outweighed by cost of production from the raw material, and some sacrifice must be made in order to use steel of a composition which makes it suitable for the operations of stamping or drawing. Production by stamping from sheet steel necessarily involves a considerable waste of metal in addition to the sacrifice of magnetic power, but in some cases the loss may be justified by the saving in manufacturing cost.

(21) The Optimum Composition of Tungsten Magnet Steel. The Alien Elements.

It has been demonstrated in the last section that, on the score of economy, tungsten magnet steel has no rival at the present time. It will now be shown that the best composition of this steel, far from being a matter of guesswork, is a problem capable of being solved once for all by methodical experiment.

It has been known for a generation or more that tungsten steel makes a better magnet than carbon steel, and anyone would think there had been ample time to discover the best proportions of tungsten and carbon, more than time enough if the problem had been attacked systematically. But that was not to be. In the past, those who had to do with the making of the steel and the magnets being, above all, practical men, their habits of thought were naturally averse to anything resembling orderly scientific method. It was inevitable that accustomed ways should be continued in the hope of finding the best mixture by trial and error. No one knowing what to aim at, progress was slow and crab-like, more especially as one greatly disturbing factor, the degradation of magnet steel by decomposition, was left out of account. With no better guide than random

experiment, the proportions of carbon and tungsten have naturally varied over a wide range. Carbon content has ranged from less than 0·5 per cent to as much as 1·0 per cent, and the tungsten from 3 per cent to 10 per cent or more. But, however slow it might be, the general movement was towards mixtures which at all events showed some approach to finality, and some twelve or more years since at least one German steelmaker was making magnet steel containing 0·70 per cent of carbon and 5 per cent of tungsten, proportions not very far from the best composition. To-day the consensus of opinion among steelmakers would probably put the carbon somewhere between 0·6 and 0·7 per cent and the tungsten at about 6 per cent. To this point, then, trial and error have managed to bring us in the course of 30 or 40 years, entirely unaided by knowledge of the factors which govern the magnetic energy maintained by magnet steel. Like all improvements founded on the same primitive methods, the advance has only been made at excessive cost in time and money. With the better knowledge of the relation between steel and permanent magnetism that is now available, it is possible to determine the best composition of any kind of magnet steel from first principles. Taking the maximum useful magnetic energy per unit volume of steel as the criterion, the necessary data can be obtained from the demagnetization curves of a number of specimens of steel in which the proportions of the several constituents are varied in suitable gradations.

For the determination of the best composition for tungsten magnet steel the necessary experimental data have already been obtained, mainly in the course of the author's investigation of the relation between carbon content and coercive force in steel containing 6 per cent of tungsten. The maximum available energy was ascertained experimentally for each of the samples of steel used in the preparation of the carbon-coercive-force curve given in Fig. 9. On plotting carbon content and available energy as co-ordinates a curve was obtained showing a steady increase of energy with increasing carbon, rising to a maximum for a carbon content of about 0·73 per cent. Beyond this point the energy gradually decreased, the curve being traced up to a carbon content of 1·3 per cent. But this preliminary determination of the most favourable carbon content was made before the discovery of the deficiency of Alpha iron in ultraheated tungsten steel. After the investigation of ultraheated steel it became clear that if any of the specimens used in determining the available energy happened to be in the ultraheated state when under test, the value of the energy computed from the observational data would be less than the maximum which the steel would be capable of maintaining if all the iron were in the Alpha state. But a deficiency in Alpha iron only affects one of the factors of magnetic energy, namely the flux. The other factor, arising indirectly from the potency of the steel, would be unaffected; since ultraheated tungsten steel when hardened has all the carbon in solution, and consequently the steel would have the full potency corresponding with the carbon content. Hence the possibly ultraheated condition of the test-pieces would affect neither the accuracy of the carbon-coercive-force curve nor the accuracy of the preliminary figure obtained for the best carbon content, namely 0·73 per cent. But by reducing the flux factor, ultraheating would result in a lower value for the energy corresponding with any given carbon content. These considerations led the author to make a careful scrutiny of all the available experimental records in order to utilize only those experiments in which the heating which the steel had undergone, before the hardening, had been sufficient to convert all the iron into the Alpha state. The energy values which survived this examination are plotted in Fig. 27. The three test-points indicated by crosses relate to three test-pieces which are not on quite the same footing as the others, the record in their case being incomplete, but so far as they go these three test-points confirm the general course of the curve.

It need hardly be said that in seeking to determine the best the steel can do, the presumption is always

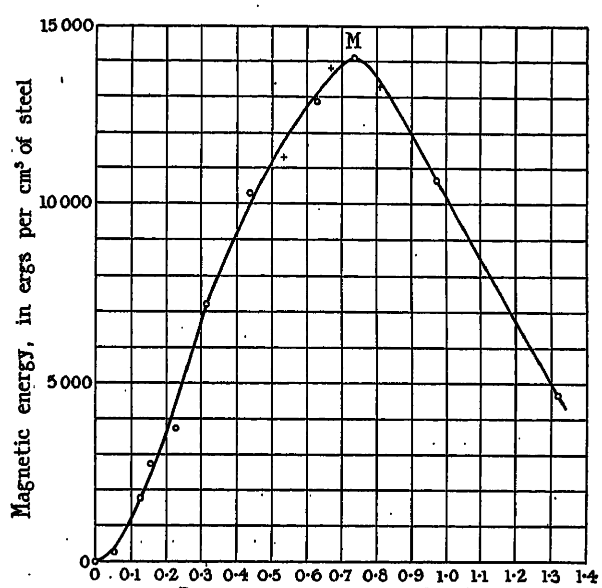

FIG. 27.—Available magnetic energy of hardened tungsten magnet steel containing 6 per cent of tungsten. Curve showing the relation between the carbon content and the available energy in ergs per cm³ of steel.

in favour of the highest observed values, subject, of course, to errors of observation. Lower values are always apt to occur from those accidental deficiencies of one kind and another to which magnet steel is only too liable. The point plotted at M deserves particular attention. It was determined from two test-pieces of 6 per cent tungsten steel used in the course of the experiments on the spoiling and restoration of magnet steel. Two pieces were cut from a length of rolled bar which had been selected for experimental use by reason of its quite exceptional uniformity in carbon content. Part of each piece was made into an ellipsoidal test-piece for the magnetometer, and the remainder submitted to chemical analysis. The demagnetization curves obtained from the two ellipsoids were indistinguishable from one another. The carbon content of the two specimens proved on analysis to be 0·735 and 0·736 per cent. In the author's experience of experimental work of this

nature, such uniformity as this is very seldom realized. It is merely a fortunate chance that the two specimens of steel happen to give an energy value closely approaching, if not actually coinciding with, the maximum ordinate of the curve in Fig. 27, and that this particular point should have been determined with exceptional precision.

The curve given in Fig. 27 expresses the law governing available energy and carbon content in 6 per cent tungsten steel, as closely as existing observational data can determine it. In the nature of things the highest point of a rounded curve such as this cannot be sharply defined, but the most favourable carbon content is certainly above 0·70 and below 0·76 per cent. It will be near enough to take the mean value, 0·73 per cent, as the optimum carbon content.

Having determined the total quantity of carbon, attention must next be directed to the proportion in which the total should be divided between the two carbides WC and Fe_3C. All the specimens of steel used in determining the maximum energy contained 6 per cent of tungsten. Hence when the steel contains the optimum proportion of carbon, namely 0·73 per cent, carbide of tungsten will utilize $6 \times 12/184$, or 0·39, leaving 0·34 to form carbide of iron. That is to say, out of a total of 73 molecules, each containing an atom of carbon, 39 molecules will be tungsten carbide and 34 will be carbide of iron. As matters stand, therefore, there is a rough equality in the number of the two kinds of potency-giving molecule. For some reason or other there is always a presumption (real or imagined) in favour of equality, and in the present case the suggestion receives support from the carbon-coercive-force curve given in Fig. 9. Examination of the two portions of the curve shows that for a carbon content of 0·73 per cent, the upper curve S2, which relates to the molecule Fe_3C, has a greater slope than the lower curve S1 at the corresponding point, namely carbon 0·39 per cent. Hence if, without changing the total carbon content, a little carbon were to be transferred from the tungsten carbide to the carbide of iron the increment of coercive force arising from Fe_3C would be greater than the decrement in the coercive force produced by the tungsten carbide, and the transfer would increase the potency of the steel. Assuming for the moment that the shape of the upper curve S2 is not affected in any way by the transference of carbon, it is easy to trace the increase in coercive force by measuring successive increments and decrements on the curves S2 and S1. The figures given in Table 10 have been arrived at in this way and it will be seen that according to the tabular figures a tungsten content of 5·2 per cent would yield the highest coercive force. But it is certain that the transfer of carbon from one carbide to the other would gradually change the shape of the curve S2. To what extent the change would affect the figures in Table 10 cannot be determined, but a comparison of the upper portion of the curve in Fig. 9 with Mme. Curie's curve for carbon steel (Fig. 8), shows that the alteration in the shape of S2 will be in the direction of a diminished slope. Now with a diminished slope it is certain that the highest coercive force would be given by a tungsten content greater than 5·2 per cent, and consequently the most favourable tungsten content must be somewhere between 5·2 and 6·0 per cent. Nearer than this it is not possible to go at the present time, and knowing no better we shall again take the average figure, putting the optimum tungsten content at 5·6 per cent. With this percentage of tungsten the carbon in the form of tungsten carbide will be $5 \cdot 6 \times 12/184$, which is 0·365 per cent. This, as it turns out, is exactly half the total amount of carbon, 0·730 per cent, and since the remainder of the carbon forms carbide of iron we shall have the number of molecules of Fe_3C exactly equal to the number of molecules of tungsten carbide. Hence, so far as it is possible to judge from the carbon-coercive-force curve, a total carbon content of 0·73 per cent will yield the maximum potency when one-half of it is in the form of tungsten carbide and the other half is carbide of iron.

TABLE 10.

Carbon as Fe_3C	Carbon as WC	Tungsten	Coercive force: Derived from Fe_3C	Coercive force: Derived from WC	Coercive force: Total

0·43	0·29	4·46	31·6	38·9	70·5
0·44	0·28	4·31	32·0	37·8	69·8

Tungsten steel containing 0·72 per cent of carbon. Computed variation in total coercive force with varying content of tungsten, showing a maximum potency with 5·2 per cent of tungsten.

* Maximum.

It should be noticed that a change in the way in which the total carbon is divided between the two carbides only affects one of the factors of magnetic energy, namely, that arising indirectly from the potency, and hence the apportionment which yields the highest potency must necessarily give the maximum available energy. The presumption in favour of equality of the two carbides is therefore justified by the facts so far as they are known.

Having ascertained the most favourable percentage for the total amount of carbon, and noted that equality of the two carbides gives the maximum energy, the optimum composition of tungsten magnet steel is settled. For easy reference the composition is set out

in Table 11 both in percentage quantities and in proportional numbers of molecules.

In every analysis of steel a number of alien elements force themselves on our attention, their prominence being out of all proportion to the quantities in which they occur. The aliens commonly present in magnet steel are sulphur, phosphorus, arsenic, silicon and manganese; but occasionally copper, nickel and chromium occur. The total quantity of alien elements found by analysis in a number of batches of tungsten magnet steel, supplied by different steelmakers, has amounted on an average to 0·53 per cent of the weight of steel; the smallest amount in any lot of steel being 0·29 per cent and the largest 0·75 per cent.

Among the aliens, sulphur, phosphorus and perhaps some others, are believed to be detrimental to the

mechanical strength of steel, but it is unlikely that any of the aliens, with the exception of manganese and chromium, have an appreciable effect on magnetic properties. If the aliens were not there, a little more space would be available for iron and to that extent their absence would be beneficial. Manganese in excess is unwelcome in a permanent magnet. This element is added to steel in order to counteract the injurious influence of sulphur on mechanical strength, the manganese combining with the sulphur to form an innocuous sulphide. But in magnet steel there is always a good deal more manganese than is necessary for this purpose, and it is to the surplus that suspicion attaches. Manganese is known to form a non-magnetic compound with iron, and the surplus quantity in magnet steel is often enough to rob the magnetic mechanism of its magnetic molecules to the extent of 3 or 4 per cent. On this account, it is desirable to limit the percentage of manganese to an amount which will serve the intended purpose without leaving more than a small excess.

Chromium needs a paragraph to itself. The great potency-giving power of carbide of chromium, and the loss of magnetism in steel containing chromium, have already been referred to in Section (6). The very high coercive force imparted to steel by chromium was discovered many years ago by Mme. Curie, who at the same time was aware of the harmful effect of chromium in magnet steel. But this knowledge has not, even yet, found its way into every steelworks. Now and again, at intervals of a few years, steel containing chromium is introduced as a newly-discovered magnet steel, stress being laid on high coercive force. But the deficiency of inherent magnetism, which invariably outweighs the gain in potency, is either overlooked or at all events passed over in silence. There can hardly be a doubt that the deficiency in Alpha iron is the result of ultraheating, just as it is in the case of tungsten steel, and it may be assumed that the harmful effect of chromium could be removed by suitable heat treatment. But judging from the behaviour of high-speed tool steels, the ultraheated condition, once acquired, is retained with extraordinary persistence when the steel contains chromium, and until a practicable remedy is forthcoming for deficiency in the inherent magnetism, chromium even in very small quantities should be avoided both in tungsten steel and carbon steel. So far the only serviceable remedy has been the introduction of another magnetic element, namely cobalt. But even this seems only a partial remedy, a considerable deficiency in magnetism being a common fault in cobalt magnet steel.

The great potency-giving power of carbon combined with chromium is naturally an alluring fact, but it seems incumbent on those who wish to exploit it that they should begin by making a thorough investigation of the action of chromium, with a view to annulling its harmful influence on magnet steel.

(22) THE CONDITION OF ROLLED MAGNET STEEL AS IT COMES FROM THE STEELWORKS.

Bars of rolled magnet steel are, for the most part, badly spoiled. They are also in the fully ultraheated condition. These statements apply both to tungsten steel and cobalt steel.

It will be convenient to attend first to the effect of ultraheating and to consider the practical steps to be taken for bringing the steel into the normal or all-Alpha state required for a good magnet. The abnormal condition of rolled magnet steel as the magnet maker receives it is illustrated by the three demagnetization curves given in Fig. 28. These curves were obtained one after another from a test-piece made from a bar of ordinary rolled magnet steel, containing 5 per cent of tungsten and 0·70 per cent of carbon. The first curve, A, was obtained when the steel was in the condition in which it was received from the rolling mill. The second curve, B, was obtained after hardening the test-piece. The third curve, C, was obtained after softening the hardened test-piece by heating it to 700° C, keeping it

at that temperature for two minutes, and then allowing it to cool in the open air to room temperature.*

A moment's consideration will show that curve A cannot represent magnet steel in a normal condition. Iron and steel are rolled at a bright red heat and after the operation the rolled bars are allowed to cool down slowly. As the temperature of the metal falls slowly through the region between 700° and 600° C. there is ample time for the whole of the surplus carbide to pass from solution to crystal, and hence if the steel after being rolled were in the normal state it would give a demagnetization curve like curve C, in which the coercive force is rather less than 18. But in fact the steel as it came from the rolling mill had a coercive force of 29, or 11 units greater than the value for the softened piece.

The phenomena of ultraheating are described at length in the Appendix, where it is shown that in

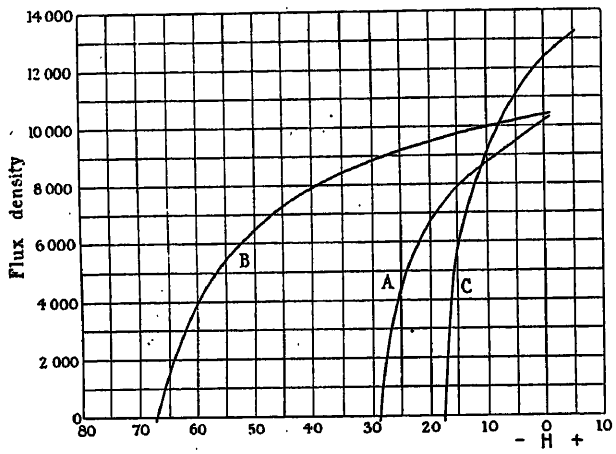

FIG. 28.—Demagnetization curves obtained from tungsten magnet steel in different states:—

Curve A, the steel in the softened state as received from the steelworks; illustrating the effect of ultraheating.
Curve B, the steel after being hardened.
Curve C, after softening the hardened steel.

tungsten magnet steel which has cooled down slowly enough to permit all the surplus carbide to pass out of solution, a coercive force so high as 29 units is a clear indication that the steel is in the fully ultraheated condition. Now the rate at which a bar of steel cools down after the rolling gives ample time for the whole of the surplus carbon to pass from solution to crystal, and consequently the piece of rolled steel from which curve A was obtained must have been in the fully ultraheated state. In the author's experience this is invariably the case with rolled magnet steel as it comes from the steelworks.

Two methods of heat treatment for curing ultraheated tungsten magnet steel are described in the Appendix. It can be done by prolonged heating at about 700° C.; or as an alternative the steel can be cured in two operations, each consisting of heating to about 750° C. and then immediately allowing the steel to cool down slowly. The latter plan is the more convenient in practice, because of the two heats which are necessary for a complete cure, one is performed incidentally in the course of forging or bending the magnets to the required shape.

Assuming that the forging or bending heat is relied on to complete the cure, the first curing heat may be performed as follows. After cutting up the rolled bars into pieces of the required length for making magnets, a number of pieces may be packed together inside a furnace and heated. As soon as the temperature of the steel has risen to 750° C., the supply of heat should be cut off and the furnace, with the steel inside it, allowed to cool down. Under these conditions the temperature of the steel will fall through the region favourable to curing, that is to say from 750° C. to about 600° C., slowly enough to remove about two-thirds of the whole effect of ultraheating. In other words, the amount of Gamma iron present in fully ultraheated 6 per cent tungsten steel will be reduced from 16 per cent to about 6 per cent.

An incidental result of this first operation for the cure of ultraheating may be noticed in passing. In the course of the operation, the temperature of the steel will be in the neighbourhood of 700° C. for some minutes. There will, therefore, be ample time for surplus carbide to pass out of solution, and consequently at the conclusion of the operation the pieces of steel will be soft and easy to machine.

For the purpose of forging or bending the pieces of steel to the required shape, they will subsequently be heated to about 900° C. At the conclusion of the process they must be allowed to cool down slowly in the ordinary way. By this means the steel will, for the second time, pass slowly through the temperature region favourable to curing and the remainder of the ultraheating effect will be removed, leaving the steel in the normal or all-Alpha state.

The preliminary heat may perhaps be regarded as an unnecessary refinement. If it is omitted, however, the slow cooling after forging will be the only opportunity given to the ultraheated steel to return to the normal state, and out of the 16 per cent of Gamma iron not more than 9 or 10 per cent can be counted on with certainty to change into the Alpha variety. Hence the steel will be likely to contain at least 6 per cent of Gamma iron and consequently the finished magnet will be 6 per cent weaker than it need be.

Turning now to the consideration of the spoiled condition in which magnet steel comes from the steelworks, it must be borne in mind from the outset that, unlike ultraheating which is a curable disease, spoiling cannot be cured effectively after the steel has been rolled down into bars. So far as the magnet maker is concerned, spoiling is an incurable disease, present in nearly all the magnet steel he buys.

Ultraheating and spoiling affect the two properties which give rise respectively to the two factors of the useful energy which a magnet is intended to maintain. Ultraheating adversely affects the inherent magnetism of the steel, spoiling injures the potency. The extent

* The reader who associates softening with the vague word annealing, easily imagines it to be a lengthy operation possibly involving slow cooling over many hours. It is, however, an affair of a few minutes when it takes place within the region of temperature just below the boundary where Beta is transformed into Alpha iron. Here the steel is still red hot and the molecular mobility so great that the whole of the surplus carbide will pass out of solution in a couple of minutes, leaving the steel quite soft. Given that brief time, slow cooling thereafter is needless, and the steel might then be dropped into cold water; it would be just as soft.

of the injury caused by spoiling varies over a wide range, the variation being much the same in every batch of rolled magnet steel. In this respect there is nothing to choose between the product of one steelmaker and another. All are alike, the uniformity of mischief pointing to a common practice in the heat treatment which the steel receives in course of manufacture. An example of the product of one steelworks will fairly represent them all, and for the purpose of illustration we shall choose a batch of tungsten steel which, in composition, closely approached the optimum proportions, the average of three analyses showing that

	202 lengths of steel in the batch.			

Spoiled condition of a typical batch of rolled tungsten magnet steel. The 202 lengths of steel in the batch are classified according to coercive force.

the steel contained 6·05 per cent of tungsten and 0·732 per cent of carbon. With the aid of the carbon-coercive-force curve given in Fig. 9, it is easy to show that when steel of this composition is in the hardened state it should have a coercive force of 71·0, provided it is unspoiled.

The batch of steel was supplied in 202 lengths rolled to a rectangular section 1 in. wide and $\frac{3}{8}$ in. thick. In accordance with the usual routine, two samples cut from each length were hardened and tested for coercive force in order to gauge the extent of degradation by spoiling. The mean value of the coercive force of a pair of samples was taken as the coercive force of the corresponding length of rolled bar. The tests are classified in Table 12, where the 202 lengths are sorted out into groups according to their coercive force, all the observed values for the different lengths in any group being within half a unit either way of the tabular figure.

It will be seen that the coercive force of this batch of steel varied from a maximum of 70 to a minimum of 53, the degradation arising from the spoiling which the steel had undergone in course of manufacture, varying from 1 unit at the best to 18 units at the worst. Precise figures for the corresponding loss of magnetic energy are not so easily obtained. They could only be arrived at by the laborious method of tracing a demagnetization curve for every length of steel in the batch. It can be shown, however, that for any given flux density the falling off in energy as the result of spoiling is nearly proportional to the falling off in coercive force. Hence with the aid of two demagnetization curves, one for unspoiled steel and the other for the same steel badly spoiled, the energy loss for any degree of spoiling which falls between the two curves can be estimated with sufficient accuracy by a method of interpolation. In the present case the demagnetization curves given in Fig. 16 are available, since they relate to the particular batch of steel we are now considering. By interpolation between curve 1 and curve 2, values have been computed for the maximum available energy of the steel in each group of lengths in the batch, and the computed figures have been inserted in Table 12. The energy of the 202 lengths of steel in the condition in which they were received from the steelworks varied from 13 800 ergs in the least spoiled length to 10 800 ergs in the most badly spoiled piece. In terms of available magnetic energy the mean degradation of the batch is a little over 11 per cent, and at the worst it is 23 per cent.

The figures given in Table 12 show how great is the need for radical improvement in the manufacture of magnet steel. Apart from the one or two lengths of really good tungsten magnet steel which sometimes occur, apparently by accident, unspoiled magnet steel, as a regular product, is unknown.* In place of it the magnet maker receives a strange assortment of more or less decomposed steel. What is he to do with it? If he designs his magnets on the basis of the available energy of the least badly spoiled steel in the batch, then the magnets in bulk will fail to meet his requirement. On the other hand, if the worst steel in the batch is taken as the basis of design, then the bulk of the magnets will contain a greater volume of steel than they need, an excess which has to be paid for.

An example with money in it will drive the point home. Suppose some piece of apparatus is to be made in considerable numbers. To fix our ideas we may suppose a thousand of them are to be made at one time, and that each requires a permanent magnetic field of 2 000 in an air space 10 cm² in area, and 0·5 cm in length measured along the lines of force. With these dimensions and strength of field, the magnetic energy maintained in the air space will be 796 000 ergs and, allowing for an equal amount in the leakage field, the total requirement will be 1 590 000 ergs. We may suppose that the permanent magnet which is to provide this energy is to be made of tungsten magnet steel like that classified in Table 12, and that the length of steel at the bottom of

* Up to the present time, the author has not come across a single piece of cobalt magnet steel that was not badly spoiled.

the list has been returned to the steelmaker as useless. The magnet must now be designed either on the basis of the best length in the batch which gives 13 800 ergs per cm^3, or on that of the worst remaining lengths, namely those in group (o), which give 11 370 ergs per cm^3. In the first case the volume of the magnet will be 1 590 000/13 800, and in the second case 1 590 000/11 370. At the best, therefore, the volume of the magnet will be 115 cm^3 and at the worst 140 cm^3, the corresponding weights being 2·07 lb. and 2·52 lb. One thousand of these magnets will be required and, allowing 10 per cent for the wastage of steel in cutting up and machining, the total quantity of steel will be 2 277 lb. in the first case or 2 772 lb. in the second. A comparison of the cost of 1 000 magnets is given in Table 13, where the price of the steel is that ruling in November 1923, for 6 per cent tungsten steel containing 0·7 per cent of carbon.

It will be seen that to ensure every magnet fulfilling the requirement, the only course open to the magnet maker is to found his design on the most badly spoiled steel in the batch. This involves an increase of 23 per cent in the quantity of steel, and in effect the material for the magnets costs 22 per cent more than it need do. In other words, if the magnets are to do what they are intended to do, the magnet maker is called upon to pay a kind of tax, amounting to between £20 and £30 a ton, for the privilege of using decomposed steel.

TABLE 13.

Condition of steel	Weight of one magnet	Cost of 1 000 magnets
	lb.	£
Spoiled	2·52	150
Unspoiled	2·07	123

Comparative cost of tungsten steel permanent magnets of equal power, made of spoiled steel and unspoiled steel.

It is desirable to find a remedy for this state of things. In the author's opinion a complete remedy is well within the bounds of possibility and, although it is the business of the steelmaker to make unspoiled magnet steel it may be useful to state briefly what are the grounds for believing it to be possible to produce rolled magnet steel in the unspoiled or restored state. But first to clear the air. Nothing is to be gained by ringing the changes on the ingredients. For so long as the potency of magnet steel is derived from molecules which, like the carbides of iron and tungsten, suffer decomposition in Gamma iron, it is surely obvious that no modification in the proportions of the constituents of the steel can have any material effect on the spoiling. The warning is called for because already one enterprising steelmaker has tried to cure the disease by changing the proportions of the solute molecules. His plan was to reduce the quantity of carbon. The argument seems to have been that since unstable carbide molecules are the origin of the mischief the fewer there are of them the better. Accordingly some of them were left out and to make up the depleted coercive force a little chromium was added. The result might have been anticipated. There was no improvement; on the contrary, the deficiency in carbon and the presence of chromium reduced the available magnetic energy in the entire batch of steel, but left the disease of spoiling untouched. In short, the attempt at improvement, however well intentioned, was misconceived; a plum pudding cannot be improved by leaving out some of the plums. Research may one day discover a new potency-giving molecule of a more stable kind; one that does not suffer any decomposition at the temperatures usually attained in making magnet steel. That would, of course, entirely remove the source of degradation by spoiling, but a remedy will never be found by tinkering with the proportions of the known constituents of magnet steel.

Pending the possible discovery of a perfectly stable molecule of the potency-giving kind, we have to make the best of the magnet steels already known, and the problem for the steelmaker is to modify the heat treatment of the steel in such a way that the rolled bars are turned out in the unspoiled or restored state. In both tungsten steel and cobalt steel slow decomposition is inevitable in course of manufacture because it is impossible to avoid the danger zone of temperature. But at any temperature above the upper boundary of the danger zone, recombination is equally certain and in that fact lies the true remedy for spoiled steel.

The author's investigations have been mainly concerned with tungsten steel. Cobalt steel behaves in much the same way both as regards spoiling and restoration, but the limits of the danger zone of temperature have not been determined. In what follows, therefore, attention will be confined to tungsten steel. The temperatures referred to will be those measured in the course of the author's experiments; they are probably true for any ordinary tungsten magnet steel within about 5 degrees either way.

It has been shown in Section (13) that the boundary where spoiling ceases occurs at about 1 214° C.; and that at 1 240° C. restoration proceeds with such rapidity that very badly spoiled steel would be completely restored in the course of two or three minutes. Hence if every piece of steel, before being rolled, were to be heated to 1 240° C. for a few minutes the problem of spoiled steel would be solved. For the steel would be restored before it was rolled and in place of the deplorable range of degradation shown in Table 12 we should have every length of steel in the batch as good as the best, all equally unspoiled.

It is for the steelmaker to find out how to carry out the restoring operation in practice. Difficulties will naturally be encountered but none are likely to be insuperable. High temperatures are in themselves a difficulty, but it is an encouraging fact that the temperatures already attained in ordinary practice are not very far below the restoring temperature. This we may easily see without prying into the secrets of the steelworks, because every length of magnet steel which comes from the rolling mill has the outline of its thermal history written at large all over it in magnetic characters.

By way of example we may consider the history of some of the lengths of steel classified in Table 12, choosing those in group (i) as representing the average of the whole batch of steel so far as spoiling is concerned. Since the lengths in this group are badly spoiled they must necessarily have been within the danger zone (between 750° and 1 214° C.) for some considerable time. But in common with all rolled tungsten magnet steel this batch of steel was in the fully ultraheated state and consequently it must have attained a temperature above 1 073° C., the ultraheating boundary. Hence the temperature of the steel preparatory to the operation of rolling must have been somewhere between 1 073° and 1 214° C. It will be sufficient for our present purpose to strike an average between these two figures and say that the temperature to which the steel was raised for the purpose of rolling was about 1 140° C. It will be observed that this is no more than 100 degrees below the temperature at which the restoration of spoiled steel takes place with great rapidity. Clearly, then, the restoration of the steel does not involve any extraordinary advance in temperature.

It remains to account for the occurrence of a few unspoiled lengths of steel now and again. Molten steel is unspoiled, but the metal cannot remain so from the time it was poured into the ingot mould until it arrived at the rolling mill, because in the interval it has cooled down and then been heated again, thus passing more than once through the danger zone. The steel is therefore necessarily more or less spoiled before it is ready for the rolling. Hence the only possible explanation of the casual production of a few lengths of unspoiled steel must be that occasionally the temperature of the rolling-mill furnace rises above 1 214° C. and sets going the process of restoration. How far restoration will go depends on three factors, namely the extent of spoiling to be made good, the margin of temperature or number of degrees above 1 214° C., and the time afforded for the progress of restoration before the steel is withdrawn from the furnace for rolling. With a small margin of a few degrees only, it might easily happen that the steel was removed from the furnace and rolled before the restoration was complete. With a larger margin, if for example the temperature rose to 1 240° C., complete restoration would be effected in two or three minutes. In this way it seems possible to account for the common occurrence of a few bars of steel very little spoiled, and the occasional production of one or two lengths which show no trace of spoiling; by accident they have been completely restored immediately before they were rolled.

Whatever the precise explanation may be, the fact that unspoiled, or perfectly restored, magnet steel is occasionally produced is conclusive evidence that the temperature of the steel, shortly before rolling, sometimes exceeds 1 214° C.; or to speak more precisely, the temperature rises now and again above the upper boundary of the danger zone and passes into the region in which restoration takes place. The means for producing the restoring temperature are therefore already in existence in every steelworks where magnet steel is made and rolled, and sometimes that temperature is attained. It may be an accident, perhaps an undesirable accident from the steelmaker's point of view. Nevertheless, when that accident is made deliberate and intentional the production of decomposed magnet steel in rolled bars will become a thing of the past. It is not a question of gradual improvement. Below 1 214° C., or whatever the precise temperature turns out to be, things will go on just as they do now. Above 1 214° C. there will be no spoiled steel. It will be improvement *per saltum*, all or none.

In the following section it is shown that permanent magnets can be produced by casting them direct from molten magnet steel, a method which may ultimately oust the traditional rolled steel magnet altogether. The cast magnet has the incidental advantage of being almost entirely unspoiled.

(23) Cast Magnets.

In the previous paper * a distinction was drawn between the customary form of magnet made from rolled steel bar of uniform sectional area, and the ideal form in which the sectional area is gradually diminished from the neutral section, along the magnet limbs, to the polar surfaces; the gradual reduction in area being done in such a way as to secure uniform flux density in the steel. It was pointed out that "magnets of this kind utilize the steel to the best advantage, but until it becomes possible to make permanent magnets in the form of magnet-steel castings, so as to permit the sectional area to be varied appropriately, the magnet of uniform density must be regarded as an ideal type."

Shortly after the publication of that paper, the suggestion that permanent magnets might be cast was taken up by the British Scientific Instrument Research Association, in order to ascertain whether it was possible, with the means already available, to make sound castings in magnet steel of the forms required for permanent magnets; and, if so, whether magnet steel in the cast state was suitable for the purpose. The problem was mainly one for the steel foundry, and the Association had the good fortune to obtain the cooperation of Sir Robert Hadfield, who undertook the preparation of such experimental castings as might be required in the course of research. At the request of the Director of Research, Sir Herbert Jackson, the present writer dealt with the magnetic part of the investigation and, by arrangement, this section of the paper takes the place of a formal Report to the Committee of the Association.

The universal and age-long practice of using rolled steel for permanent magnets has led, not unnaturally, to the idea that in some way or other the rolled state of steel and permanent magnetism go together, almost as cause and effect. It is not easy to rid ourselves of a notion of this kind, even when there is no rational foundation for it. The first step, therefore, was to ascertain what magnetic difference there is, if any, between the rolled and the cast state of magnet steels. For this purpose a few cylindrical rods, of about 1 in. diameter, were cast in tungsten magnet steel for comparison with rolled steel of approximately the same composition, the cast metal containing, by analysis, carbon 0·69 per cent and tungsten 6·1 per cent. The cast rods presented

* *Journal I.E.E.*, 1920, vol. 58, p. 797.

much the same external appearance as ordinary steel castings, the surface being perhaps rather more deeply pitted than usual; but of porosity there was no sign. Having turned off the skin in the lathe and finished the cast rods as true cylinders, their average density, computed from their weight and dimensions, was found to be 7·92. This figure is to be compared with 8·17, which is the density of rolled tungsten steel of the same composition, the difference being 3·1 per cent. On sawing the rods in half lengthways so as to secure a longitudinal section, a small " pipe " was found, extending along the axis for the greater part of the length. The pipe is, of course, the result of the contraction during cooling, and it accounts for most of the difference in density just noticed. Elsewhere the steel was sound, only one or two very small bubbles being visible on the sawn surfaces.

Two magnetometer test-pieces of ellipsoidal form were machined from the sawn cylinders, care being taken

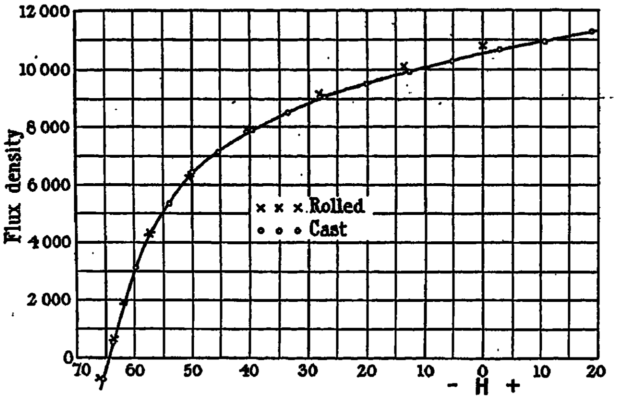

FIG. 29.—Cast tungsten magnet steel. Demagnetization curve obtained from a specimen of the cast steel in the hardened state. The points marked by crosses are taken from a typical specimen of rolled tungsten magnet steel in the hardened state.

to avoid using the steel in the neighbourhood of the pipe. These two test-pieces having been accurately measured and weighed, their densities were found to be 8·081 and 8·134 respectively, the mean value being 8·107, which is less than 1 per cent below the density of the rolled steel.

The test-pieces were next hardened by quenching from a temperature of 850° C. It has been shown in Section (16) that immediately after hardening the coercive force of magnet steel is abnormally high, and it only settles down to a reasonably steady value after several hours. For this reason it is necessary in all work of precision to allow a good many hours to elapse after the hardening before embarking on magnetic tests. In all the investigations described in this paper, including those referred to in the present section, a long interval, on no occasion less than 17 hours, has been allowed for the hardened steel to settle down.

The two hardened test-pieces proved to be so nearly identical in their magnetic properties that the differences between them would be barely perceptible on the scale of the magnetic curves in this paper. A demagnetization curve plotted from the mean values of the observations made on the two test-pieces is given in Fig. 29. For comparison a number of points, marked on the diagram by crosses, have been taken from the demagnetization curve of a specimen of rolled tungsten steel of approximately the same composition as the cast steel, namely about 0·7 per cent of carbon and 6 per cent of tungsten. A quantitative comparison of the rolled and cast specimens is given in Table 14.

The figures in the table show that, of the two test-pieces, the cast steel is slightly inferior to the rolled metal, but the differences are no greater than those frequently met with between two specimens of rolled steel taken from different bars in the same batch, or even from the same bar; and they probably arise from the same cause, namely small variations in the content of carbon. The small differences in the tabular figures dispose at once of the idea that the rolling of magnet steel has any marked influence on magnetic properties. For the purpose of making magnets there is clearly no

TABLE 14.

Maximum available energy in ergs per cm³ of steel..	13 150	12 880

Magnetic comparison of cast tungsten magnet steel with rolled steel of the same composition.

material difference between the cast and the rolled state of tungsten magnet steel.

At the suggestion of Sir Robert Hadfield a similar comparison was made between cast and rolled specimens of cobalt magnet steel, the composition chosen for experiment being one which gives a maximum available energy of about 24 000 ergs per cm³ of steel, not far short of double the energy of tungsten magnet steel.

In the case of tungsten steel, magnetic data for the rolled state were already available in abundance and it was unnecessary to make special tests of the rolled metal for the purpose of comparison. But that is far from being the case with cobalt steel, and it was necessary to adopt a different procedure in order to make a strict comparison between the cast and the rolled metal. The method adopted was to melt the required quantity of steel in a crucible and to cast several test rods and a small ingot from the molten metal, thus ensuring uniformity of composition. The cast cylindrical rods were dealt with in precisely the same way as that already described in connection with tungsten steel, two magnetometer test-pieces of standard ellipsoidal form being machined from them. The ingot was cogged and rolled down into a bar of convenient section, from which two similar magnetometer test-pieces were prepared. The four test-pieces were then hardened by quenching them

from 900° C., and a complete demagnetization curve was obtained from each test-piece after the lapse of about 20 hours.

The two curves for the cast metal being very nearly alike, an average curve plotted from the mean ordinates of the pair of curves will fairly represent the magnetic

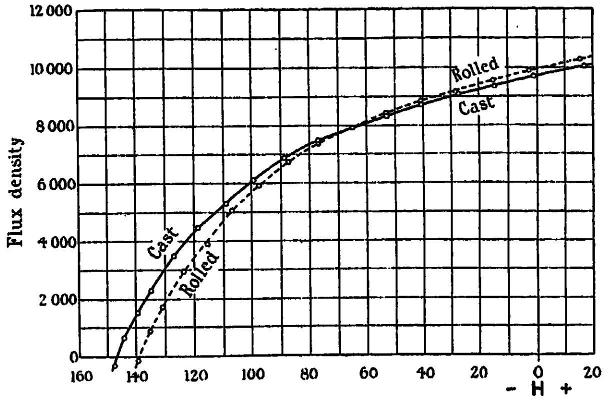

FIG. 30.—Cast cobalt magnet steel. Demagnetization curves obtained from the cast and the rolled steel, in the hardened state.

condition of the cast metal. The same applies to the two curves obtained from the rolled steel specimens. The two average demagnetization curves are shown in Fig. 30, and a quantitative comparison between the rolled and the cast metal is given in Table 15, the figures being derived from the average curves.

TABLE 15.

Magnetic quantity	Rolled steel	Cast steel
Coercive force..	138	147
Remanent flux density ..	9 900	9 650
Economic flux density ..	6 400	6 400
Available M.M.F. per cm at the economic flux density	91·0	94·6
Maximum available energy in ergs per cm³ of steel..	23 200	24 000

Magnetic comparison of cast cobalt magnet steel with rolled steel of the same composition.

It will be noticed that in this comparison the advantage rests with the cast steel, although the difference is but small. The available energy of the rolled metal is less than that of the cast to the extent of about 3 per cent, and the reason for this inferiority is not far to seek. If the two demagnetization curves in Fig. 30 are compared with those for spoiled and unspoiled magnet steel in Fig. 16, it will be seen at once that the difference between the two curves for cobalt steel is of the same character as that which results from partial spoiling, or decomposition of the solute molecules. The spoiling effect is always much more noticeable in cobalt magnet steels than it is in tungsten steels, and in the present example a small degree of spoiling no doubt took place during the heating preparatory to cogging and rolling down the ingot.

Here we light upon an incidental, but most important, advantage possessed by magnet steel in the cast state. It has escaped the liability to dangerous heat treatment which is encountered by rolled steel; a casting only passes once, and that fairly quickly, through the danger zone of temperature.

Having shown that for practical purposes cast magnet steel is just as good as the rolled bar, the next step was to attempt the casting of some typical permanent magnet. The question what is a typical form of magnet was not easily answered. The simplest course would have been to choose some form of magnet already widely used and make an exact copy of it in wood to serve as a pattern for the steel foundry. But to do this would have been to repeat the blunder made by primitive man at the time when he gave up chipping axes out of nodules of flint and took to casting them in bronze. He made the bronze axe exactly the same shape as the stone axe and by so doing preserved the ancient difficulty of fastening the axe to the handle. His sluggish mind took centuries to realize that in casting the bronze a hole might easily be made for the handle.

To copy a rolled steel magnet would have been to turn a blind eye to half the advantage to be gained by casting a magnet. In making a magnet from rolled bar the designer is naturally restricted to such forms as may be readily fashioned by merely bending the bar, a restriction which often involves some sacrifice of magnetic efficiency. There need be no hampering limitation of that kind about a cast magnet, which might evidently be made of any shape the designer chooses, provided the pattern lends itself reasonably well, by its rounded outlines, to the viscous flow of molten magnet steel—a fluid which runs more like thick treacle than limpid water.

With this wide freedom as regards shape, the same considerations that led the designer of dynamos and motors to discard the primitive electromagnet with its yoke and limbs, in favour of the field magnet system of the present day with its internal poles enclosed by a ring casing, suggested that the cast magnet might well take a similar form. One point of advantage possessed by the ring with internal poles is the decreased magnetic leakage, a matter of far greater consequence for a permanent magnet than for the electromagnet. Accordingly several alternative patterns of the ring type were prepared and castings were made from them, both in tungsten steel and in cobalt steel.

Excellent castings were obtained from all the patterns, the specific gravity, determined by weighing in water, giving no measurable indication of porosity. There being nothing to choose between the different castings it was only necessary to select, as a good example of a cast magnet, the pattern which appeared to lend itself best to magnetic and structural requirements. This model is shown in Fig. 31, the upper figure being the casting as received from the foundry, and the lower figure the finished magnet. A cylindrical iron core is shown, fixed concentrically with the polar surfaces to form air-gaps to receive a moving coil of standard

size. The main object being to ascertain the possibility of casting a magnet of ordinary capacity as regards magnetic energy, actual dimensions were of secondary importance. Nevertheless the size of the pattern had been roughly proportioned to an ordinary requirement, on the basis of a casting in tungsten magnet steel. It was intended that the magnet, when fully magnetized, should maintain a magnetic field of about 2 500 in the air-gaps, and a rough computation, based on the demagnetization curve for cast tungsten steel (Fig. 29) showed that to fulfil this requirement the length of the magnet, measured along the magnetic axis, should be about 26 cm, and the total sectional area of the two half-rings in parallel should be about 6·8 cm². The foundry pattern was therefore designed with a view to obtain castings of those dimensions, but beyond this rough adaptation of the size of the magnet to what it was intended to do no attempt was made at any refinement in design.

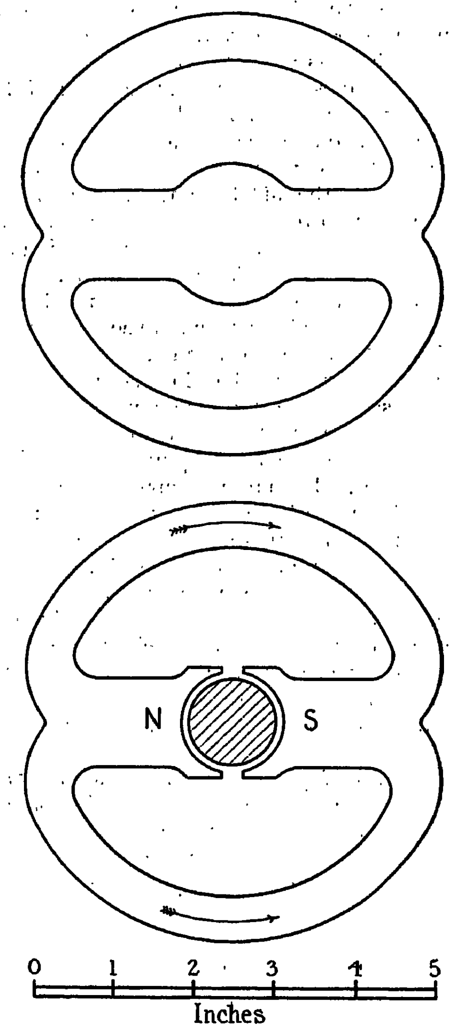

FIG. 31.—A permanent magnet cast in the form of a ring with internally projecting poles. (Cast by Hadfields for the British Scientific Instrument Research Association.)

It was unnecessary to make similar ring patterns of the very different proportions which would be required in magnets made of cobalt steel. There would be no difficulty in doing this in the event of the method of making magnets by casting them proving successful.

The selected tungsten steel magnet was hardened in the ordinary way, by quenching it in cool water from a temperature of 850° C.; no difficulty was encountered and it is clear that the established methods of hardening rolled steel magnets are equally applicable to cast magnets. It was anticipated that with cast steel in in the form of a closed ring, distortion might be a good deal less than in the case of bent magnets of rolled steel. This proved to be the case, the amount of distortion on hardening all the specimen cast magnets, both tungsten steel and cobalt steel, being remarkably small. Too much stress must not be laid on these few examples, however, because the element of chance has a good deal to do with distortion, and it often happens that a bent magnet shows little or no distortion after being hardened.

TABLE 16.

Quantity Compared	Rolled steel magnet	Cast steel magnet
Weight of magnet steel, lb.	4·00	4·47
Weight of magnet with pole pieces, lb...	5·62	4·47
Magnetic field in air-gaps ..	2 330	2 450
Potential difference across the poles	1 080	1 135
Useful magnetic energy, in ergs	1 000 000	997 000

Magnetic comparison of the cast tungsten steel magnet shown in Fig. 31, with a compound bent magnet of rolled tungsten magnet steel.

Having been hardened, the selected magnet was fully magnetized in the direction of the arrows seen in Fig. 31, by means of a current of 1 500 amperes in two temporary coils of 11 turns each, one wound on each half of the ring, the two coils being connected in series in opposite directions. The strength of the magnetizing field applied in this way was 800 per cm of steel, which is more than enough for the complete magnetization of tungsten magnet steel.

The performance of this magnet was in good agreement with the rough predetermination, the measured value of the field in the air-gaps, with the magnet in the fully magnetized state, being 2 450. With a field of this magnitude the potential difference between the polar surfaces is 1 135. The effective air-gap area being about 9 cm², the useful flux would be 2 450 × 9 or 22 000 lines, and the product of useful flux into potential difference is therefore 24 970 000. Dividing the product by 8π, the useful energy maintained by the magnet is found to be almost exactly one million ergs.

This magnet, the first attempt at a cast magnet fit for industrial use, may be compared with a standard pattern compound magnet of rolled tungsten steel. The com-

pound magnet consists of two bent magnets fitted to pole-pieces. These are bored to the same diameter as the polar surfaces of the cast magnet, and the magnetic circuit is completed by a concentric iron core. The effective area of the air-gap path for useful flux is 10 cm^2 in the case of the rolled steel magnet, which compares with 9 cm^2 for the cast magnet; otherwise the air-gaps were identical. Comparative figures for the two magnets are given in Table 16.

As it stands, the experimental cast magnet is in no respect inferior to the rolled steel magnet, and a cast magnet of the same ring pattern, properly designed for the magnetic requirement fulfilled by the magnet of rolled steel, would doubtless show to advantage compared with the bent magnet and its iron pole-pieces.

A useful energy of about a million ergs is not far short of the maximum for a tungsten steel magnet consisting of a single bent bar of rolled steel, without making use of a rolled section of exceptional area. It

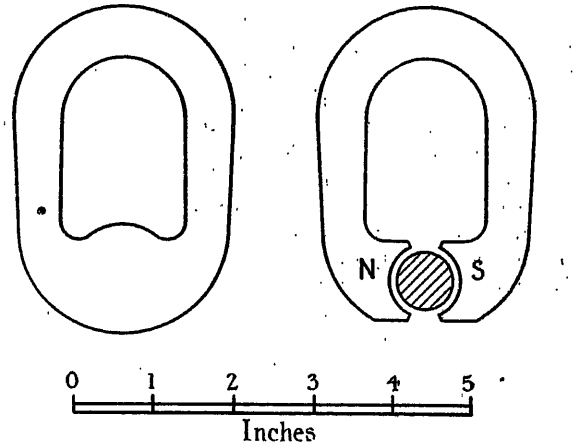

FIG. 32.—A permanent magnet cast in tungsten magnet steel. Designed for uniform flux density and maximum economy, in a form to replace an ordinary bent magnet of rolled steel. (Cast by Hadfields for the British Scientific Instrument Research Association.)

was thought worth while to obtain trial castings in tungsten steel for a magnet of smaller size, more representative of the magnets which are used in vast numbers for electric supply meters and other measuring apparatus.

In addition to the question of size there was another problem to be solved. The introduction of the method of production by casting might well give rise to a demand for cast magnets to replace existing magnets of rolled steel in apparatus of standard design which it might be impracticable to modify. In such cases it would be necessary to adapt the cast magnet to the available space, and the designer might find himself compelled to follow, more or less closely, the conventional shape of the rolled steel magnet which the cast magnet was intended to replace. It was therefore proposed to select some existing instrument containing a small magnet of rolled steel, and to replace it by a cast magnet of the same capacity. The choice fell on a moving-coil voltmeter of conventional type, in which the magnet was closely surrounded by various structures which could not be shifted without an entire reconstruction of the instrument. The cast magnet shown in Fig. 32 was designed to fit into the restricted space without making any alteration in other parts of the instrument.

In the selected instrument the gross magnetic requirement was a field of about 2 000 in two air-gaps constituting an air path 0·479 cm in total length and 5·36 cm^2 in area, figures which correspond with a useful magnetic energy of about 409 000 ergs—less than half the energy of the experimental cast ring magnet. On the basis of these figures the design proceeded and for the first time in any magnet, other than the ellipsoidal bar magnet of the laboratory, the ideal condition of uniform flux density was aimed at. The magnet limbs were designed for a flux density of the economic value already determined for cast tungsten steel from the demagnetization curve given in Fig. 29. It is obviously impossible to fulfil the economic condition in the steel adjacent to the polar surfaces where the flux density necessarily has the same value as the field in the air-gaps and is, therefore, far below the economic value. Away from the immediate neighbourhood of the polar surfaces, a close approach to uniform economic density could have been attained by a somewhat elaborate shaping of the polar ends of the magnet, but in this instance it was regarded as being of the first importance to secure a sound casting, and for this reason simplicity of outline was preserved at the sacrifice of some economy in the utilization of the steel.

The design of the foundry pattern is shown on the left hand in Fig. 32, and the finished magnet on the right. Three or four trial castings in tungsten magnet steel were made from the pattern, all being good sound castings fit for use. Two of the castings were machined and drilled, hardened by quenching from 850° C. and finished at the polar surfaces by grinding. The measured value of the magnetic field in the air-gaps, with the magnets in the fully magnetized state, was in excellent agreement with the predetermined value, being exactly 2 000 in one magnet and 2 130 in the other. Under the same conditions the field maintained by the bent magnet of rolled steel, which the cast magnet was to replace, is 1918, this figure being the average of six of these magnets taken from stock. These figures show that the equipment of existing apparatus with cast magnets is practicable even under rather difficult conditions as regards available space.

With this experiment in replacement the research was brought to a close. The first attempt to make permanent magnets by casting them in magnet steel has met with immediate success from the technical point of view.

The commercial success of the cast magnet depends on which way the balance of the cost of production turns. In the steelworks, the casting of ingots is replaced by the more troublesome process of casting magnets. The cogging and rolling of the ingots into bars, a process which involves the maintenance and running costs of reheating furnaces in addition to rolling-mill charges, would be replaced by the moulding of foundry patterns. Looking at it broadly and making some allowance for the troubles attendant on the production of sound steel castings, it seems that magnet castings should cost less than rolled bar.

Cast magnets greatly simplify the task of the magnet maker. There are no rolled bars to cut into magnet lengths; no bending to shape; no pole-pieces to make, and in their absence no supporting framework to hold magnet and pole-pieces together. The cast magnet is its own support and in the case of the ring pattern with internal polar projections, the magnet may well form the base to which all parts of the working mechanism of the apparatus are attached, much in the same way as the field magnet of the modern motor or dynamo serves to carry the whole machine. Against these favourable points, there will naturally be some additional cost in machining the cast magnet as compared with similar operations on soft-iron or mild-steel pole-pieces; cast magnet steel, even when in the softened state, being much harder than iron.

Upon the whole it appears that both in the steelworks and in the factory of the magnet maker, the balance of cost is likely to turn in favour of the cast magnet, once the initial difficulties of a novel method have been overcome. The development of the cast magnet to the point of commercial success rests quite as much with the magnet user as with the steel founder, because, although most of the troubles will arise in the foundry and be finally overcome there, they will not be overcome, perhaps not even attacked, without an incentive; and the most potent incentive to any manufacturer who is faced with unfamiliar difficulties is an insistent demand.

(24) Hardening.

In the previous section a brief excursion was made into the present century in order to look at cast magnets. We must now return to the Middle Ages in order to carry out the ancient process of hardening, keeping our twentieth century wits about us however.

What happens when magnet steel is hardened has already been described in Section (15). A permanent magnet must have potency, and potency arises from the presence of carbide molecules in solution in iron. But when magnet steel is at room temperature the whole of the solvent iron it contains is, or should be, of the Alpha variety and under ordinary conditions Alpha iron is only capable of dissolving about one-third of the whole amount of carbon present in magnet steel. What is aimed at in the process of hardening is first to dissolve the whole of the carbon while the solvent iron is in the Beta or Gamma state and then to prevent it from passing out of solution when the iron returns to the Alpha state. In that way the steel is endowed with the potency necessary for a good magnet, and, the solvent iron being in the Alpha condition, the steel is fully magnetic.

When magnet steel is ready for the hardening, it will have been brought into the form of a magnet either by bending a piece of rolled bar or by casting the molten metal to the required shape. In either case the steel is likely to be in the softened state. The bent magnet will have been allowed to cool down slowly after the bending operation and there will have been ample time for the whole of the surplus carbide to pass out of solution. The cast magnet must be machined and drilled before it is hardened, and for that purpose it will have been necessary to soften it, the casting as it comes from the foundry being fully ultraheated and therefore too hard for easy machining. It may be assumed, therefore, that whether bent or cast to shape, the steel will be in the softened state when the time arrives to harden it. Moreover, if the effect of ultraheating has been entirely removed, as it should be, by a second heating to 750° C. followed by slow cooling, there will have been a favourable opportunity for crystal growth, and a considerable development in the size of the crystal grains may well have taken place.

The first stage of the hardening process is easy; the whole of the surplus carbide will readily dissolve, provided the solvent iron is of the Beta, Gamma or Delta variety. The iron is therefore converted into Beta by heating the steel to a temperature above the upper boundary of the region within which the transformation from Alpha to Beta takes place. Solution of the surplus carbide then follows as a matter of course. Reference to Fig. 10 shows that in tungsten magnet steel the conversion of Alpha into Beta iron is practically complete at 790° C. In cobalt magnet steel the corresponding temperature, the *dissolving temperature* as it may be called, is considerably higher. Judging from a heating curve, the dissolving temperature for cobalt magnet steel is about 870° C.

Having reached the dissolving temperature, the gradual passage of the surplus carbide from crystal to solution is only a matter of time, since the quantity of iron in the steel, provided it is wholly Beta or Gamma, is capable of dissolving a good deal more carbide than the whole amount present in any kind of magnet steel. It is natural to enquire how long it will take for the surplus carbide to dissolve after the temperature has been raised to the dissolving point. The question does not admit of a precise answer, the available experimental evidence leaving a good many doubtful matters undetermined. When magnet steel is heated slowly the inverse-rate heating curve indicates that the carbide passes from solution concurrently, or nearly so, with the transition of the solvent iron from Alpha to Beta. But when the steel is heated in the ordinary way for the purpose of hardening, by putting it into a fully-heated furnace, the temperature of the metal rises with great rapidity. In these circumstances the progress of the change from crystal to solution apparently lags by an appreciable time behind the allotropic change in the iron, and at the conclusion of the transformation from Alpha to Beta there is still some carbide remaining undissolved. Hence in practice, if the full potency of the steel is to be attained, it is necessary to wait several minutes after reaching the dissolving temperature in order to give ample time for the whole of the carbide to dissolve before the steel is quenched. Under precise laboratory conditions the author has found that a waiting time of 2 minutes is not always enough to ensure complete solution—judging the state of solution from the resulting coercive force of the steel when hardened. On the other hand, in a very large number of hardenings in which the waiting time was increased to 7 minutes there has not been a single instance of failure to secure complete solution. It seems then that the necessary waiting period is somewhere between 2 minutes and

7 minutes, the data at present available not permitting of a more exact statement.*

In the workshop the undisciplined mind has to be reckoned with and the rigid conditions of the laboratory are seldom, if ever, attained. In practice, therefore, ample margins must be allowed both as regards the dissolving temperature and the waiting time. In the author's practice it has been found that it is enough to allow a margin of 50 degrees in temperature, and including this allowance for the shortcomings of the workshop the temperature to which tungsten magnet steel should be raised for the purpose of dissolving the carbide molecules will be 840° C. For cobalt magnet steel the corresponding temperature will be 920° C. At these temperatures the waiting period need not exceed 5 minutes, although no harm (beyond a slight amount of spoiling) will be done by making 10 minutes the rule.

The first stage in the operation of hardening has now been accomplished, the whole of the carbon present in the steel, in the form of carbides, having dissolved in the iron which has been transformed into Beta or Gamma. Whether the solvent iron is of the Beta or Gamma variety is of no practical consequence and, as a matter of fact, with a quickly-rising temperature the change from Alpha to Beta overlaps the conversion of Beta into Gamma, so that atoms of all three varieties may be present together during the transitional stage. But by the time the temperature of tungsten magnet steel reaches 840° C. or that of cobalt magnet steel 920° C., most of the solvent iron, if not the whole of it, will be of the Gamma variety.

The next thing to be done is to cool the steel down to room temperature, and to do it so quickly that there is no time for the surplus carbide to pass out of solution when the solvent iron is transformed once more into Alpha iron. In performing this operation we are taking advantage of the fact that the passage from solution to crystal is essentially a slow process, even when the steel is red hot and the molecular mobility relatively great. As the temperature falls, the mobility decreases with great rapidity and at room temperature it is so slight as to be barely perceptible. Let the steel pass from a red heat to room temperature in a few seconds of time, and before an appreciable fraction of the surplus carbide can pass out of solution the steel is cold and the molecular mobility gone.

Like any other hot body, the steel will lose heat by radiation; but to cool it quickly heat must also be removed by conduction. That is to say, the steel must be brought into thermal contact with a cold body which is a good conductor of heat and, if the cooling is to be rapid enough for the purpose of hardening, the entire surface of the steel must be in close contact with the cold body. In short the cold body must closely envelop the steel, and the simplest way to secure this condition is to have the cooling body in a fluid state. This discovery was made long ago by accident. The discoverer, the primitive blacksmith already referred to, employed water as the cold body, and on the whole water is the most convenient cooling agent. A few other fluids are available; mercury or oil or air may be used, but they none of them serve the purpose quite so well. Water is not only cheap but it has the advantage of being a good conductor of heat, and another point in its favour is a high specific heat. Its one serious disadvantage is its low boiling point. Mercury is an even better conductor of heat and it has a higher boiling point; but its great density is against it, to say nothing of its cost. Oils with a high boiling point are available, but the heat conductivity of oil is much less than that of water. The low specific heat and the inflammability of oil are further disadvantages. Air is plentiful but at ordinary pressures it is a poor conductor of heat compared with either oil or water. Compressed air would be a better conductor and might make a good cooling agent if the obvious practical difficulties in the way of its use could be overcome.

Primitive man ignored all these considerations. Luck was on his side; water was at hand, the red-hot steel was plunged into it and the great discovery was made. The steel was hard.

To-day, with all the accumulated experience of centuries nothing better than water is known and nothing takes the place of sudden immersion. It is true that modifications have been introduced in the hardening of cutting tools, mainly as the result of the use of ultra-heated tungsten and chromium steels. But there is a sharp distinction between the hardening of a tool and the hardening of a magnet, and what answers the purpose of the toolmaker may be quite useless for the magnet maker. In the case of a tool the only parts that need be hardened are those which form the cutting edges. In a large milling cutter, for example, the teeth alone need to be hard, the central core may be left unhardened. Contrast this with the case of the permanent magnet. For a good magnet it is essential to have uniform potency over the entire sectional area, a condition which demands equal hardness throughout, from the surface to the innermost core of the steel. To leave any portion of the transverse section unhardened, or imperfectly hardened, is equivalent to shunting the effective part of the magnet with soft iron and at the same time diminishing the volume of fully potent steel; it constitutes a double weakness. In hardening a magnet, therefore, our object must be to cool the entire volume of steel so quickly that no more than a negligible fraction of the dissolved carbon has time to pass from solution to crystal before the steel becomes cold.

Rapid cooling does not begin at the instant when the steel is taken out of the furnace preparatory to quenching it, and having dissolved the whole of the carbide it is essential that as little of it as possible should be given the opportunity to pass from solution to crystal in the interval between the withdrawal of the steel from the furnace and the moment when rapid cooling begins in the quenching bath. So much of this interval of time as is occupied in moving the steel from the furnace into the bath is under control and with suitable arrangements can be reduced to a negligible duration. But the immediate effect of the sudden immersion in water, for example, is to surround the

* Probably the time necessary for complete solution varies a good deal according to the condition of the steel. It may be conjectured that it depends partly on the extent to which crystal growth has taken place; for the growing of crystal grains is a comparatively slow process and their unbuilding preparatory to solution may be equally slow.

red-hot steel with a heat-insulating envelope of steam, and there is often a sensible delay before the cold water comes into effective contact with the hot metal and sets up rapid cooling. The time spent in this way is largely a matter of chance and is liable to irregular variations. Now during this awkward interval the temperature of the steel is slowly falling, and it may happen that before the conditions for rapid cooling are established, the critical temperature is reached at which the carbide begins to pass out of solution. This contingency must be guarded against by arranging that the temperature of the steel at the moment of immersion shall be well above the critical point; far enough above it to ensure that under the most unfavourable circumstances, as regards delay, rapid cooling shall be in active progress before the temperature has fallen to the critical point at which surplus carbon begins to pass out of solution. The critical temperature for tungsten magnet steel is that given in Section (12), namely 708° C. The corresponding temperature for cobalt magnet steel is 802° C.

The margin of temperature, above the critical points, to be made for the awkward interval between the withdrawal of the steel from the furnace and the beginning of rapid cooling is easily determined by quenching a number of pieces of the steel at different temperatures, appropriately graded, and then measuring their coercive force. An example of this method is given in Fig. 33, which records the results obtained by quenching a number of large bars of tungsten magnet steel from different temperatures, the series being 900°, 850°, 800°, 750°, 720°, 710° and 680° C.* At least two bars were quenched at each temperature, the heat treatment being as follows. Each bar was first heated to 900° C. and kept at that temperature for 10 minutes in order to ensure complete solution of the carbon. The temperature was then lowered to the desired point for quenching and, after keeping the steel at that temperature for 5 minutes, the bar was quenched by allowing it to drop out of the furnace into a tank of cool water fixed immediately below. It will be noticed that at all temperatures down to and including 750° C. the full coercive force of the steel was attained in every case, proving that the whole of the carbon present in the steel in the form of carbides was retained in solution. But at 720° C. there was no such certainty of result. At that temperature the accidental circumstances which give rise to delay in the setting up of rapid cooling after immersion, evidently have a very marked influence on the potency of the quenched steel and it appears to be entirely a matter of chance whether much or little hardening takes place. Since hardness depends on the amount of carbon in solution—and that is governed by the rapidity with which the temperature of the steel is lowered to a region in which molecular mobility is negligible—it is a plausible inference that, at a quenching temperature but little above the critical point, hardness will depend on the rapidity with which the heat-insulating envelope of steam happens to be broken up. But what actually takes place during the brief and turbulent period of quenching could only be ascertained with certainty by the aid of the kinematograph.*

* The tests illustrated in Fig. 33 were undertaken to ascertain the influence of the quenching temperature on cracking, and the temperatures were chosen with that object in view. For a precise determination of the point considered in the text, the series should have included one or two additional temperatures between 700° and 750° C.

From the experiments illustrated in Fig. 33 it is apparent that somewhere between 750° and 720° C. a temperature could be found which just sufficed to guard against the haphazard accidents of quenching. To be on the safe side, however, we may regard 750° C. as the lowest temperature at which tungsten magnet steel should be withdrawn from the furnace for the purpose of quenching in water, the critical temperature of the steel being 708° C. In other words 40 degrees or thereabouts, is a sufficient allowance to make for the slow fall in temperature during the time which elapses between the withdrawal of a piece of steel from the furnace and the actual beginning of the process of rapid

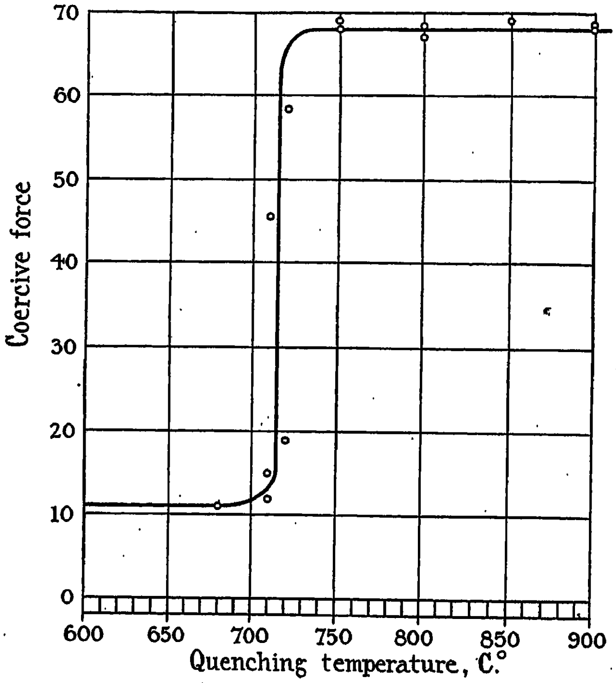

FIG. 33.—Graph showing the coercive force of tungsten magnet steel quenched in water from different temperatures.

cooling by quenching. Since the delay arises from conditions outside the cooling body, the same allowance of 40 degrees will evidently suffice for any kind of steel.

Adding the allowance of about 40 degrees to the critical temperatures, the lowest working temperature, preparatory to quenching in water will be 840° C. for cobalt magnet steel, and 750° C. for tungsten magnet steel. Comparing these figures with the temperatures to which these steels must be raised in order to ensure the solution of the carbon, namely 920° and 850° C, we find

* A point of interest may be referred to in passing. It will have been noticed in Fig. 33 that when the steel was quenched from 680° C. the resulting coercive force was only 11 units. That is to say, although suddenly cooled from a red heat by quenching in cold water, the steel was in the completely softened condition. To those, and they are many, who are rooted in the belief that quenching red-hot steel inevitably hardens it, such a result as this presents a paradox. The explanation is, of course, that in cooling the steel to 680° C. a temperature well below the critical point—the carbon passes rapidly out of solution and including the 5 minutes' waiting time at that temperature, there was more than enough time for the whole of the surplus carbon to pass from solution to crystal. Once that has taken place, quenching can do nothing; it is equivalent to locking the stable door after the steed is stolen.

that the quenching in water could be carried out with full effect at temperatures from 80 to 100 degrees below those required for solution. This difference, arrived at from the conditions occurring in practice, is (as it should be) in reasonably good agreement with the difference between the temperature at which Alpha iron is completely transformed into Beta and that at which the reverse change occurs in the particular steels in question.

The violent method of cooling red-hot steel by quenching it in cold water, subjects the metal, temporarily at least, to severe stresses which are sometimes beyond its strength. On this ground alone it seems desirable to carry out the process at the lowest initial temperature that will ensure complete hardening. To do this it would be necessary after heating the steel to the dissolving temperature, either to lower the heat to the minimum safe temperature for quenching, or to divide the furnace into two compartments or regions of heat, of which one would be maintained at the dissolving temperature and the other at the quenching heat; the pieces of steel being shifted one at a time from one region to the other. But the hardening furnaces in common use at the present time do not lend themselves to any such procedure and hence, in practice, the steel is withdrawn from the furnace at the dissolving temperature and immediately quenched. Whether the liability to cracking is seriously increased, by quenching at a temperature from 80 to 100 degrees higher than is necessary, is a matter which needs investigation.

Among the various matters of secondary importance, connected with the practice of hardening steel by quenching, is the temperature of the cooling bath. This has not been taken into account in the general view of the subject presented in this paper, but some reference to it seems called for in the present section.

Since what is aimed at when red-hot steel is quenched in water is great rapidity of cooling, it is only natural to suppose that the colder the water the better. Primitive man thought so, and in making the sword of the legendary hero it seems to have been considered good practice to harden it by plunging the steel, white hot, into the ice-cold water of a mountain stream. But in these prosaic days the toolmaker knows better. He has discovered that a better result is obtained if the water is slightly warm. Whatever the reason, there is little room to doubt the fact.

What seems to be true of the tool is certainly true of the magnet, the author having observed a small but quite consistent increase in the coercive force of hardened magnets of small size, as the temperature of the cooling water was raised from the freezing point upwards. The effect was traced up to a water temperature of 50° C., at which point an opposing effect obtruded itself and suddenly put an end to rapid cooling. On this account it was found impossible to harden the little magnets when the temperature of the water was raised above 50° C., so long as the quenching was done in the ordinary way by immersion. But with the aid of elaborate means to prevent the formation of an envelope of steam, the increase of coercive force was traced up to a water temperature of 100° C., the increment as the water was raised from 20° C. to 100° C. being no less than 8 units in the case of small bar magnets 0·7 cm in diameter. The warm water effect has not been investigated in larger magnets, but there is good reason for believing that it falls off rapidly as the sectional area of the steel is increased; and in view of the many uncertain factors giving rise to small variations in the coercive force of hardened steel, a possible increase of 1 or 2 units arising from the use of warm water might easily pass unnoticed in workshop practice.

So far as the author is aware, no explanation of the warm water effect has been suggested. It seems not unlikely that it arises from the extremely rapid abstraction of heat from the steel which must take place at the instant when the layer of water in contact with the surface of the steel is suddenly converted into steam, with an accompanying absorption of energy. Assuming it to originate in this way the effect would be proportional to the ratio of the surface of the steel to its volume and would naturally be much greater in magnets of small sectional area than in large ones.

But however we may explain this odd effect, so contrary to our preconceived ideas, there is evidently good reason to follow the practice of the toolmaker by avoiding the use of very cold water. On the other hand, to have the cooling water at a temperature approaching 50° C. would be to court failure, if the quenching is done in the ordinary way. A convenient compromise is to maintain the temperature of the cooling water somewhere between 20° C. and 30° C. The benefit to be derived in this way is small, but since it costs nothing it is worth having.

In the workshop traditional ideas still linger round the practice of hardening, workmen of the older generation being acquainted with many an infallible nostrum. Notwithstanding the legendary use of the pure water of the mountain stream, a favourite notion has been to put something into the quenching water, the workman reasoning perhaps from a familiar analogy. Salt, stale beer, oatmeal, all manner of strange things have been supposed to improve the hardening power of water in one way or another Of all these salt alone has any claim to attention. In so far as the presence of salt, dissolved in the cooling water, raises the boiling point, it probably has some influence on the hardening, but we may search in vain for any experimental evidence of the supposed benefit. For the hardening of cylindrical bar magnets the author has, for many years past, employed a nearly saturated solution of calcium chloride in water, not with any mediæval motive, but in order to put a stop to the frequent splitting of cylindrical bars of steel from end to end when they are quenched in water. There seems little or no reason to believe that a solution of calcium chloride would be of general utility in hardening.

Setting aside the spoiling of magnet steel during manufacture, there is nothing in the making of permanent magnets more in need of improvement than the process of hardening, and surely no other technical process has ever shown so obstinate a resistance to modern ideas. Chemistry, pyrometers, Doctors of Science, metallurgy, electric furnaces, the Higher Education of works managers—all these inestimable blessings have failed to impress themselves on the practice of

hardening magnets. Haphazard, risky, yet clumsily effective, the sudden quenching of red-hot steel in cold water remains a stubborn survival of prehistoric times.

(25) Ageing the Hardened Steel.

It has long been common knowledge that a permanent magnet generally becomes weaker with age, and accordingly when a magnet is to be applied to some purpose where constancy is essential it is usual to submit it to some treatment intended to secure immunity from weakening influences. Any process by which the magnet maker hopes to secure constancy of magnetization is called—somewhat inconsequentially—" ageing " the magnet.

Whether constancy of magnetic power is of much or little consequence depends on the function the magnet is intended to fulfil. In many applications of permanent magnetism the working of the apparatus is little, if at all, affected by variations in the magnetization of the magnet. The magnetic compass, the polarized relay and the moving-coil ohmmeter are examples within this category. In these and some other applications, the acting principle of the instrument requires the presence of permanent magnetism but does not depend on its rigid constancy; the compass, for example, still points to the north even when the magnetic needle has lost a large proportion of its magnetism. But there are other applications of permanent magnetism which depend absolutely on constancy. In moving-coil voltmeters and ammeters, for example, it is essential that the magnetic field maintained by the magnet should be constant; and above all there must be constancy in the brake magnet of an electric supply meter.

It is widely recognized that permanent magnets are apt to suffer from three diseases of a weakening kind, namely, heat, vibration, and the malign influence of stray magnetic fields. To guard against these harmful influences it is common practice, after fully magnetizing a magnet, to weaken it to a moderate extent by an adverse magnetic field, by heat, by vibration, or by any two or all three of these agencies; the idea being that a permanent magnet so treated has, as it were, been innoculated and will suffer no further injury from those three diseases during its useful life. The idea does not rest on good experimental evidence and it would be easy to pick holes in the logic of it, yet mingled with some confusion of thought there is a substratum of sound common sense at the bottom of it.

Much of the confusion will disappear if we begin by drawing a clear distinction between the different causes of loss in magnetic power, according to whether they come from outside the magnet or arise in the steel itself. Stray magnetic fields, heat and vibration all have their origin outside the magnet. On the other hand the gradual loss of potency in hardened steel, disclosed by the experiments described in Section (16), is internal in origin. It is a secular change in the structure of the steel—the molecular pattern which gives the steel its potency, slowly giving way as time goes on. If, as we believe, this slow modification of structure is caused by the passage of carbide molecules out of solution, the change appears to be inevitable in any hardened steel which consists of an over-saturated solution of carbon in Alpha iron. But although it is the steel itself which changes and the cause has nothing to do with magnetism, nevertheless one consequence of the structural change is to rob the steel of some of its magnetic potency by removing the carbide molecules which serve, so to speak, as props to support the magnetic mechanism. Hence if the hardened steel happens to have been made into a permanent magnet the change in the molecular condition, which inevitably occurs with lapse of time, will result in a diminished magnetization. In the present Section attention will be confined to the slow secular change in the hardened steel and the means by which it may be partially forestalled. The weakening effects of stray magnetic fields and different kinds of vibration will be reserved for consideration in subsequent Sections.

It does not appear that anything can be done to prevent the gradual loss of potency in hardened steel as the carbide molecules pass one after the other out of solution and thereby cease to act as supports, but it is an easy matter to forestall the loss. This is done, knowingly or not, by temporarily increasing the molecular mobility by means of heat, and in that way causing any desired fraction of the surplus carbide to pass quickly out of solution before the steel is put to use as a permanent magnet. When this has been done the hardened steel begins life as a magnet with a potency already reduced to a value which in the ordinary course of nature would be reached only after years of slow decay. A certain number of years of natural decay having been forestalled by an immediate reduction in potency, the magnet may be said to have been artificially *aged* by so many years. It is obviously appropriate to describe the process which reduces the potency as " ageing " the steel. This is in fact the only legitimate use of the term and when the hardened steel has been aged in this way the magnet is virtually so many years old, so far as the molecular pattern of the steel is concerned. Ageing in this strict sense has nothing to do with magnetization, and the ageing process may just as well be carried out before the hardened steel is magnetized as afterwards, since it is the steel which requires the treatment and not the magnetization.

There is no difficulty in grasping the principle underlying the practice of ageing magnet steel. The process only differs in degree from the tempering of cutting tools, made of carbon steel, by moderate and temporary heating. In both the aim is to allow just enough carbon to pass out of solution to gain the desired end. The object of the toolmaker is to avoid the extreme brittleness of fully hardened steel and yet to leave enough carbon in solution to give the tool adequate hardness. The object of the magnet maker should be to forestall some years of natural decay in the potency, while leaving enough carbon in solution to give the steel the potency needed for a powerful magnet. It is evident that the two conditions are incompatible, and hence only a compromise is possible.

In the absence of accurate knowledge of the law of decay at different temperatures it is not possible to frame a strict rule for the ageing of magnet steel, but the few facts already available afford some sort of

guidance. Taking tungsten magnet steel as an example, we know from Fig. 21 that within four years from the hardening the coercive force will have fallen from 71·0 to 63·5. By means of the carbon-coercive-force curve given in Fig. 9 these figures may be converted into the percentage quantities of carbon in solution, and it appears that about one-tenth of a gramme of carbon per 100 grammes of steel passes out of solution in the course of the four years after the hardening. Hence to age the hardened steel by four years it will be necessary to heat it to an ageing temperature and then, having allowed one-tenth of a gramme of carbon to pass out of solution, the steel must be cooled again. To determine a convenient ageing temperature, there are only one or two isolated facts to go upon. Referring once more to the experiment recorded in Fig. 12, it will be recalled we pass at once from 345° C. to 100° C., at which temperature the early portion of a decay curve happens to have been obtained in the course of experimental work on another branch of the subject. This curve of decay at 100° C. is reproduced in Fig. 34 and it will be seen that in the course of 7 hours the coercive force fell from 64·8 to 61·4, figures which indicate the passage of about 0·04 gramme of carbon solution to crystal. To occupy 7 hours in the transference of less than half the intended quantity of carbon seems a needlessly slow rate of ageing and it would appear that a temperature somewhat above 100° C. would serve the purpose better. But boiling water is so convenient as a heating agent that the possibilities of ageing at 100° C. may well be examined more closely.

The decay curve in Fig. 34 was obtained from a

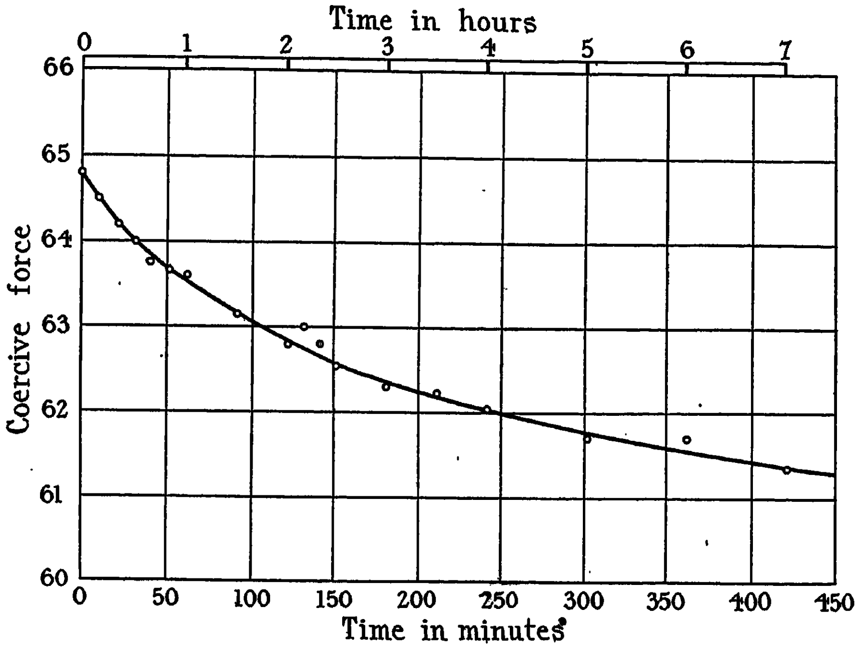

FIG. 34.—Rapid decay in the potency of hardened tungsten magnet steel at a temperature of 100° C.

that when the temperature of the steel was about 700° C. the whole of the surplus carbide, amounting to nearly half a gramme in 100 grammes of magnet steel, passed out of solution in 2 minutes; a rate of one-tenth of a gramme in less than half a minute. Such extreme rapidity is clearly out of the question in an ageing process, and a much lower ageing temperature must be sought. The next indication of a lower rate of transfer from solution to crystal is that given by the curve in Fig. 41.* Here we have the whole of the surplus carbide passing out of solution in 43 minutes while the temperature of the steel falls from 460° C. to 230° C., a mean temperature of 345° C. At that rate one-tenth of a gramme would pass out of solution in about 9 minutes and, although that might not be too rapid under laboratory conditions, so short a time would certainly lead to mishaps in the workshop. No experiments at intermediate temperatures being available, tungsten steel magnet which had already been in the hardened state for 77 days, during which time the early and more rapid natural decay had been in progress. Hence if a true comparison is to be made between ageing at 100° C. and natural decay at room temperature, the decay shown in Fig. 34 should be compared with what goes on at room temperature after the lapse of 77 days from the hardening. Now the curve of natural decay given in Fig. 21 shows that 77 days after the hardening the coercive force had declined to 66·5, and that during the subsequent period of 1 215 days (or 3·33 years) the coercive force fell to 63·8. This is a decrease of 2·7 units in 3·33 years, an average rate of decay of 0·81 unit a year at an average temperature of about 18° C. Comparing this with the rate of decay at 100° C., we notice that in Fig. 34 the coercive force decreases from 64·8 to 62·1, a fall of 2·7 units, in 3·67 hours, an average rate of 0·74 units an *hour* at a temperature of 100° C. The ratio of the figures 0·81 and 0·74 being 1·1, it

* See Appendix, page 803.

appears from this comparison that in hardened tungsten magnet steel the loss of potency which occurs in a year under the ordinary conditions of natural decay, takes place in 1·1 hours when the temperature of the steel is raised to 100° C. Strictly speaking this proportion only applies to the progress of decay when 77 days have already elapsed since the hardening, but by far the greater part of the decay occurring in that time takes place within a few hours after hardening, and hence it seems very probable that the proportion would have been much the same if the comparative periods at 18° C. and 100° C. had begun very much earlier. Making that assumption, a provisional rule for ageing hardened magnet steel at 100° C. may be given. In practice it will be convenient to divide the ageing into two stages. Immediately after the hardening the loss of potency goes on so quickly that the steel may very well be left at room temperature for 24 hours or so to age itself. During that time the coercive force of tungsten steel will decline by about 3 units, and cobalt steel will lose 6 or 7 units. This early and rapid decline having taken place at room temperature, the first stage is over. The second stage is to forestall the subsequent slow progress of natural decay by maintaining the hardened steel at 100° C. The heating is most easily done with the necessary precision by putting the steel into boiling water, and the duration of this heat treatment must be determined by the provisional rule that each period of 1·1 hours at 100° C. adds one year to the "age" of the hardened steel. The experimental data on which this rule is founded leave much to be desired, but once the underlying principle is recognized there should be little difficulty in obtaining more accurate measurements of decay at different temperatures, and the provisional rule can then be amended accordingly.

There is no simple relation between the decay in potency, as measured by the Hopkinsonian coercive force, and the consequent falling off in the useful magnetic energy which a permanent magnet maintains. An example of the effect of decay on the course taken by the demagnetization curve has been given in Fig. 23. The curves in this instance were obtained from cobalt magnet steel, in which the phenomena of decay are particularly prominent and on that account the more easily observed with accuracy. As determined from the demagnetization curve taken one day after the hardening, the economic flux density in the particular specimen of cobalt steel was 6 000, and the magnetic energy maintained by a magnet designed for economy of steel would have been 27 200 ergs per cm^3 at that age of the hardened steel. The demagnetization curve obtained from the same magnet after the lapse of 1 006 days (2·9 years) shows that the amount of energy which the magnet was capable of maintaining, after being again fully magnetized, had fallen to 23 900 ergs per cm^3 of steel, as the result of decay; a decrease of 12 per cent. In the same time the coercive force diminished from 175·0 to 161·5, a decrease of 7·7 per cent. The ratio of the two percentage figures is 1·57 and in this instance, therefore, the loss of useful magnetic energy was 1·57 times the loss of coercive force.

A little consideration will show that some such proportion may be anticipated from first principles. Decay is the removal of carbide molecules from the solution positions in which they give the steel its potency. For small changes, the percentage decrease in coercive force is a rough measure of the proportion of carbon passing out of solution, and since each carbide molecule controls a group of magnetic molecules, giving the group its individual potency, a loss of 7·7 in coercive force implies a corresponding diminution in the number of active groups in the magnetic mechanism. Hence without taking into account the greater magnetic freedom which the active groups acquire when some of their neighbours lose their potency, the magnetomotive force and flux density should each diminish by about 7·7 per cent, and the loss of useful magnetic energy would therefore be about 14·8 per cent. But in virtue of the greater freedom which they have acquired, the active groups will slightly increase their orientation and thereby provide a small additional magnetomotive force. Hence although the active groups will be fewer in number each of them will have a slightly greater magnetomotive force, and the small individual gain must be set off against loss in numbers. What the gain would amount to there is no present means of knowing, apart from what can be ascertained from the demagnetization curves themselves. In the present example the difference between the roughly computed figure for the loss of useful energy, namely, 14·8 per cent, and the observed loss of 12·0 per cent, would be explained if the magnetomotive force of the oriented magnetic molecules in each individual active group increased by about 1·4 per cent, an amount which would be well accounted for by the slightly greater freedom of independent magnetic action which active groups acquire as the result of other groups becoming inactive.

The figures for the comparison made in the last paragraph were obtained from cobalt steel. Decay occurs on a much smaller scale in tungsten steel, and a similar comparison between loss of coercive force and loss of useful magnetic energy is not so easily made with accuracy. But the magnetic characteristics of the two steels differ in degree rather than in kind, and in all probability the magnetic effects of decay seen in Fig. 23 are typical of both steels so far as the relative magnitudes of comparatively small changes are concerned. To sum up the facts so far as they are known at present, the effects of the decay of potency on the magnetic properties of a permanent magnet (made of any kind of steel) are a loss of coercive force and a consequential loss in the useful magnetic energy which the magnet can maintain when it has been fully magnetized; the percentage loss of energy being from 1·5 to 1·6 times the percentage loss of coercive force.

It will not have passed unnoticed that the comparison drawn from the demagnetization curves given in Fig. 23 is made between a newly magnetized magnet one day after the hardening, and the same magnet when, after the lapse of 1 006 days, it was completely re-magnetized —a refreshment that does not come to a magnet in ordinary use. In other words, the comparison was one between the useful magnetic energy which an economic magnet maintained when one day old and immediately after magnetization, and the maximum energy which

the same magnet was capable of maintaining when re-magnetized after suffering natural decay for a period of 1 006 days. On that basis the observed loss of useful energy was 12 per cent. It is not possible to give even an approximate figure for what the loss would have been under the ordinary conditions of use with the magnetization slowly giving way as the potency of the steel decayed. Obviously the loss would not have been less than 12 per cent; almost certainly it would have been considerably in excess of that figure, even if the magnet had been carefully shielded from every weakening agency other than decay in the steel.

(26) Magnetic Stability: Resistance to Stray Fields.

We may now suppose the steel to have been hardened and aged. The next step is to magnetize it, and having done that the stability of the magnetization must be considered. It will be convenient to take as an example a particular magnet from which complete experimental data have been obtained. The magnet was made of tungsten steel and, being of ellipsoidal form and designed for economy of steel, it represents the ideal case of a simple magnetic circuit of magnetized steel in series with an air-gap, the magnetic field in the gap being maintained with maximum economy. Magnetization was effected by placing the magnet in the uniform magnetic field of an exciting coil, and in what follows we shall distinguish between the magnetic field created by the oriented magnetic molecules of Alpha iron in the steel—the *self-created field*—and the additional field supplied by the exciting coil—the *coil field*. The sum of the two fields constitutes the flux density in the magnet as it would be observed by search coil and ballistic galvanometer. The two fields act together as the orienting magnetic field—the field which compels the magnetic molecules to take up angular positions in which their magnetomotive forces are directed more or less along the magnet. The flux in the magnet may be either augmented or diminished by the exciting coil according to the direction of the current, and, for convenience in reckoning, the orienting field may be regarded as the algebraic sum of the self-created field and the coil field.

The magnetic mechanism of the permanent magnet, as seen through the mental microscope constructed by Ampère, Weber and Ewing, has been described in the previous paper. The magnetic machine is composed of groups of magnetic molecules, each group being capable of existing in stable equilibrium either as a closed magnetic circuit which has no magnetic action beyond its own confines, or as an open magnetic circuit in which the constituent molecules are all more or less oriented in one direction. Orientation gives the group a resultant magnetomotive force in the direction of the magnetic field by which the orientation was effected. In the unmagnetized steel every group is in its primitive condition as a closed magnetic circuit, and magnetization consists in compelling the primitive groups to re-arrange themselves as oriented groups. This is effected by the orienting field, which applies a deflecting moment to every magnetic molecule.

To understand the process of magnetization in iron and steel it is necessary to bear constantly in mind the fact that the self-created field is, by itself, very nearly enough to maintain the magnetic mechanism in the oriented state. Very nearly, but never quite enough, and a small addition to the orienting power of the self-created field is needed for equilibrium. In the electromagnet (and our permanent magnet during magnetization is in effect an electromagnet) the additional orienting force is provided by the coil field. In iron and steel the necessary additional deflecting force—the balance, so to speak—is always small compared with the force of the self-created field, and hence the oriented mass of molecules never possesses more than a small margin of stability and sometimes no margin at all. It follows that a trifling change in the balancing force is often enough to cause a very large change in the magnetization.

To obtain the greatest possible magnetic power in a permanent magnet, every primitive group in the steel must be converted, temporarily at all events, into an oriented group. What strength of orienting field is needed to do this is not known with any certainty, but so far as it is possible to judge from magnetization curves of iron and steel, a magnetic field of between 15 000 and 16 000 is enough for the purpose. No ordinary exciting coil can possibly create a field of such magnitude, but what the coil cannot do the inherent magnetomotive force of myriads of magnetic molecules of Alpha iron will easily accomplish if only they can be induced to orient themselves. They need a little assistance to begin with, something to deflect them a little in the required direction; and that assistance is given them by the field of the exciting coil.

We proceed to magnetize the magnet, initiating the all-but automatic process by means of a coil field of small magnitude. Aiming at an orienting field of about 16 000 so as to ensure the conversion of every primitive group into the oriented state, we find by experiment that the tungsten steel magnet requires an orienting field of about 16 500 to maintain an orientation sufficient to generate a self-created field of 16 000. Accordingly the coil field is raised to 500, the oriented molecules generate a field of 16 000, and magnetization is assumed to be complete; every group of magnetic molecules has been compelled to orient itself.*

Having fully magnetized the magnet or, rather having with a little assistance induced the magnetic molecules to orient themselves, thus building up a wonderful arrangement of oriented groups, the exciting current is cut off and the coil field falls to zero. With the loss of the small balancing force needed for their equilibrium, the oriented groups begin to return one after the other to the primitive state. The disappearance of their magnetomotive force causes the self-created field to fall off to a corresponding extent, thus upsetting the equilibrium of other oriented groups. In short the elaborate oriented edifice comes tumbling down like a house of cards, and if it were not for the mutual induction of the constituent molecules of each

* For the complete magnetization of cobalt magnet steel the coil field should be at least 1 000 to arrive at an orienting field of 15 000 or more. It is worthy of notice in passing that even in the rather extreme case of the magnetization of hardened magnet steel as an electromagnet, the magnetic molecules in tungsten steel generate 97 per cent of the whole flux, and in cobalt steel 94 per cent. The exciting coil only generates the balance of 3 per cent and 6 per cent respectively.

oriented group (a magnetic bond which gives the group a limited power of self-preservation) the downfall would be complete.

Any self-preserving power possessed by an oriented group arises from the flux generated by the constituent magnetic molecules in local paths adjacent to the group, and the strength of this magnetic bond depends on how much space is freely available for the flux. If an oriented group could be isolated and afforded unlimited free space, its power of preserving itself as an oriented system would be a maximum. On the other hand, when an oriented group is closely surrounded by other oriented groups, the self-preserving power is greatly restricted by mutual magnetic interference, the different groups all competing for the same space. Under such conditions any individual group can only monopolize groups to revert to the primitive state. At what stage in the downfall the orienting forces arising from the local magnetic bonds will add just what is required to the orienting force of the self-created field in order to balance the de-orienting forces, cannot be foretold. Equilibrium will depend partly on the molecular pattern of the steel, and partly on what proportion of the whole length of the magnetic circuit is occupied by the magnetic generating mechanism contained in the hardened steel. But whatever the particular values of these determining factors may be, the growing strength of the magnetic bonds which hold the oriented groups together must sooner or later provide the small balance needed for equilibrium in what remains of the oriented system. At that point the downfall is arrested and the permanent magnet is born.

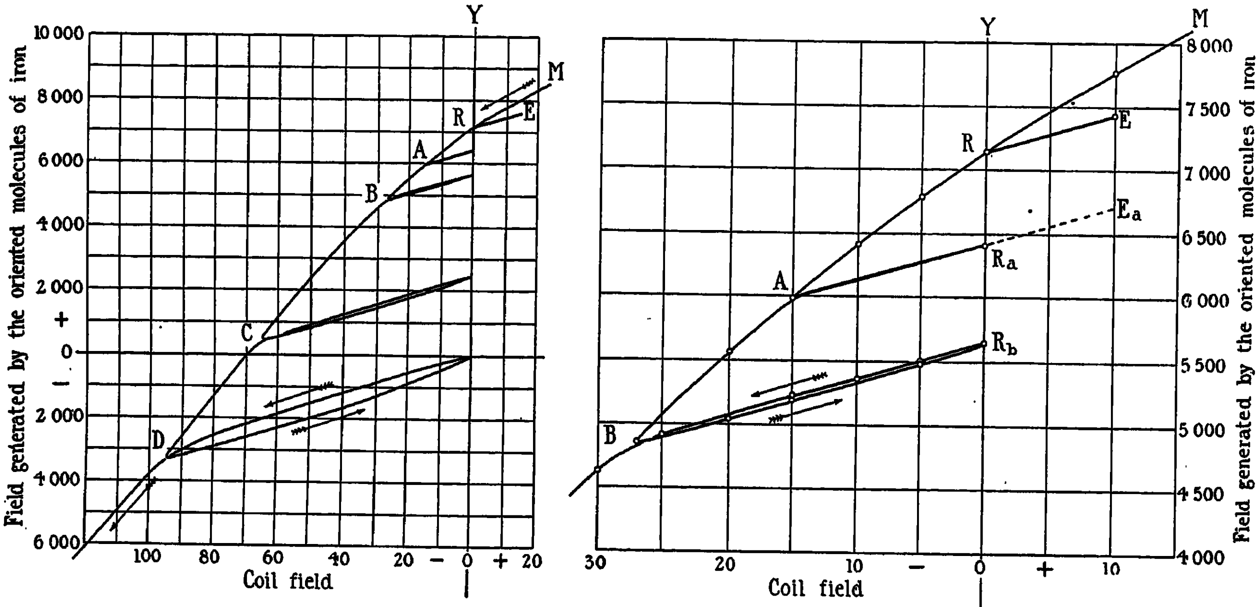

FIG. 35.—Demagnetization curve obtained from the magnetic circuit of a permanent magnet of tungsten steel, showing four recoil loops. The upper portion of the curve, with two recoil loops, is shown in the right-hand figure on a greatly enlarged scale.

a very small portion of the adjacent space and, the local flux paths being confined within narrow limits, the magnetic bond or self-preserving power is much reduced in strength. It follows that when all the groups in the magnet were oriented in the course of magnetization, their self-preserving power was at a minimum. But the coil field has now been reduced to zero and oriented groups are rapidly returning to the primitive state, thereby diminishing the magnetic interference experienced by groups which remain oriented. As the downfall of magnetization proceeds, the remaining oriented groups gain more and more freedom to act as independent magnetic systems, and the magnetic bonds which hold them together grow in strength. In this way self-preservation comes into play as an active deflectional force assisting the self-created field in maintaining the orientation of the magnetic mechanism, and ultimately these two forces acting in the orienting direction will balance the forces which tend to cause oriented

The downfall of the system of oriented magnetic molecules is represented by the demagnetization curve. For the magnet taken as an example, the approach to equilibrium at the point of arrest is indicated in Fig. 35 by the line MR which forms part of the demagnetization curve of the magnetic circuit of magnet and air path. In the diagram the self-created field is indicated by the vertical co-ordinates, and the horizontal co-ordinates give the amount by which the self-created field is augmented or diminished by the coil field. The sum, or difference, of the vertical and horizontal co-ordinates of any point on the curve gives the magnitude of the orienting field. It has already been noticed that this is the quantity which, when measured by search coil and ballistic galvanometer, is called the flux density in the magnet. The diagram represents the magnetic condition of the steel in a magnetic circuit composed of magnet and air-gap in series, and in the absence of any magnetomotive forces, other than those inherent in

the magnetic molecules, the magnetic field inside the steel will be indicated by some point on the vertical axis OY. Immediately after magnetization, equilibrium was established at the arrest point R. The coil field being zero, the self-created field indicated by the point R is the same thing as the orienting field or the flux density in the magnet, a particular value generally described as the remanent flux density of the magnet. In the present instance the remanent flux density was 7 150 at the moment when the downfall of the oriented system was arrested at R.

Although the magnetization of the steel is in equilibrium at the point of arrest, there is no margin of stability, and any further diminution of the orienting field will renew the downfall of the oriented system. Hence, if the field is diminished by an adverse coil-field the demagnetization curve will be continued from R downwards towards the point A. But the converse does not hold good. It is, of course, well known that if the remanent flux density is augmented by the addition of a coil field in the same direction, the demagnetization curve is not retraced along the line RM. It takes a course lower down and in the present example it was found by experiment that upon adding a coil field of gradually increasing magnitude the magnetization followed the line RE. It was further noticed that within narrow limits of observational error the trace from R to E was a straight line, the increments of self-created field being simply proportional to the increment of coil field, provided the latter did not exceed about 15 units. Again, on gradually decreasing the coil field to zero, the magnetization returned to the point R, the trace returning along the same line from E to R.

To understand the nature of the equilibrium in the magnet as a whole when the magnetization is at a point of arrest, we must attend to the conditions of equilibrium in an individual oriented group. The constituent magnetic molecules, in virtue of their magnetic moments as current rings, experience turning moments in contrary senses, and their angular positions of equilibrium are determined by the balance of these clockwise and counter-clockwise forces. Two turning forces act in the orienting sense. There is the moment due to the orienting field and under conditions already referred to there is an additional turning moment, in the same sense, arising from the local flux generated by the group as an independent oriented system. Acting in the opposite sense is a de-orienting moment. To trace the de-orienting moment to its source would land us in many difficulties, but it will suffice for our present purpose to recognize the existence of a negative or backwards turning moment, a de-orienting moment which is constantly tending to deflect the molecules away from their oriented positions towards angular positions at which they suddenly lose stability, and return to their primitive state as a closed magnetic circuit.

The angular positions of the magnetic molecules when the oriented group is in stable equilibrium may be denoted by θ_s, and the average angle at which the molecules become unstable by θ_u. The margin of stability will then be defined by the difference $\theta_s - \theta_u$, the margin angle. Increasing the orienting field increases θ_s, and as θ_s grows the margin grows. On the other hand if the orienting field decreases, θ_s gradually approaches θ_u, the angle of instability, the margin becoming smaller and smaller. Obviously, the magnetic molecules in any oriented group which has a margin of stability may be deflected on either side of their equilibrium angle θ_s without loss of stability, provided the deflection is less than the margin angle $\theta_s-\theta_u$; moreover, when the turning moment which caused the deflection is withdrawn, the molecules will return to their equilibrium angle θ_s.

To impart stability to the magnetization of the magnet, our aim must be to ensure that every oriented group in the magnetic mechanism has an adequate margin of stability; there must be no oriented groups in which $\theta_s-\theta_u$ is zero. Now the magnetic mechanism of the magnet is composed of an assemblage of crystal grains of Alpha iron in which crystal growth has taken place at all sorts of different inclinations. Hence if the group which forms a unit in the magnetic machine is identified with the elementary crystal group, the natural magnetic axes of the oriented groups will point in many directions. It is not difficult to see that, whatever the stage of magnetization may be, this variety of inclinations in the structure of different crystal grains must give oriented groups widely different degrees of stability. During the downfall of magnetization, different groups would vary in stability from a maximum to no margin at all, the groups with no margin being those in which the magnetic molecules, having arrived at the end of their tether, are on the point of reverting to the primitive group-form, as the gradual diminution in the orienting field continues.

With the aid of this picture of oriented groups, the difference between continued downfall from the arrest point R, and a return along the line RE, is readily explained. Downfall consists in oriented groups reverting to the primitive state, their constituent molecules toppling over into that arrangement when they reach the end of their tether as parts of an oriented system. Hence when the orienting field is diminished, after arriving at an arrest point, every group which happens to have reached the point of instability will immediately return to the primitive state, and the demagnetization curve from M to R may be continued towards A without a break by means of an adverse coil field which serves to diminish the orienting field. On the other hand, if the orienting field is augmented by means of a coil field acting in the same direction as the self-created field, then the magnetic molecules in every group will swing round through a small angle in the orienting sense. The effect of this general movement will be to deflect all those molecules which happen to have arrived at the end of their tether into angular positions a little removed from their positions of instability, thus giving them, and the oriented groups to which they belong, a margin angle of stability. In other words, those groups in which $\theta_s-\theta_u$ was all but zero will acquire a definite margin measured by the angular difference $\theta_s-\theta_u$. Incidentally the general movement of deflection, resulting from the increase in the orienting field, will add to the margin angle of all those groups which already had more or less margin. It is clear, however, that on increasing the orienting field by any

given amount, the margin of stability imparted to the magnet as a whole will be neither more nor less than the margin given to those oriented groups which, at the moment of arrest, were on the verge of instability. The weakest link in the chain determines the strength.

In considering the effect of the coil field, the cumulative action of the magnetic molecules themselves must always be taken into account. In the present case the effect of making a small addition to the orienting field, by means of a coil field, is a general increase in the angle of orientation of the molecules. The immediate result is an increase in their effective magnetomotive force and consequently in the self-created field. This is an addition to the orienting field and brings about a further addition to the angle of orientation, the cumulative action going on until the falling off in the moment of the orienting force arising from the local flux created by each oriented group, balances the gain due to the increased orienting field. At that point a new equilibrium is established.

In the tungsten steel magnet which has been chosen as a typical example, the remanent flux density—self-created field, or orienting field—was 7 150 at the arrest point R. The instantaneous effect of the addition of a coil field of 10 units is to raise the orienting field to 7 160. But, by experiment, it was found that as the result of the cumulative deflectional movement of the magnetic molecules in an orienting sense, the self-created field actually rose from 7 150 to 7 430, an increase of 280 units. That is to say the coil field of 10 units initiated changes in the angular positions of the molecules which gave them a greater effective magnetomotive force, and the outcome was an increase of 280 units in the self-created field, each unit of coil field inducing the magnetic molecules to generate 28 units. For small deflectional changes, such as we are now considering in connection with the line RE, there should be simple proportionality between increment of coil field, increment of deflection, increment of magnetomotive force and increment of self-created field. Hence from what we can make out of the behaviour of magnetic molecules we should expect to find the connection between coil field and self-created field in the region between R and E expressed by the straight-line law which experiment has already disclosed.

So far as can be ascertained by magnetometer readings of precision, the proportionality of self-created field to added coil field holds good for values of the latter up to 15 units or more, the first clear indication of any departure from a straight-line law occurring with a coil field of 20 units. In the diagram, therefore, the arithmetical relation of the two fields is represented by a straight line from R to E, and any departure from strict proportionality, either with increasing or decreasing magnitudes, is well within the thickness of the line. This simple state of things can only hold for such changes of the self-created field as can be made by deflecting the magnetic molecules one way or the other within their marginal angles of stability. When those limits are exceeded on either side of the angle of equilibrium, then on the one side oriented groups will revert to the primitive state and on the other side primitive groups will be compelled to orient themselves. In either case the transition from one group-form to the other involves a loss of energy, and the changes in orientation angle, in effective molecular magnetomotive force, and in magnetic fields, are no longer in simple proportion. This state of things is indicated by the line RE beginning to curve upwards, the return line ER showing a corresponding curvature downwards, and the two lines then form a narrow loop enclosing an area. The area of the loop is, of course, a measure of the loss of energy, the hysteresis loss resulting from the unstable movements of the molecules when groups change from one form to the other.

There is a close analogy between the oriented group which has a margin of stability, and the more familiar elastic spring. Just as the spring, in virtue of its elasticity, may be deflected in either direction within the elastic limit, so the constituent magnetic molecules of the group may be deflected either way within limits; and just as the spring returns to zero when the deflecting force is removed, so the magnetic molecules return to their angular positions of equilibrium. When every oriented group in a mass of magnetized iron or steel has been endowed with a margin of stability, the whole magnetic mechanism, the whole magnet, responds to variations in the strength of the orienting field in a spring-like fashion, a condition of deflectional stability in orientation which has been described by Ewing as one of quasi-elasticity.* To retain the idea without suggesting all that is implied by the word elastic we shall refer to magnetized iron and steel which has been brought into the pseudo-elastic condition as being in a state of *recoil* † and lines drawn from an arrest point and back again, like the line between R and E in Fig. 35, will be described as *recoil lines* or *recoil loops* as the case may be.

The downfall of magnetization can be arrested at any point by adjusting the coil field to the appropriate value, either adverse to the self-created field or in the direction to assist it. In the example already considered the downfall was arrested at the point R, Fig. 35, by reducing the coil field to zero, and recoil was traced from R to E and back again to R. Other recoil lines are shown in the diagram originating at the points of arrest A, B, C and D. At each of these points the condition of the magnetic mechanism as regards stability is similar to that already described in connection with the point R. That is to say, there will be numerous oriented groups of magnetic molecules on the verge of instability, and to give them a margin the orienting field must be increased so as to cause the molecules to swing away from their precarious positions and take up angular positions of equilibrium which give them a margin. When the downfall of magnetization is to be arrested at a point on the left-hand side of the axis OY, the arrest is brought about by means of a coil field in the opposite direction to the self-created field, and the increase in the orienting field which is required to give a margin of stability is effected by gradually reducing the strength of the adverse coil field.

The recoil lines from the points A, B, C and D were traced by experiment from the point of arrest to the

* J. A. Ewing: "Magnetic Induction in Iron and Other Metals" (1893), chap. 11.

† Recoil:—v.t. to start back. From French *reculer*. No connection with the coils of a spiral spring, or with the exciting coil of a magnet.

axis OY and then back again to the main demagnetization curve. An adverse coil field of 15 units served to reduce the self-created field from 7 150 at R to 5 980 at A, and from this point of arrest the recoil line was traced by reducing the coil field step by step to zero. The consequent increase in the orienting field gave rise to an increase in the self-created field which finally reached the value 6 410 on the axis OY, an increase of 430 units. Dividing 430 by 15 we find that along the recoil line from A each decrement of one unit in the coil field (or increment of one unit in the orienting field) results in an increase of 28·6 units in the self-created field, the field generated by the magnetic molecules. It was just possible to distinguish a slight curvature in the recoil from A, and when the line was traced beyond the axis OY, as indicated by the dotted line, the direction of recoil became very nearly parallel with the corresponding recoil line RE. We have already noticed that along RE the increment of self-created field is 28 times the increment of coil field, and it is now seen that in the course of recoil from the point A this proportion has the value 28·6 on the left-hand side of the axis. Continuing the line of recoil on the right-hand side towards E_a, a small curvature in the upward direction can just be distinguished. As the point of arrest falls further and further down the curve of demagnetization, curvature of the lines of recoil becomes more prominent; partly because of the greater horizontal distance between the arrest point and the axial line OY and partly by reason of the decreased flux density. Judging by the rapidly growing area of the recoil loops, it would seem that the molecular groups change from one form to the other more readily in weak orienting fields than they do in stronger fields. It may be noticed in passing that the position of the arrest point D was so chosen that, upon recoil, the magnet was left in a completely demagnetized condition.

We now have to consider how far the state of recoil renders a permanent magnet immune to stray magnetic fields, and it will be convenient to begin with the most unfavourable case—that of the bar magnet. We have an example of a bar magnet ready to hand in the ellipsoidal magnet of tungsten steel to which Fig. 35 relates, and we may suppose this magnet to have been brought into a state of recoil from the point A by the application and removal of an adverse coil field of 15 units, the remanent flux density in the magnet being indicated by the point R_a. If the magnet, when in this condition, comes under the influence of a stray field not exceeding 15 units and acting in the adverse or weakening direction, the temporary effect will be to carry the magnetization to some point on the line R_aA. On the disappearance of the stray field the magnetization will return along the line of recoil to the remanent point R_a. If the stray field had been in the assisting or strengthening direction the magnetization would have been carried to some point on the extended line by recoil R_aE_a, and again, on the disappearance of the stray field, the magnetization would return along the recoil line to R_a. Hence a bar magnet which has been brought into a state of recoil by the temporary application of an adverse coil field of given strength is immune to stray fields which do not exceed that strength, immune in the sense that the strength of the magnet is not permanently affected one way or the other by the stray field. But the proviso must be made that immunity is only absolute so far as recoil follows a straight-line law. As recoil lines acquire more and more curvature, giving rise to recoil loops, so the immunity from stray fields becomes less perfect; but even so the extent of the permanent change in the strength of a bar magnet, following the action of a stray field, will always be limited to an amount not exceeding the vertical width of the loop.

So much for the immunity of the bar magnet. The only other case which need be considered here is that of the bent magnet with two straight and parallel limbs. We shall again assume that recoil has been effected by an adverse coil field of 15 units, leaving the magnetization at the point R_a in the diagram. Obviously any stray magnetic field which is uniform throughout the space occupied by the magnet will act equally but in opposite directions in the two limbs of the magnet. Hence in one limb the temporary change in magnetization will follow the recoil line R_aA and in the other limb the line R_aE_a. Although these two lines are nearly straight they are not exactly in line with each other, and hence the temporary change in one limb will not be exactly neutralized by the contrary change in the other limb. Nevertheless, the difference will be very small and where a bar magnet would suffer a considerable temporary change of strength, the change in the bent magnet would be hardly perceptible. On the disappearance of the stray field, the magnetization in each limb of the bent magnet will return to the point R_a, the strength of the magnet not suffering any permanent change provided the stray field has not exceeded the magnitude of the coil field which effected the recoil.

The method of imparting stability to a permanent magnet by recoil from some point on the main demagnetization curve leaves little to be desired, except on the score of symmetry on either side of the remanence line of the magnet; a want of symmetry which arises from the fact that the recoil lines R_aA and RE_a are not exactly in line with each other. It is, however, easy to obtain exact symmetry by first adjusting the coil field to the desired value for recoil and then reversing its direction half a dozen times or more by means of a reversing switch in the circuit of the coil. An example of a symmetrical recoil loop is shown in Fig. 36. The scale of the diagram has been magnified almost to the limit of what the magnetometer readings would bear, in order to exhibit the characteristic features of recoil loops as clearly as possible. The magnetometer readings were taken after 15 reversals of the coil field, by which time the orientation had settled down into a condition in which the cyclic change followed the same course time after time. It will be seen that in the case of a bar magnet the permanent effect of a stray magnetic field of 15 units acting in the positive direction would be to leave the magnetization at the point R_2, whereas if the stray field had been in the negative direction the magnetization would be left at R_1. At these two points the flux density was 6 410 and 6 380 respectively, a difference of 30 units or 0·47 per cent. This is the maximum permanent change in strength which could

be effected by the temporary existence of a stray field of 15 units. A refinement in the method of the symmetrical recoil loop is to reduce the coil-current step by step to zero while the reversing switch is worked to and fro. This has the effect of performing a number of cyclic changes in the coil field with a gradually decreasing amplitude, finally ending at zero and leaving the magnetization at a point midway between R_2 and R_1. In a bar magnet which has been brought into this condition of ideal symmetry, the greatest permanent change in strength which could be caused by a stray field of 15

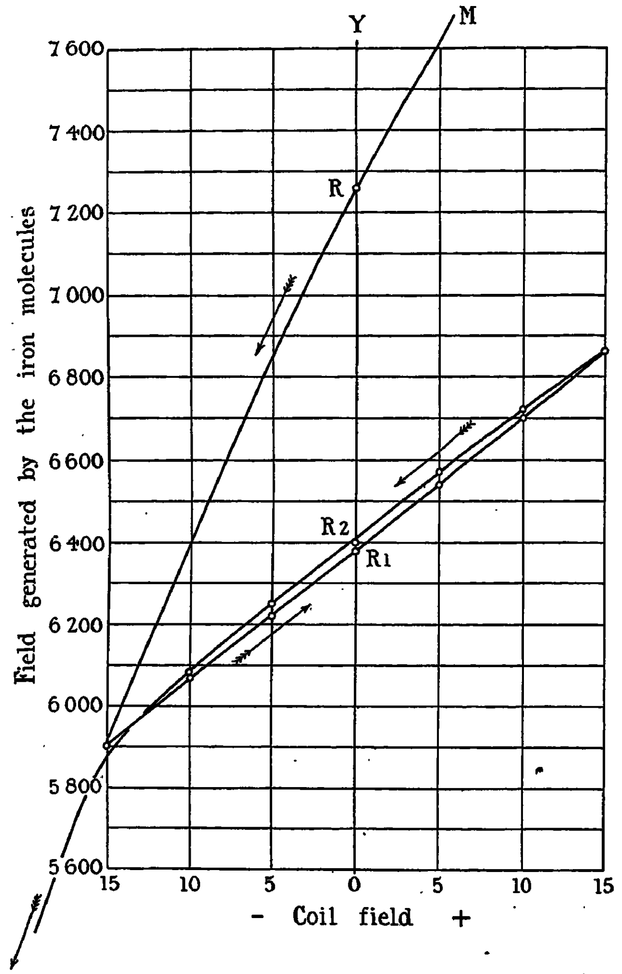

FIG. 36.—A recoil loop symmetrical about the axis of remanence, OY.

units would be less than 0·24 per cent; and a bar magnet is the worst case.

In the foregoing description of the method of giving a margin of stability to a magnet it has been assumed, for simplicity of statement, that the exciting coil used for the magnetization is afterwards available for creating the adverse coil field which serves to shift the orientation into a condition of recoil and stability. In practice, however, it is not generally convenient to use the magnetizing coil for this purpose, and a separate coil must be provided. A coil intended to impart stability may take the form of a pair of large Helmholtz coils giving a uniform magnetic field of any desired value up to about 20 units throughout a space big enough to contain the largest magnet.

What is done by reversals of direct current may be done by alternating current. But it is essential that the coil field should penetrate to the centre of the magnet section, and to fulfil that condition in a bar of steel, perhaps half an inch in thickness, a supply of alternating current at very low frequency would be required. On the whole, the advantage seems to rest with direct current and a reversing switch.

After being fully magnetized, a permanent magnet has its maximum strength when the magnetization has been allowed to settle down at the natural arrest point, R in Fig. 35. This is the point of maximum remanent flux density, and shifting the orientation of the magnetic molecules into a state of recoil, in order to give the magnet a margin of stability, involves a loss of strength. It is seldom that the magnitude of the stray magnetic fields to which a magnet may be subjected can be foreseen, and the designer can only exercise his judgement in determining what sacrifice of strength to make for the sake of securing immunity from the effects of stray fields which a magnet may or may not encounter in the course of its life. Stray magnetic fields in any space in which a permanent magnet is likely to be used do not usually amount to more than a few units, and perhaps as good a rule as any would be to make permanent magnets immune to any fields not exceeding 10 units* in all cases where constancy of permanent magnetism is essential. In the typical example of a tungsten steel magnet, to which Fig. 35 relates, immunity from stray magnetic fields of 10 units involves a sacrifice of 7·5 per cent of the maximum possible strength, or 11·9 per cent if the immunity figure is raised to 15 units. In a magnet made of cobalt steel the same immunity would only involve a sacrifice of strength amounting to about one quarter of those percentage figures.

(27) MAGNETIC STABILITY: RESISTANCE TO VIBRATION.

Stray magnetic fields having been guarded against, it remains to consider the effect of vibration on the delicately poised magnetic molecules when they are in the sensitive state of orientation which follows magnetization. Each molecule is a body of definite mass, and owing to the inertia arising from their mass, the molecules will be liable to disturbance by any kind of vibration, whether that associated with temperature or the less regular vibrational motions due to mechanical shock. Hence the molecules in any oriented group which happens to be on the verge of instability could not be expected to withstand energetic vibration, and whether we set them in stronger vibration by raising the temperature or joggle them by dropping the magnet on the floor, it seems certain that the result will be the same: the group of oriented molecules, already at the end of their tether, must inevitably return to the primitive condition of a closed magnetic circuit. The same thing will be likely to happen to oriented groups which possess a small margin of stability, provided the mechanical

* The strength of the magnetic field 20 cm (8 in.) from a long straight conductor carrying a current of 1 000 amperes is 10 units.

disturbance is sufficiently energetic. So far as Ewing's theory holds the truth, all this may safely be predicted, and experiment amply justifies the prediction. If a permanent magnet which has just been magnetized is struck by any kind of non-magnetic hammer or dropped on the floor, it is found that the flux density decreases by a measurable amount. After the jolting of unstable groups back into the primitive state, the magnetic mechanism only contains oriented groups which have some power of self-preservation, and hence the violent mechanical disturbance, if continued, should have less and less effect. This again, is borne out by experiment, for the first few blows have the most effect. The author has found that when a tungsten steel magnet, which had just been magnetized, was dropped repeatedly on the floor, making it ring with a clear musical note, the first 20 blows reduced the initial remanent flux density by 2·75 per cent, but it needed 180 additional blows to increase the loss by 2·15 per cent, the total loss after 200

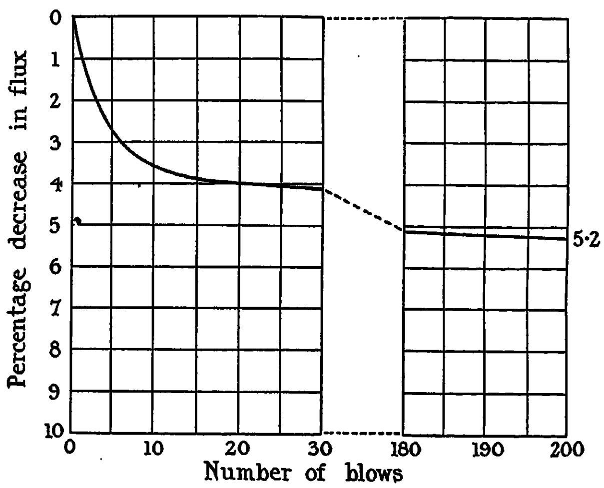

FIG. 37.—Effect of mechanical vibration in reducing the magnetization (orientation of the magnetic molecules) in a permanent magnet of cobalt steel. (Honda.)

blows being 4·9 per cent. In the end, after striking the magnet several thousand times with a brass hammer it appeared that a limit had been reached to what could be done by mechanical vibration of the kind, the magnet having lost, altogether, 5·5 per cent of the initial remanent flux density.

A similar experiment has been recorded by Prof. Honda as an example of the decrease in the flux density of a cobalt steel magnet caused by mechanical disturbance.* From this experiment (illustrated in Fig. 37) it appears that when the magnet was dropped on a wood floor from a height of 1 metre, the first 20 blows effected a reduction of 4 per cent in the flux density. After 200 similar blows the loss had increased to a maximum of 5·2 per cent, a figure not very different from that obtained by the present writer from tungsten steel. But the rough conditions of such experiments as these hardly justify a numerical comparison, and it must suffice to record the fact that in both tungsten magnet steel and cobalt magnet steel, violent disturbance by mechanical vibration or shock causes an immediate reduction of between 5 and 6 per cent in the flux density. Whether the loss of orientation, and therefore of flux density, would be increased if the vibration were continued for an indefinitely long time is a matter of considerable uncertainty and it does not appear that any investigation under stringent conditions has been attempted.

* HONDA and SEIZÔ SAITÔ: "On K.S. magnet steel," *Science Reports of the Tohoku Imperial University* (Japan), 1920, vol. 9, No. 5.

Returning to our tungsten steel magnet, we shall suppose it to have been fully magnetized once more and that the magnetization has settled down again at the natural point of arrest. To impart stability involves the return of a number of the more unstable oriented groups to the primitive state, and we are now acquainted with two ways of doing this. It can be done by the application of a coil field in the adverse direction, or by dropping the magnet on the floor and so jerking the weaker groups into the primitive state. The question now arises whether these two methods are identical in their effect; whether in causing oriented groups to return to the primitive state, mechanical vibration gets hold of the same groups as those whose balance is upset by an adverse coil field. Since in either case the groups with little or no margin will be the first to lose their balance, the probability is that mechanical action and action by adverse magnetic field are, in some measure, alternative ways of doing the same thing. That they are so to a considerable extent, is shown by the following simple experiment.

An ellipsoid bar magnet of tungsten steel having been fully magnetized, the remanent flux density was measured by magnetometer and found to be 7 310. The magnet was next subjected to mechanical vibration by giving it 500 blows in a way capable of repetition. The effect was to decrease the flux density to 7 010, a fall of 300 units. The magnet was now fully magnetized again and the remanent flux density was observed to be 7 310 as before. The next step was to bring the magnetization into a state of recoil by the application and removal of an adverse magnetic field, the strength of the adverse field being 7 units. After recoil from the arrest point determined by the adverse coil field, the remanent flux density proved to be 6 890. In this state of recoil the magnet was of course immune to stray magnetic fields of any value not exceeding 7 units, and the question to be answered was whether the magnet was also immune to vibration. To determine the point the magnet was again subjected to mechanical vibration by giving it 500 blows of the same energy as those given in the preliminary test. The result was to diminish the flux density from 6 890 to 6 830, a fall of 60 units.

The experiment shows that the effect of a particular course of mechanical vibration, which caused a loss of 300 units when nothing had been done to give the magnet stability, caused a loss of only 60 units when a small margin of stability had been imparted to the magnet by means of an adverse field. In other words, when the magnet was in a state of recoil following the application of a negative coil field of 7 units the sensitiveness of the oriented mass of molecules to mechanical vibration was only one-fifth of what it was in the untreated magnet. To that partial extent, therefore, the method of the adverse magnetic field gave immunity to

mechanical vibration, and there can hardly be a doubt that a negative coil field of greater strength would have resulted in a larger degree of immunity to vibration. It is hoped to obtain a numerical relation between strength of adverse magnetic field and immunity from vibration by imparting vibrational energy to the magnet in a regular and measurable form.

The questions which arise with regard to the effect of heat vibrations are identical with those already raised in connection with mechanical vibration. The vibrational effect of heat on the remanent flux density of a magnet is illustrated by the two experiments recorded in Figs. 38 and 39. For these experiments two tungsten

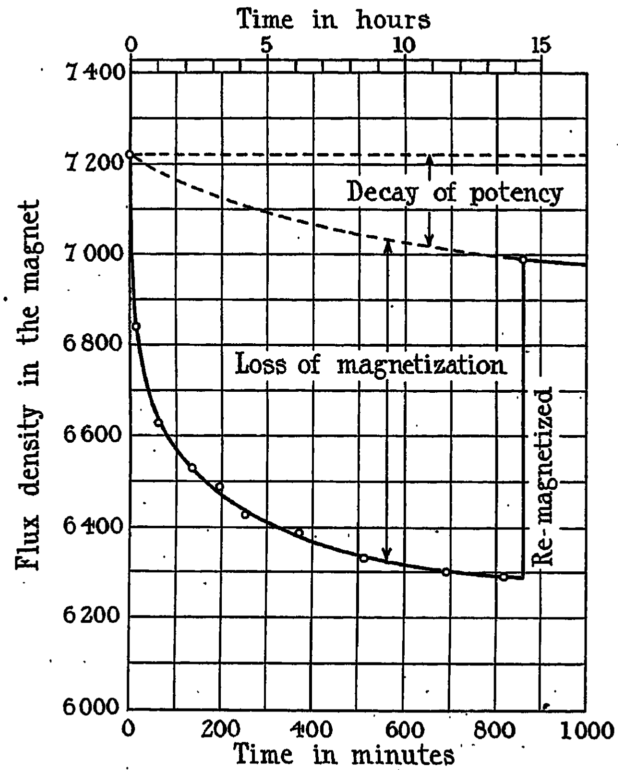

FIG. 38.—Effect of heat vibrations in reducing the magnetization or orientation in a permanent magnet of tungsten steel.

steel magnets were chosen which had not been subjected to any heat treatment since they were hardened. The two magnets were nearly identical in their magnetic characteristics, having been made from the same specimen of steel. In the first experiment, the magnet, after being fully magnetized, had a remanent flux density of 7 220. After making this measurement the magnet was heated to 100° C. for successive periods of time, amounting altogether to 13·7 hours. At the end of each period the magnet was allowed to cool down in order to measure the flux density at room temperature. During the prolonged heating, decay of potency occurred to a noticeable extent, and to ascertain what effect it had on the flux density the magnet was fully magnetized again at the conclusion of the experiment. The total reduction in flux density resulting from 13·7 hours at 100° C. was 930 units, of which 230 were due to decay in the steel. The balance of 700 units is therefore the loss to be attributed to the vibrational effect of the heating on the oriented mass of molecules.

The magnet used in the second experiment had a remanent flux density of 7 130 after being fully magnetized. The first step was to give the magnet a margin of stability, this being done by several temporary applications of an adverse coil field of 18 units. Upon recoil after this treatment the flux density was 6 345. In this condition the magnet was heated to 100° C. for successive periods amounting altogether to 13·4 hours, measurements of flux density being made as in the previous experiment. The total loss of flux density

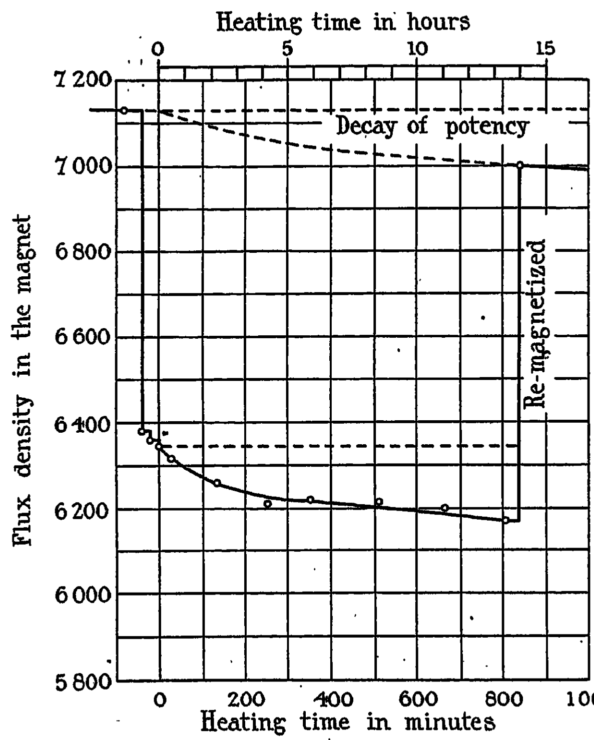

FIG. 39.—Effect of heat vibrations on a permanent magnet of tungsten steel which had previously been given a margin of stability by the application of an adverse coil field of 18 units.

caused by the heating was 185 units, and re-magnetization of the magnet showed that of this amount 130 units was due to decay in the steel. The balance of 45 units is attributable to the vibrational effect of the heating, and comparing this with the 700 units lost from the same cause in the first experiment, it is evident that when the oriented mass of magnetic molecules has been given a margin of stability by means of an adverse magnetic field it is very largely immune to heat vibrations. The immunity is far greater than it was in the case of mechanical vibration. But this is probably to be explained by the greater strength of the adverse field used in the heat experiment, 18 units compared with 7 units in the experiment with mechanical vibration. To obtain a just comparison between the effects of heat vibrations and mechanical vibrations it would be

necessary to make a somewhat elaborate investigation under rigid conditions.*

Much remains to be done to provide conclusive answers to the questions involved in the ageing and stability of a permanent magnet. Once it is recognized that hardened magnet steel suffers a gradual decay, ageing in the strict sense becomes a comparatively simple matter; what is needed is a better knowledge of the rates of decay at different temperatures. Stability of orientation is a more difficult subject, and, although the facts adduced in the present section throw some light on the behaviour of the oriented magnetic molecules in a permanent magnet under different forms of vibration, it still remains doubtful how far the state of recoil, which gives immunity so far as stray magnetic fields are concerned, renders a magnet immune to vibration. Whether in the absence of other disturbing influences, prolonged vibration by heat or by mechanical means has a cumulative effect, is another doubtful matter which could only be cleared up by long-continued experiment.

(28) Conclusion.

With the treatment which imparts stability to the oriented magnetic molecules, the making of the magnet comes to an end. The previous paper began by presenting a picture of the magnetic mechanism, and now in taking a final view our attention has once more been riveted on the wonder-working magnetic molecules and the fragile nature of the means by which they hold themselves together as an oriented system of magnetomotive forces. That any man should be able to build up so delicate a mechanism and preserve it intact for even five minutes would appear impossible if we did not know that permanent magnets are being made by the hundred every day. Apparently, then, the weaving of the elaborate molecular pattern is a simple business; one which the steelmaker and the magnet maker, between them, have long succeeded in doing in a rough and ready fashion. And until recent years they managed to accomplish the feat with their eyes shut. But their success has been very largely a matter of luck. It so happened that primitive man used carbon for smelting iron ore and, some of the carbon finding its way into the iron, steel was produced—by accident. A truly astonishing stroke of luck for the human race, a fortunate chance to which the industry of steel making owes its very existence. If any other element than carbon had been available as the natural fuel for smelting, mankind might well have had to wait for the metallurgical chemist to discover how to make steel for hard tools and permanent magnets. However, by chance the fuel was carbon and the benefit to civilized man—and steelmakers—has been past all reckoning.

Nature provides magnetic molecules of iron ready made. Primitive man introduced carbon by accident. With these two essentials already there the permanent magnet almost makes itself. Nowadays there is no great difficulty in melting scrap steel and improving it with a handful of ferro-tungsten and a pinch of carbon; in casting the molten metal, in hardening it and, finally, in magnetizing it. The product is bound to be a permanent magnet of some sort, good or bad. But the manufacture of uniformly powerful magnets is a very different problem, and it would be hard to find any similar industry so full of pitfalls for the unwary. At every stage from the molten metal to the final treatment for magnetic stability, difficulties crop up one after the other.

The trouble begins in the mixing of the ingredients of magnet steel, uniformity of carbon content being apparently difficult to achieve in practice. But the optimum composition of tungsten magnet steel has now been determined, and it may be hoped that some well-equipped research laboratory will undertake the much more difficult task of determining the optimum composition of cobalt magnet steel. The general use of optimum compositions should leave the steelmaker free to concentrate his efforts on uniformity of composition, more particularly with regard to carbon content. The day for tinkering with the proportions, a little more of this ingredient, a little less of that, is definitely over.

Spoiling the steel by decomposition is the next trouble, and a serious one. But the production of spoiled steel can be prevented and the necessary modifications in steelworks practice will no doubt be made. Reluctance to give up old ways may delay the change; but not for long, when magnet makers begin to be unwilling to buy decomposed steel. Cast magnets are almost unspoiled and their introduction will accustom the magnet maker to something better than badly spoiled rolled steel.

Ultraheating is manifestly quite unavoidable. But ultraheated magnet steel is a trap for the unwary magnet maker rather than a serious difficulty. It is easy to restore it to the normal or all-Alpha state.

The hardening of steel for use as permanent magnets presents several drawbacks, cracking and distortion among them. But as a means of securing the solution of enough carbon to give the necessary degree of potency, hardening is at present indispensable. What it does, in effect, is to prevent the carbide molecules from leaving their solution positions when the allotropic change from Beta to Alpha iron takes place. The carbide molecules may be said to be frozen in their solution positions by the sudden lowering of the temperature of the metal to a point at which very little molecular mobility remains. Temporarily, at all events, this method of compelling more carbide molecules to remain in solution than the solvent Alpha iron naturally holds is entirely successful.

But molecular mobility at ordinary room temperatures, although very slight, is not zero. Little by little the carbide, artificially retained in solution, passes from solution to crystal. Year by year the potency decays. Whether decay will ultimately stop at some point short of the passage of the whole of the surplus carbide out of solution, cannot be foretold. All that is known at present is that four years after the hardening there is no sign of arrest in the progress of decay.

By temporarily heating the steel so as to allow a certain proportion of carbide to pass quickly out of solution, it is easy to forestall the natural decay of years. But this treatment only diminishes the rate

* The experiments recorded in Figs. 38 and 39 formed part of a premature attempt to determine the co-efficient of the temperature variation of magnetization. They were made before the discovery of the decay of potency, and it is only recently that they have been found to throw light on the question of immunity from heat vibration.

of decay to some lower value to which in the natural course of events it would have fallen after a certain number of years. It does not appear that anything can be done to put a stop to the decay of hardened steel.

The discovery of a potency-giving molecule which did not suffer decomposition at temperatures attained during the manufacture of magnet steel would be advantageous, but perhaps the greatest improvement it is possible to imagine, in connection with the manufacture of permanent magnets, would be to dispense with the hazardous process of hardening. What is needed is a potency-giving molecule which will dissolve so much more freely in Alpha iron than any of the carbides at present in use, that the necessary potency will be given by a solution which is in equilibrium at ordinary temperatures. No carbide molecule now in use dissolves in Alpha iron in sufficient quantity, but is it impossible to find one that will? Then again, carbon appears to be the only element which is capable of forming a potency-giving molecule; but is there any ground for supposing that it is necessarily the only element that will serve the purpose? For these questions there seems to be only one reply. No one knows what can be done, because no one has tried.

In the event of the discovery of a potency-giving substance freely soluble in Alpha iron, the advantage of doing away with the risky process of hardening will have one drawback. It may be confidently predicted that iron containing in solution the desired quantity of the hypothetical substance will be too hard to machine in any way but grinding; for it can hardly be doubted that potency and hardness both arise from the molecular pattern of solution.

In a more speculative field for discovery there is the possibility that the powerful magnetomotive forces latent in the atoms of the so-called non-magnetic elements may be made available for use in the same way that the magnetism of iron is now used in permanent magnets. Iron itself has long been calling attention, in vain, to the fact that an element can exist in either of two forms, magnetic and non-magnetic, the change from one to the other involving a fundamental reconstruction of the molecule if not the atom. The discovery of the electron and the electrical constitution of matter has opened our eyes and it is now generally recognized that the atom is not the unchangeable entity it was long supposed to be. If iron can be reconstructed why not other elements? Iron can exist at room temperature in either the magnetic or the non-magnetic form; and again why not other elements?

The immediate practical outcome of the conversion of a non-magnetic into a magnetic element may be glanced at. The 26 planetary electrons in the atom of iron, running round their orbits, provide the magnetomotive force used in the permanent magnet of steel. If only it were possible to induce the 50 planetary electrons in the atom of tin, for example, or better still the 82 in the atom of lead, to behave in the same way as the electrons of the iron atom, we should have a magnetic mechanism of two or three times the magnetomotive force of iron, and where the permanent magnet based on the iron atom maintains a working flux density of 7 000, the magnet of tin would give 13 500, and with the reconstructed atom of lead as the basis of the magnet, a working flux density of 22 000 would be attained. A good deal could be done with such magnets as these.

Whether or no the future holds in store any such revolutionary discoveries in permanent magnetism, we have in the meantime to make the best of the permanent magnet as we know it. An attempt has been made in the present paper to look inside the steel and follow the progress of the molecules as they arrange themselves in the pattern of solution that gives a permanent magnet its power. After much discussion following on a lengthy experimental investigation, and the discovery of more than one troublesome metallurgical fact, we have at last managed to complete the making of what is called a permanent magnet. Beginning with the molecule of iron with its electrons travelling round their planetary orbits, the magnetic machine has been put together molecule by molecule. To obtain the molecular pattern that gives potency it has been necessary to support the mechanism by introducing certain molecules containing carbon—molecules which when in solution appear to behave like props retaining the magnetic mechanism in the required form. Having accomplished this with success, we become aware of the awkward fact that the carbide molecules do not stay where we put them. One after another they drift away from the positions of solution, and how to stop them we do not know.

Looking back on all this and seeing the elaborate molecular pattern slowly falling to pieces, it is only natural that the word permanent, as applied to the magnet of hardened steel, should lose something of its force. But after all, even permanence is relative. It may be said that a permanent magnet is nothing apart from the man who makes use of it, and from that point of view perhaps it is enough that the magnet should be rather more permanent than the man. Anyone who needs greater permanence than that must be content with a magnet made of steel in the softened state. In that condition the steel is a solution in stable equilibrium and the potency is therefore everlasting. But for a given amount of useful magnetic energy, the volume of the magnet would be more than three times that of the hardened steel magnet, and there would be the further drawback that a magnet of softened steel is very easily demagnetized by stray magnetic fields.

So matters stand to-day. But the field of metallurgical discovery is still largely unexplored, and hidden away somewhere the material for the permanent magnet of the future may be waiting to be unearthed. It is already possible to foresee its essential characteristics. It will be endowed with great inherent magnetomotive force and a high degree of potency, imparted by the pattern of solution. Above all, it will be a solution in stable equilibrium, a permanent mechanism for a permanent magnet.

APPENDIX.

ULTRAHEATED MAGNET STEEL.

When steel containing tungsten or chromium, or some other foreign element of the kind, is heated to a high temperature beyond a certain critical point, it undergoes strange modifications in structure which affect the properties of the metal in remarkable ways. In tungsten steels the changes in molecular structure have formed the subject of a prolonged research by Honda and Murakami,* who have based their metallurgical conclusions on the varied forms assumed by the curves which represent the recovery of magnetism as the steel specimen cools down. Setting aside magnetic phenomena, the peculiar properties of high-speed tool steels have frequently been investigated by metallurgists; so far without arriving at a consensus of opinion as to the nature of the changes brought about by the high-temperature treatment. But, although a good deal of exploration has already been done, the fact that magnet steel which has undergone the high-temperature treatment makes a weak magnet, seems to have remained unnoticed until it forced itself on the attention of the present writer while this paper was in preparation.

To make a good magnet out of tungsten steel or cobalt steel, the metal must be in the normal condition in which all the solvent iron is of the magnetic or Alpha variety. But these steels, even at ordinary room temperatures, are often in a peculiar condition in which some of the solvent iron is non-magnetic, and, to the extent that the iron is non-magnetic, the steel is deficient in the inherent magnetomotive force which is essential for a permanent magnet. It is proposed first to consider the circumstances that give rise to this unwanted state of things, and then, after investigating the conditions which determine whether iron molecules are held in the non-magnetic state or revert to their magnetic form, we shall go on to ascertain what is to be done to convert the abnormal steel into the wholly magnetic or all-Alpha state. When non-magnetic iron is present in steel at room temperature, it is often a matter of uncertainty whether it is of the Beta or the Gamma kind, but for the present purpose the point is of no consequence, and for simplicity of statement non-magnetic iron will be referred to as Gamma iron.

It has long been known from the researches of Osmond, Böhler and others, that when steel containing tungsten is heated to any temperature above a certain point in the neighbourhood of 1 100° C., a remarkable change takes place which manifests itself in the subsequent behaviour of the steel. Having undergone some occult change the steel is, temporarily at all events, in an abnormal state, indicated by the much lower temperatures at which the allotropic changes take place when the steel cools down, and by other significant departures from the normal behaviour. It does not appear that any distinctive term has been suggested for this effect, but a word seems to be needed if only to avoid circumlocution. Since the peculiar condition is brought about by heating the steel beyond a certain boundary temperature, it will be appropriate to refer to it as the *ultraheated* state.

The ultraheating effect appears to be entirely absent in plain carbon steel. It is, however, by no means confined to tungsten steel, for it occurs also in steels containing chromium and other kindred elements. In the so-called high-speed tool steels, which often contain both chromium and tungsten in addition to the dominant element carbon, the ultraheating effect is very greatly enhanced—so much so that nearly all the solvent iron remains in the Gamma state when the steel cools down, and consequently all the carbide compounds are retained in solution without the necessity for the hazardous process of sudden cooling by quenching. Moreover, the solvent iron persists in the Gamma state even when the temperature of the steel is raised as high as 500 or 600° C., and so long as it is in that state the carbon remains in solution. It is this natural and persistent state of solution which gives to steels of the high-speed type the immensely valuable property of retaining their hardness notwithstanding the great heat generated by rapid cutting. The extensive use of high-speed tool steels has naturally led metallurgists to attend to the mechanical rather than the magnetic properties of ultraheated steel, but in what follows the phenomena of ultraheating will be described from the magnetic standpoint.

The temperatures recorded by different observers, for the boundary above which ultraheating takes place in tungsten steel, are not very consistent, but they indicate a point somewhere between 1 060 and 1 100° C. The ultraheating effect is known to be accompanied by a considerable absorption of energy, and consequently the boundary temperature may be ascertained by any of the methods employed for detecting changes in the normal rate of heating. For example, the boundary is sharply indicated for tungsten magnet steel in the inverse-rate heating curve shown in Fig. 40. This curve was obtained for the author by Mr. Rolfe from a specimen of magnet steel containing about 0·70 per cent of carbon and 5 per cent of tungsten. It will be noticed that at a point on the temperature scale where the figures given above would lead us to expect the ultraheating effect to begin, there is a sudden and very marked retardation in the rate of heating. It begins sharply at 1 073° C., and comes to an end somewhere between 1 085 and 1 091° C., the magnitude of the departure from the normal course indicating a very rapid absorption of energy. This extremely sudden and active stage quickly comes to an end. It is followed by a retardation of much smaller amplitude which continues for awhile and comes to an end at about 1 215° C., having lasted about ten minutes.

The very sudden absorption of energy, beginning at 1 073° C., must arise from some nearly instantaneous action, and strongly suggests the occurrence of some kind of rearrangement in the structure of atoms or molecules. The subsequent and much less rapid absorption of energy went on for many minutes, and on the view taken in this paper, a duration measured by minutes is a clear indication of changes which involve molecular journeys from place to place. The inverse-rate curve seems, therefore, to point to some instan-

* HONDA and MURAKAMI: "On the structure of Tungsten Steels, *Science Reports of the Tohoku Imperial University* (Japan), 1918; vol. 6, No. 5 (April).

taneous transformation of atoms or molecules, followed by consequential and relatively slow rearrangements of the molecular pattern. It is probable that the entire process of ultraheating would take place at a temperature just above the boundary at 1 073° C., provided enough time were given for the slow consequential changes to be carried to completion. This deduction is confirmed by experimental records drawn from various sources. In some cases ultraheating appears to have been completely effected at temperatures not exceeding 1 100° C. In other instances where the steel was carried to a higher temperature it seems probable that the full development of the ultraheated state was not caused by the higher temperature itself, but was due to the time occupied in raising the temperature. Again, in one of the author's experiments, a specimen of tungsten

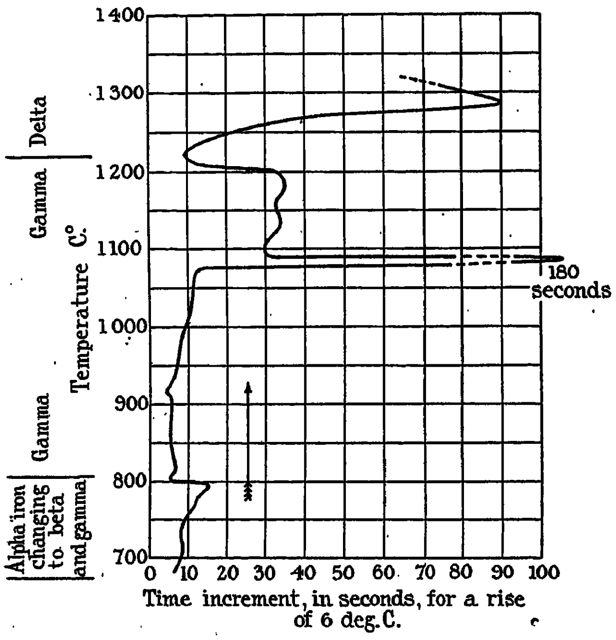

FIG. 40.—Inverse-rate heating curve obtained from a typical specimen of tungsten magnet steel. (R. Rolfe.)

magnet steel which had been rapidly heated to 1 300° C. and then allowed to cool down, was found to be only partially ultraheated notwithstanding the very high maximum temperature. This experiment was made before discovering the importance of allowing ample time for the development of ultraheating, and the temperature of the steel was raised to 1 300° C. as quickly as possible. It was not realized at the time that the rate of heating was excessive, and the significance of the experiment was not understood. But a comparison of the experiment with the inverse-rate curve in Fig. 40 suggests a ready explanation of the fact that the ultraheated state was not fully developed. The inverse-rate curve indicates that ultraheating takes place within a temperature range extending from 1 073 to 1 215° C., and that full development occupies about 10 minutes. Now it appears from an examination of the record of the author's experiment that in heating the steel to 1 300° C., the range from 1 073 to 1 215° C. was traversed in about 3 minutes, and this being less than one-third of the time required for full development, namely about 10 minutes, the partially ultraheated state of the steel at the conclusion of the experiment is well accounted for. Further experiments on ultraheating, paying particular attention to the time element, would doubtless explain many of the discrepancies in existing experimental records.

So much for the thermal conditions that give rise to the ultraheated state. The immediate consequence of ultraheating is shown in Fig. 41. This diagram has been prepared by integrating an inverse-rate cooling curve which Mr. Rolfe had obtained from a specimen of tungsten magnet steel. The steel was cooling down from a temperature of 1 300° C. and as the result of the high temperature it had of course acquired the ultraheated condition.

In the diagram, the lower curve gives the departure from the normal rate of cooling, the amplitude of departure being measured in degrees per minute. The upper curve gives the rate of change of magnetic intensity, or in other words the rate at which the iron in the steel was being transformed into the Alpha variety.* In addition to the time scale, a scale of temperature is included in Fig. 41, and since no recalescence occurred during the cooling of the steel, the scale is continuous although necessarily uneven.

Looking at the two curves in Fig. 41 it will be seen that a small quantity of Alpha iron made its appearance at about the normal temperature in the neighbourhood of 760° C., a transformation which was accompanied by a correspondingly small release of energy. The major portion of the transformation, however, did not begin until the temperature had fallen to 560° C., and the conversion into Alpha iron only ended when the temperature had fallen to 390° C. Turning to the departure curve, it will be noticed that the passing of the carbides from solution to crystal only began at about 460° C. and proceeded so slowly that the temperature had fallen to 180° C. before the whole of the available surplus quantity of carbide had crystallized out of solution.

Comparing this diagram with Fig. 12, which relates to tungsten magnet steel in the normal state, we see at once how great is the contrast between steel in the normal state and ultraheated steel. As the result of ultraheating there is, first of all, a general and very pronounced lowering of the temperatures at which the several allotropic transformations occur, and those at which the process of crystallization begins and ends. In this lowering of temperature there is something that inevitably brings to mind the state of things in an undercooled solution, but steel contains so many unfathomed mysteries that it is perhaps better not to rely on ideas derived from the behaviour of the less complicated liquid solutions.

Another respect in which ultraheated steel obviously differs from normal steel, is in the time occupied by the process of crystallization. Again comparing Fig. 41

* The upper curve in Fig. 41 was obtained from a specimen of tungsten magnet steel of nearly the same composition as that to which the departure curve relates. But unlike the graphs given in Fig. 7 and Fig. 12, the departure curve and magnetic curve in Fig. 41 do not actually record concurrent observations.

with Fig. 12, we see that when the steel is in the normal state the whole of the surplus carbide was able to pass from solution to crystal in a couple of minutes, whereas in the ultraheated condition the same process occupied more than 40 minutes. The longer duration is, of course, the natural consequence of the largely decreased molecular mobility throughout the lower range of temperature within which the passing of the carbide from solution to crystal takes place when the steel is ultraheated.

The general lowering of significant temperatures in ultraheated steel being a very noticeable effect, the boundary temperature above which the ultraheated condition is acquired is often called the "lowering temperature," a term introduced by Dr. Swinden.

If ultraheating did nothing more than lower the temperature range within which the change from solution to crystal takes place, the effect would be as useful in making magnets as it is in making cutting tools; because it would enable the hardening of a magnet to be carried out at a much lower temperature and consequently with less risk of cracking and distortion. But at this point the cutting tool and the magnet part company. For the purpose of a tool, hardness is the main thing, and it is advantageous to retain the solvent iron in the Gamma state, because the amount of carbon necessary for hardness is then held naturally in solution and the risky process of hardening by quenching can be dispensed with: the fact that Gamma iron is non-magnetic is immaterial. But the case of the magnet is very different. Although it is as important in the magnet as it is in the tool to have all the carbon in solution, the presence of non-magnetic iron robs the steel of some of its magnetomotive force and hence, in the magnet, Gamma iron must be avoided.

Now, when tungsten magnet steel—and cobalt magnet steel too, for that matter—cools down to room temperature after being ultraheated, a sensible fraction of the iron does in fact remain in the Gamma state. It is easy to overlook this failure to return to the all-Alpha state, for there is nothing in such experiments as those recorded in Fig. 41, for example, to suggest that the whole of the iron had not been converted into the Alpha variety. But the effect is noticeable, as a deficiency of magnetism, in nearly all curves representing the recovery of magnetism in tungsten magnet steels which have been ultraheated. The author's attention was drawn to the deficiency of magnetism in ultraheated magnet steel by what, at first sight, appeared to be errors of observation in certain determinations of the loss and recovery of magnetism which were undertaken for the present paper, and it was only after examining a number of experimental records that the apparent discrepancies were traced to the effect of ultraheating.

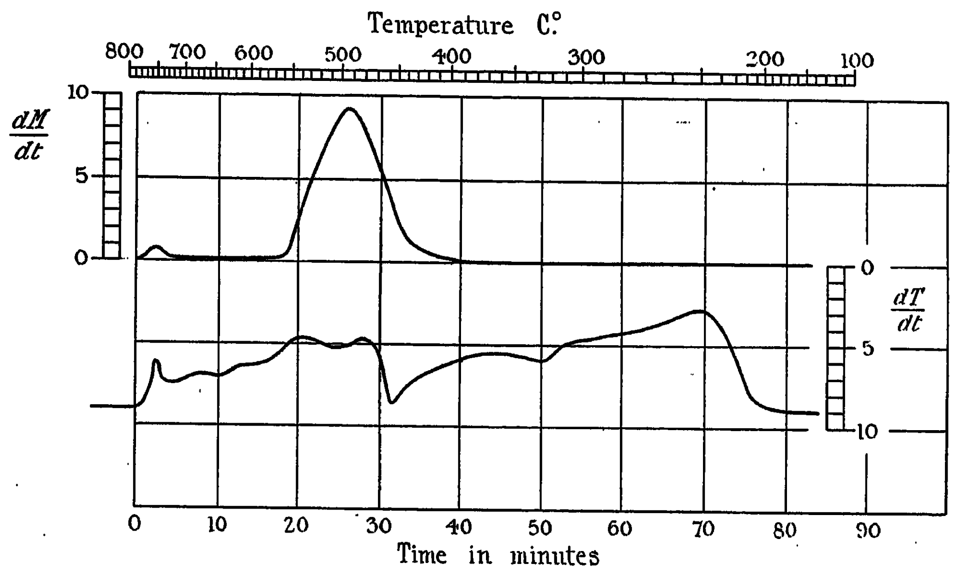

FIG. 41.—Tungsten magnet steel cooling from 1 300° C. Curves showing the rate of change of magnetic intensity during the recovery of magnetism, and departure from the normal rate of cooling consequent on the release of energy as heat.

Finally, the whole matter was made clear by plotting a sequence of curves connecting inherent magnetism with temperature as tungsten magnet steel passed from the normal to the ultraheated state, and back again to the normal condition. These curves are reproduced in Fig. 42, where the vertical ordinates give the percentage of inherent magnetism, or percentage of Alpha iron in a given volume of steel, pure iron at room temperature being represented by 100. The steel to which the curves relate contained 6 per cent of tungsten, 0·65 per cent of carbon, and alien elements 0·70 per cent.

Following the events recorded in Fig. 42, the sequence begins with curve A, which represents the loss of magnetism in a test-piece which was apparently in the normal state, the initial reading at 17° C. being 94·2. The curve follows the usual course, loss of magnetism being practically complete at 800° C., the ordinary temperature for tungsten steel.

Curve B shows the recovery of magnetism in the

same steel, when the test-piece, having been heated to 1 300° C., was allowed to cool down to room temperature. As the result of the ultraheating, recovery does not begin until the steel has cooled down to 600° C.; the transformation into Alpha iron going on at the greatest rate round about 500° C., at which point the difference of temperature between the loss of magnetism on heating and its recovery on cooling is no less than 260° C. Recovery continues as the temperature falls, but it will be noticed that it is still incomplete when the steel has become cold, the inherent magnetism at room temperature being now only 85·2 compared with the initial value of 94·2. The deficiency is roughly 10 per cent and points to the presence of about that percentage of Gamma iron.

Curve C shows the loss of magnetism when the test-piece was heated above the point where the iron loses its magnetism. The curve begins by following the course it continued along some such path as that indicated by the dotted line, and in that case the deficiency of inherent magnetism would evidently have been much the same as it was when the test-piece cooled down from 1 300° C. The actual course of events, however, was very different. Following curve D as the temperature falls, it will be seen that at 600° C. a sudden change took place in the direction of curvature, the curve bending upwards at N and following a course which ultimately brought it close to the normal curve A. The inference seems to be that at 600° C. the deficiency in Alpha iron suddenly began to be made good, the undoing of the mischief wrought by ultraheating making such progress that by the time the temperature had fallen to 200° C. the inherent magnetism or percentage of Alpha iron had risen to 92·7. Observation stopped at this point, but the experiment had been carried far enough to demonstrate the magnetic effects of ultraheating in a general

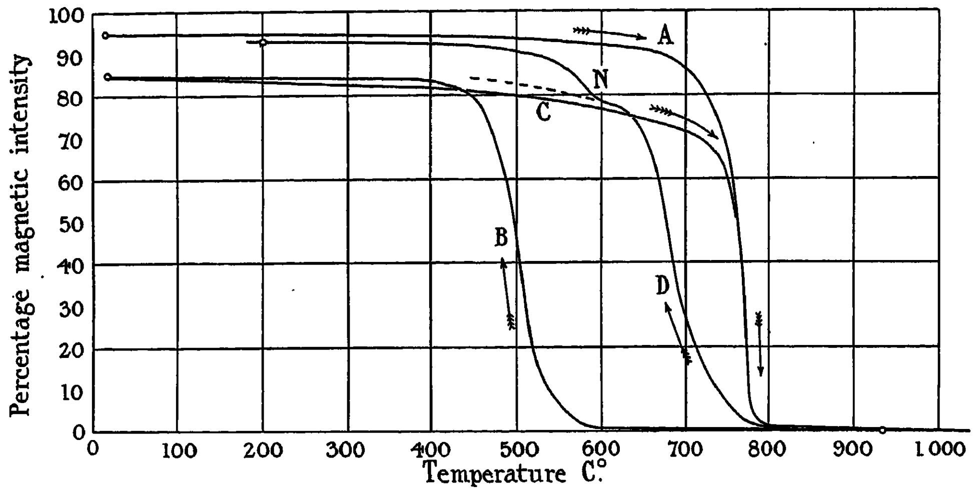

FIG. 42.—A sequence of curves of loss and recovery of magnetism in tungsten magnet steel:—

A. The steel in the normal state. Temperature rising to 1 300° C.
B. The temperature falling from 1 300°; the steel in the ultraheated state.
C. The steel in the ultraheated state; the temperature rising to 935°.
D. The temperature falling from 935°; ultraheating partially cured.

would be expected to take, that is to say it runs more or less parallel with curve A and roughly 10 per cent below it. At about 750° C. curve C makes a near approach to curve A and as the temperature rises above that point the two curves follow the same course, the magnetism vanishing at 800° C. The heating of the test-piece was stopped at 900° C. in order to avoid entering or even approaching the region of ultraheating.

The temperature having reached a maximum of 935° C., the steel was allowed to cool down again, the recovery of magnetism being shown in curve D. In this curve magnetism begins to appear at about 800° C., the effect of ultraheating in lowering the temperature at which the iron begins to change into Alpha having disappeared. But although recovery of magnetism appears to go on much as it would do in normal magnet steel, the influence of ultraheating has not entirely gone. The course taken by curve D as the temperature falls from 650 to 600° C. suggests that it might have way, and to show that the ultraheated state is not permanent. Whatever that state may be—whatever ultraheating actually does to the steel—it can evidently be undone by appropriate heat treatment.

The experiments recorded in Fig. 42 were intended to demonstrate the lowering of the temperature of the magnetic change in ultraheated steel and, as it happened, the conditions were unfavourable for the development of the maximum deficiency of magnetism, the steel having been too rapidly heated to 1 300° C. Moreover, the subsequent cooling from 935° C. was carried out at a speed which afforded barely enough time for the steel to return to the all-Alpha state. The rate of cooling from 750° C. down to 600° C. was about 26 degrees a minute, and the fact that the making good of the magnetic deficiency occurred as a separate event, after the greater part of the magnetic recovery had been completed, suggests that cooling at any greater speed might have resulted in total failure to recover from the effect of ultraheating. The point is one of

importance in practice, and when magnet steel is heated and cooled to remove the effects of ultraheating, the cooling speed may well be limited to something considerably less than 26 degrees a minute in order to avoid the chance of failure.

A deficiency of inherent magnetism in ultraheated tungsten steel is disclosed in several of the author's experiments, the proportion of Gamma iron, as indicated by magnetic deficiency, varying from 8 per cent to 11 per cent. But the experiments were limited in scope and there was nothing to show whether the ultraheated condition had been fully developed or not. Hence the experimental data do not afford a basis for the determination of the maximum possible proportion of Gamma iron in fully ultraheated tungsten magnet steel.

Fortunately the required information can be obtained from the numerous magnetic recovery curves observed by Honda and Murakami. It has already been mentioned that the object in tracing these curves was to determine the molecular constitution of tungsten steels from an examination of the way in which magnetism was recovered as the specimens cooled down. For this purpose it was not thought necessary to take into account the different values of the final intensity of magnetization after the steel had cooled down from different temperatures. Nevertheless each recovery curve was followed down to a final temperature of 50° C., and from the recorded values of the intensity of magnetization at that temperature the present writer has determined the amount of non-magnetic iron present in each ultraheated specimen. None of the 53 tungsten steels examined by Honda and Murakami had the composition of the best tungsten magnet steel, but by a method of interpolation it has been possible to make an accurate computation of the percentage of non-magnetic iron in ultraheated tungsten magnet steel of the composition in common use at the present time. Taking 6 per cent of tungsten and 0·7 per cent of carbon as a typical composition for magnet steel, and supposing the steel to be in the fully ultraheated condition, the author finds that it will contain 16·4 grammes of non-magnetic iron per 100 grammes of solvent iron.

The figure just given shows that if a permanent magnet made of good tungsten magnet steel happened to be in the fully ultraheated state it would be roughly 16 per cent weaker than a similar magnet made of the same steel but in the normal or all-Alpha state. It is hardly possible for the steel to retain the ultraheated condition to the full extent when it comes to the hardening, but ultraheating must often cause permanent magnets to be 10 or 12 per cent weaker than they need be. The weakness arises from the deficiency of magnetic molecules and not from any loss of potency; for, provided the hardening is fully effective, the whole of the carbon in magnet steel will be retained in solution, giving the maximum potency whether the steel is ultraheated or normal.

When magnet steel is in the softened state there is a remarkable difference between the normal and the ultraheated condition; the potency of ultraheated steel in the softened state being much greater than that of the same steel when normal and in the softened state. This unexpected state of things is easily demonstrated by a few measurements of the coercive force of a piece of magnet steel in the softened condition, first after cooling it down from a temperature well above the ultraheating boundary, and then after cooling from a point well below the boundary. Some typical measurements of this kind are given in Table 17. The tabular figures record the results of five tests made one after the other on a piece of ordinary 6 per cent tungsten magnet steel received from the steelworks in the form of rolled bar. Each test was made with the steel in the completely softened state, that is to say, in every case the steel was cooled slowly enough to permit all the surplus carbide which could pass out of solution to do so. It will be noticed that when the steel was in the normal or all-Alpha state the coercive force was 15, a very usual figure for softened tungsten magnet steel; whereas when the same piece of steel was in the ultraheated state the coercive force was 25·8, on an average of three tests, an excess of nearly 11 units. Similar experiments are quite likely to result in figures differing by two or three units from those in the table, but it will always be found that the coercive force of the ultraheated steel is 10 or 11 units greater than that of the same steel in the normal state when both are in the softened condition. It is not uncommon for the coercive force of softened tungsten magnet steel in the fully ultraheated state to be as high as 28 or 29, the latter figure being the highest value of which the author has any record. Taking 26 and 29 as extreme values, a rough average value would be 27·5 units.

TABLE 17.

	Condition of the steel and its heat treatment	Coercive force
a	As received from the rolling mill ..	26·5
b	After heating at 1 130° C. for 5 minutes, followed by slow cooling to 20° C.	25·0

(a), (b) and (e) in the ultraheated condition; (c) nearly normal; (d) quite normal.

Coercive force of softened tungsten magnet steel in the ultraheated state, and in the normal or all-Alpha state.

A coercive force of 27·5 in ultraheated tungsten magnet steel, in the softened state, can be accounted for if we suppose that the potency of the steel as a whole depends not solely on the carbon dissolved in the Alpha iron (which alone constitutes the magnetic mechanism), but on the whole amount of carbon in

solution, without distinguishing between what is dissolved in non-magnetic iron and what in magnetic iron. The surplus carbon rejected from solution when the greater part of the solvent iron is transformed into the Alpha variety will naturally dissolve in the surviving Gamma iron which will ultimately become a saturated solution containing 1·02 gramme of carbon per 100 grammes of iron.* Alpha iron will retain about 0·24 gramme of carbon in solution per 100 grammes of iron, and, assuming the ultraheated condition has been fully developed, the solvent iron will be 83·6 per cent Alpha and 16·4 per cent Gamma iron. Hence the quantity of carbon dissolved in the Alpha iron will be $0{\cdot}24 \times 0{\cdot}836$, and in the Gamma iron $1{\cdot}02 \times 0{\cdot}164$. That is to say, the amount of carbon in solution will be about 0·20 gramme in the Alpha iron, plus 0·17 gramme in the Gamma iron, making a total of 0·37 gramme of carbon in solution per 100 grammes of solvent iron. In steel containing 6 per cent of tungsten and 0·70 per cent of carbon, the solvent iron constitutes about 92 per cent of the weight of the steel, and consequently the 0·37 gramme of carbon when reckoned on the weight of steel becomes 0·34 per cent. The steel being supposed to contain 0·70 per cent of carbon, 0·39 per cent would be present as tungsten carbide and 0·31 per cent would be carbide of iron. Assuming the quantity of carbon in solution in the softened steel, namely 0·34 per cent, to be divided between the two carbides in the same proportion, 0·19 per cent must be reckoned as tungsten carbide and 0·15 per cent as carbide of iron. Reading from the carbon-coercive-force curve for 6 per cent tungsten steel (Fig. 9) it will be found that the corresponding items of coercive force arising from these percentages of carbon in solution are 24 units and 3 units respectively. The total coercive force would therefore be 27 units, this being the estimated coercive force of the ultraheated steel when in the softened state.

The estimated value of the coercive force, arrived at in the last paragraph, agrees so closely with the values commonly observed in specimens of ultraheated tungsten magnet steel in the softened state as to leave very little doubt that the total amount of carbon in solution is in fact the governing quantity as regards potency. It seems clear that any carbon dissolved in the magnetically inoperative Gamma iron creates potency in the magnetic mechanism, just as it would do if it were actually in solution in the Alpha iron which constitutes that mechanism. The ability of carbide molecules dissolved in Gamma iron to exert a potency-giving force in neighbouring Alpha iron suggests that it is the solution pressure of the dissolved carbide compounds which gives rise to the potency, a pressure exerted throughout the mass of mingled Alpha and Gamma iron without regard to the precise locality of the solute molecules. But an explanation of this kind does not really carry us very far. The phrase "solution pressure" belongs to the statistical view of solute molecules. It does not tell us anything of the doings of individual molecules, and in the author's view the secret of potency in steel lies in the action of the individual carbide molecule on a small group of magnetic molecules.

The method used above in estimating the coercive force of fully ultraheated magnet steel in the softened state may be employed to compute the coercive force of partially ultraheated steel containing any given proportion of Gamma or non-magnetic iron. Having calculated a number of co-ordinate values they may be used to construct a graph showing the relation between the percentage of Gamma iron in the solvent iron and the coercive force of the steel when in the softened state. A graph of this kind relating to 6 per cent tungsten steel containing 0·70 per cent of carbon is given in Fig. 43.

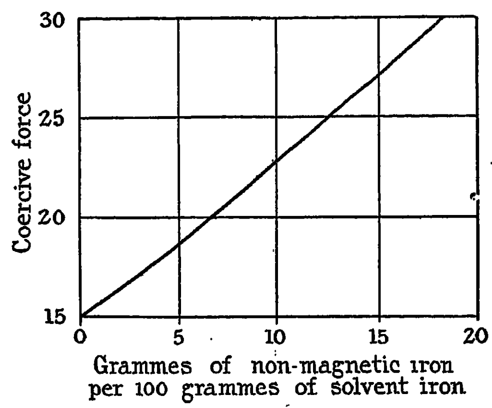

FIG. 43.—Ultraheated tungsten magnet steel in the softened state. Graph giving the relation between the percentage of non-magnetic iron and the coercive force of the softened steel. (Computed by the author.)

Both cobalt steel and tungsten steel are liable to ultraheating, and no matter how magnet steel is made it is inevitably fully ultraheated in course of manufacture. Magnet steel as it comes from the steelworks is therefore always in an ultraheated condition, the deficiency in magnetism varying according to the heat treatment which the steel has undergone since it was ultraheated. A direct measurement of the deficiency in magnetism is not easily made with accuracy, but by measuring the coercive force of the steel when in the softened state and referring to a graph like that given in Fig. 43, the proportion of Gamma or non-magnetic iron present in the steel is seen at a glance. The percentage of non-magnetic iron is the same thing as the deficiency in the inherent magnetism of the steel and, knowing that, the percentage loss of useful magnetic power is determined. It will be seen from Fig. 43 that in the case of tungsten magnet steel tested in the softened state, a coercive force anywhere between 20 and 30 is a sure indication of the presence of a considerable percentage of non-magnetic iron.

Ultraheated magnet steel naturally makes a poor magnet, but fortunately the mischief done by ultra-

* The percentage of carbon in the saturated solution is here assumed to be the same in tungsten magnet steel as it is stated to be in carbon steel. Metallurgical textbooks give 1 atom of carbon to 24 atoms of iron as the eutectoid proportion in carbon steel, but whether this ratio dropped from the sky or was determined by chemical analysis does not appear. Assuming the correctness of the proportion and giving three of the iron atoms to the carbon atom to form Fe_3C, there will be 21 atoms of solvent iron to each carbide molecule. Hence the percentage weight of carbon to solvent iron will be $100 \frac{12 \times 1}{55{\cdot}85 \times 21}$ which is 1·02, the figure used in the text.

heating is not irreparable. It can be undone by suitable heat treatment, and from the point of view of the magnet maker perhaps the most important discovery to make about the ultraheated state is how to get rid of it—how to cure ultraheated steel.

There are several ways of restoring ultraheated steel to the normal state in which all the solvent iron is magnetic. The methods which depend on heat treatment all act in essentially the same way, and the choice between them turns only on what happens to be convenient in practice. A possible alternative to heat treatment is to lower the temperature of the steel to some point, at present undetermined, at which any non-magnetic iron would revert to the magnetic state. So far as permanent magnets are concerned, everything turns on the solvent iron being wholly converted into the magnetic state, and the various ways of removing the effects of ultraheating will be better understood if we begin with an examination of the conditions which bring about the magnetic change when the steel is in the ultraheated state.

In Section (11) it has been shown that the occurrence of the magnetic change at some particular zone of temperature, can be accounted for first by supposing that each iron molecule is constantly urged to assume the magnetic form by a force of reversion which is inherent in the system of electric currents embodied in the molecule, and then by assuming that this inherent force of reversion is opposed by a general pressure acting equally on every molecule of iron throughout the mass. It may be that pressure is not the sole variable force opposing the reversion of non-magnetic iron to the magnetic state, but so far as steel in the normal condition is concerned, pressure appears to be the principal factor on which the magnetic change depends. Apart from hypothesis, there is the outstanding fact that in any kind of steel, provided it is in the normal state, the condition which brings about the magnetic change affects the whole of the solvent iron. Above the temperature zone where the magnetic change occurs, all the iron is non-magnetic; below that zone all the iron is magnetic. Clearly, whatever the nature and origin of the force which determines the magnetic change, it is a force which acts on all iron molecules alike; it is a general and not a selective force.

We now turn to the consideration of the conditions which bring about the magnetic change in ultraheated steel. It will be convenient to take ordinary tungsten magnet steel as our example, since it is the type of steel with which we are concerned in this paper and exhibits all the phenomena of ultraheated steel. Experimental records of the magnetic change in ultraheated tungsten magnet steel have already been given earlier in this Appendix, and there is, in addition, a most valuable fund of information of the same sort to be found in the magnetic recovery curves obtained by Honda and Murakami.* In high-speed tool steels ultraheating is developed to a much greater extent than it ever can be in magnet steels, but these steels do not appear to have been investigated by magnetic methods. So far, thermal evidence alone seems to have been obtained and in the absence of magnetic data the key to ultraheating is missing.

We have seen in Fig. 41 that when tungsten magnet steel cools down from a temperature above the ultraheating boundary, the magnetic change does not take place until the temperature has fallen a long way below the zone where magnetism is regained when the steel is in the normal state. Without further inquiry this lowering of the temperature, at which the solvent iron reverts to the magnetic state, might be attributed to an increase in the pressure; an increase in solution pressure might be supposed to result from some occult molecular change brought about by ultraheating. But we already know that Fig. 41 does not tell the whole story. It omits to record the significant fact, disclosed by recovery curve B in Fig. 42, that when the partially ultraheated steel had cooled down to room temperature 10 per cent of the solvent iron was still in the non-magnetic state, and the magnetic change which ended at 390° C. was therefore limited to the conversion of 90 per cent of the solvent iron from the non-magnetic to the magnetic state. The same limited reversion to the magnetic condition is shown over and over again in the magnetic recovery curves recorded by Honda and Murakami. In the case of tungsten magnet steel which has cooled down to room temperature after being fully ultraheated, about 84 per cent of the solvent iron will be found to have reverted to the magnetic state, leaving 16 per cent still in the non-magnetic and therefore useless form. Here we have clear evidence of the existence of forces of widely different strength, acting selectively on the iron molecules and opposing their inherent tendency to revert to the magnetic state. Out of every 100 molecules, 84 are under the restraint of some individual opposing force in addition to the pressure. These two forces together constitute a total force of restraint which is only finally outweighed by the inherent force of reversion when the temperature has fallen to 390° C. and by so doing greatly reduced the pressure.

The temperature having fallen to 390° C., about 84 per cent of the solvent iron has changed into Alpha iron and a corresponding proportion of surplus carbide is released from solution. The passage of carbide from solution to crystal proceeds as the temperature falls, and by the time the steel has cooled down to room temperature the transfer will be at an end, as the lower curve in Fig. 41 clearly shows. Hence when the steel is cold the pressure will have fallen not only as the result of the fall in temparature, but because a quantity of solute will have passed out of solution, thus making a further reduction in pressure. Taking the diminution in solution pressure into account, it is easy to show that the total pressure at 15° C. must be much less than half what it was at 390° C., yet notwithstanding this great reduction in the general force opposing the reversion of non-magnetic iron to the magnetic state, roughly 16 per cent of the solvent iron is still held in the non-magnetic form. The inference must be that out of every 100 molecules, 16 are under the restraint of some opposing force acting individually on each of them, and that this force is

* The author is indebted to Professor Honda for copies of the three Science Reports relating to the structure of tungsten steels and the characteristic properties of cobalt magnet steel.

of far greater strength than that which opposed the reversion of the 84 molecules.

In ultraheated steel, then, every molecule of solvent iron is acted on by one or the other of two selective forces, in addition to the general pressure which is present in any case, whether the steel is ultraheated or not. The existence of these selective forces may be accounted for by supposing that ultraheating creates bonds between certain of the solute molecules and groups of iron molecules, a binding together by intermolecular forces which may perhaps be akin to chemical union, although the bonds are apparently of a somewhat transient character. But the explanation, which is at present only in a tentative stage, belongs to a remote metallurgical region beyond the scope of this paper. For the immediate purpose it is not necessary to attach metallurgical labels to the two bonds; it is enough to recognize their existence in ultraheated steel, each holding in bondage a definite proportion of the whole quantity of solvent iron and opposing the reversion to the magnetic state. To mark the fact that one bond is much stronger than the other we shall refer to them as the major and minor bonds.

The proportion in which any particle of the solvent iron is divided between the two bonds depends on the composition of the steel and the extent to which it has been ultraheated. In high-speed tool steels containing both tungsten and chromium in additon to carbon, it is possible for the whole of the solvent iron to be under the influence of the major bond, provided the ultraheated state is fully developed. In that condition the steel should of course be non-magnetic at room temperature, but the author is not aware of any evidence on the point. For ordinary tungsten magnet steel in the fully ultraheated state the proportion in which the iron molecules are divided between the two bonds has already been given, 84 molecules out of every 100 being caught, as it were, in the minor bond and 16 in the major bond, these figures being close approximations to the true proportions. Strictly speaking, the proportion 84 to 16 only applies to the state of things existing in the steel when the temperature is above the zone where the magnetic change would occur if the steel were in the normal state. We have already seen that in cooling down to a temperature below 390° C. the minor bond comes undone, and consequently at room temperature the major bond alone survives, holding about 16 per cent of the solvent iron in the non-magnetic state. With the steel in this condition we may once more note the play of forces on each non-magnetic molecule of iron. Since the molecule is non-magnetic the system of electric currents embodied in it is not one of stable equilibrium, and hence there is a constant force urging the molecule to revert to the magnetic state which alone gives it stable equilibrium. Acting in opposition to this inherent force of reversion there is the pressure arising from the temperature, the pressure arising from the presence of solute molecules, and the force of the major bond. At room temperature the sum of these three opposing forces exceeds the force of reversion and consequently the molecule is held in the non-magnetic form. This state of things applies to 16 out of every 100 molecules of solvent iron and robs the steel of 16 per cent of its useful power as a permanent magnet. That in a few words describes the condition of tungsten magnet steel in the fully ultraheated state.

That the magnetic or non-magnetic state of an iron molecule must depend on the preponderance of forces, one way or the other, is of course self-evident, but some sort of working hypothesis, such as that outlined in the foregoing paragraphs, was needed in order to provide a string of coherent ideas. With their aid we proceed to consider the curing of ultraheated steel.

Since the effect of ultraheating is to create bonds which prevent the solvent iron from reverting to the magnetic state, and the magnetic state is essential for permanent magnetism, the most obvious remedy is to sever the bonds, assuming that to be possible. But it would answer the purpose equally well if, leaving the bonds intact, the sum of all the forces opposing the reversion of non-magnetic molecules to their magnetic form could be reduced to the point at which the total opposing force was outweighed by the force of reversion. This is in fact the natural and easy way of disposing of the influence of the minor bond, for the reduction in pressure when the steel cools down to room temperature brings the sum of the opposing forces well below the force of reversion, and consequently by the time the ultraheated steel is cold all the solvent iron caught in the minor bond has already reverted to the magnetic state. To that extent, therefore, the harmful effect of ultraheating on the magnetism of iron is removed by the simple expedient of cooling the steel down to room temperature, and having overcome its influence in the simplest possible way there is no occasion to take further notice of the minor bond.
